The two figures above show that not only does the new model provide accurate values of displacement of the center of mass and pressure forces generated by the liquid motion, but it is also possible to visualize the global liquid motion by evaluating displacement of each node. In addition, it is also possible to find an approximation of the shape of the liquid free surface by linking the adjacent nodes that represent the free surface.

#### IV. CONCLUSION

In this study, a new 3D-dynamical model is described and used to simulate liquid sloshing in an elliptical tank. Firstly, we showed a brief description of the dynamical model. This model is based on the idea of modeling the liquid as a deformable body using a spring-mass lattice. A special method is used for liquid discretization. Each mass of the liquid is simulated by a node of the mesh that represents its center of mass. The adjacent nodes are linked by a flexible link containing a parallel spring and damper. Afterwards, stiffness and damping coefficient of each link are computed using some assumptions. The equations of motion of each node are then calculated and compiled to obtain the global system of equations of the 3D model. All formulas and equations are programmed and solved using Maple 16 software. To compare the results of the model with the literature, identical dimensions of an elliptical tank are used as well as the filling rate, the external force applied and the liquid properties. Comparing the results with the literature allows to conclude that the new model provide results closer to the numerical models that require a longer computation time. Moreover, the new model allows a visualization of the global movement of the liquid by evaluating displacement of each node of the mesh. Future works will focus on generating more results for other tank geometries, filling rates and other vehicle maneuver. It will be possible to compare results generated by this new model with other researches.

**Abstract**— As an industrial practice, complex structures are analyzed under a large set of dynamic operating conditions from which design load cases are selected. During design optimization, response tracking mechanisms based on modal participation factors could lead to large computational savings. In this paper we review the use of static modal participation factors as an inexpensive method to approximate the modal response of a dynamic system and extend the analysis to estimate the peak modal response when the structure is subject to a shock or pulse disturbances. A case study is presented as a proof of concept where the derived approximate peak loads are also estimated.

**Keywords:** *modal contribution factor, modal contribution factors, dynamic analysis, static modal decomposition*

## I. INTRODUCTION

In practice, complex structures must be analyzed under a large set of dynamic operating conditions to ensure that the design will meet prescribed requirement.

During optimization, a relatively small number of such operating conditions are selected as critical and are used to minimize or maximize the objective function. However, the dynamic response is strongly dependent on the physical characteristics of the structure and thus the use of a deterministic set may lead to unexpected dynamic behaviors during different stages of design optimization.

To alleviate some of this issues, constraints such as frequency range, displacement and stresses were sometimes imposed in the optimization algorithms to tailor the structures dynamic response [1-3]; other approach was to specify a certain amount of material to attain a specific natural frequency [4]. These approaches relay heavily on a deterministic set of dynamic responses and could often lead to conservative and even off-optimal-performance designs.

Alternatively, several researchers [5-7] considered the inclusion of the dynamic behavior within the optimization problem through equivalent static load (ESL) sets that were

computed using the solution of the transient analysis or approximated using modal analysis.

In the same spirit as [5-7], the dynamic behavior of any multi-degree of freedom system can be approximated through static modal participation factors (SMPF) as shown in [8]. The SMPF are inexpensive to compute and allow to assess the importance of a mode in the solution. Changes in modes with large participation factors, will then, induce large changes in the dynamic response. Thus, a response tracking mechanism based on static modal participation factors could lead to large computational savings and improve the optimization process by monitoring the dynamic response and the internal peak load of elements.

In this paper, an improved method based on SMPF is presented to approximate the modal peak responses when the structure is subjected to a shock or pulse disturbances. A case study is presented as a proof of concept, where the approximated peak out of plane bending moment at the wing root of an aircraft is approximated using SMPF.

## II. MODAL CONTRIBITION FACTORS

The complex response of a dynamic structural system can be deconstructed into a set of simple harmonic motions  $q_i(t)$ , also known as modal responses, linearly coupled with amplitude ratios. This transformation is achieved by finding the system modal pairs in the form of natural frequencies  $\omega_i$  and mode shapes  $\Phi_i$  that satisfy the characteristic equation of undamped free vibration system which are employed to find the system response as the following variable change:

$$u(t) = \Phi q(t) \quad (1)$$

Where  $u(t)$  is the nodal vector of physical displacements, and  $\Phi$  is the modal matrix of column concatenated eigenvectors.

Expanding (1) in a summation form we obtain:

$$u_n(t) = \phi_{n,1}q_1(t) + \dots + \phi_{n,i}q_i(t) \quad (2)$$

From (2), the **modal contribution** can be defined as the quantity of movement that each mode contributes to the total nodal response [9, 10]. In other words, it is the product between

the modal response  $q_i(t)$  and the amplitude ratio  $\phi_{n,i}$ , denoted here with the Greek letter gamma ( $\gamma$ ) as:

$$\gamma_{n,i}(t) = \phi_{n,i} q_i(t) \quad (3)$$

The amplitude of each modal response can be expressed as the product of a constant called modal participation factor  $\Gamma_i$  and a time dependent term  $D_i(t)$  [9-11] which is expressed as:

$$q_i(t) = \Gamma_i D_i(t) \quad (4)$$

Though in general the time history of the response may be of interest, it is the value of the maximum displacement that will be used for the sizing or the design optimization of a structure. Thus, from (5), the maximum value of the response is directly proportional to the maximum dynamic response which is expressed as:

$$u^0 = \Phi \Gamma D^0 \quad (5)$$

Where  $u^0$  is the vector of maximum nodal displacements,  $D^0$  is the dynamic modal response vector subjected to a unitary load and  $\Gamma$  is the diagonal matrix of modal participation factors.

Appropriate expressions for  $\Gamma$  and  $D^0$  can be found through static modal decomposition as addressed in the next section.

### III. STATIC MODAL PARTICIPATION FACTORS

The distribution of external forces acting on the structure can be expressed as a time invariant vector  $f$  and a time dependent expression  $p(t)$ .

$$F(t) = f p(t) \quad (6)$$

Since the vector  $f$  is independent of time we can try to estimate a static modal deflection caused by the distribution of the forces by expanding  $f$  into a matrix of static forces  $f^s$  acting at each node  $j$  and within each mode  $i$ ; where the sum of the columns of  $f^s$  is equal to the magnitude of the  $j$ -th component of the vector  $f$  [8-11] which is expressed as:

$$f_{j,i}^{st} = \Gamma_{i,i} \phi_{j,i} \quad \begin{cases} \text{for } i=1,2,\dots,N \\ \text{for } j=1,2,\dots,n \end{cases} \quad (7)$$

Where  $n$  and  $N$  are the number of nodes and number of modes retained in the solution, respectively

$$\Gamma = \text{diag}(\Phi^T f) \quad (8)$$

When the eigenvectors are normalized with respect to mass, the vector of total static displacement can be found by the use of Hooke's law, which yields to:

$$u_j^{st} = \sum_{i=1}^N \frac{\Gamma_{i,i}}{\omega_i^2} \phi_{j,i} \quad \text{for } i=1,2,\dots,N \quad (9)$$

The vector of total static displacement can then be related to the vector of total dynamic displacements by introducing (9) into (5) which results in:

$$u_j^0 = u_j^{st} \omega_i^2 D_i^0 \quad (10)$$

To derive an appropriate expression for  $D^0$ , we begin by recalling the classical equation of motion in the modal coordinates, where the eigenvectors have been mass-normalized:

$$\ddot{q}_i(t) + \omega_i^2 q_i(t) = \Phi^T f p(t) \quad (11)$$

Where the operator  $(\cdot)$  denotes the second derivative with respect to time.

By introducing (4) and (8) into (11), we obtain (12), where the term  $\Gamma$  is factored out of the resulting expression resulting in:

$$\ddot{D}_i(t) + \omega_i^2 D_i(t) = p(t) \quad (12)$$

Equation (12) is simply the modal equations of motion subjected to a unit dynamic load; thus, depending on the form of the excitation force  $p(t)$ , a particular method can be selected to find an analytical solution to (12) and consequently  $D^0$ .

#### A. Steady-state Response

When  $p(t)$  is a periodic function, a dynamic amplification factor  $R_i$  can be defined as the ratio between the amplitudes of the dynamic response  $D_i^0$  and the static response  $D_i^{st}$  [9] expressed as:

$$R_i = \frac{D_i^0}{D_i^{st}} \quad (13)$$

The amplitude of the static response is found by neglecting the contribution of the acceleration term in the well-known mass-normalized modal equations of motion, yielding to (14).

$$D_i^{st} = \frac{1}{\omega_i^2} \quad (14)$$

The dynamic amplification factor is the *steady-state* amplitude of an undamped system subjected to a unit periodic function which is expressed as:

$$R_i = \frac{1}{(\omega_i^2 - \omega^2)} \quad (15)$$

By introducing (13-15) into (10), we find the inexpensive expression, i.e. (16) that allows to estimate the maximum amplitude of the nodal physical displacements during steady-state vibration, which is expressed as:

$$u^0 = u^{st} R \quad (16)$$

To compare the output of this method with respect to the proposed methodology, a steady-state modal participation fraction  $L_i^{st}$  is defined in (17). This fractional number allows to compare the relative amplitudes of the modal responses  $q_i$  for a given design and loading condition.

$$L_i^{st} = \frac{|\Gamma_i D_i^0|}{\sum_i^N |\Gamma_i D_i^0|} = \frac{|\Gamma_i / (\omega_i^2 (\omega_i^2 - \omega^2))|}{\sum_i^N |\Gamma_i / (\omega_i^2 (\omega_i^2 - \omega^2))|} \quad (17)$$

#### B. Transient Response I

The steady participation factors neglect the contribution of the transient components of the time domain solution. When the global maximum is of particular interest, we aim here to estimate the maximum dynamic amplitude of system response computed as:

$$D_i^{\max} = \max(D_i(t)) \quad (18)$$

The transient participation fraction  $L_i^{ts}$  can then be defined similarly to the steady participation fraction as the ratio between the maximum amplitude of the harmonic solution and the sum of the maximum amplitude of all the modes retained in the system which is expressed as:

$$L_i^{ts} = \frac{|\Gamma_i D_i^{\max}|}{\sum_i^N |\Gamma_i D_i^{\max}|} \quad (19)$$

### C. Transient Response II – Analytical solutions

To obtain (19) the solution of the modal equations of motion, necessary for (18) calculations, is required a priori. As shown in [12] the solution of (18) was approximated using a quasi-static solution. Here we introduce a new participation factor based on the closed form solution of a Single Degree of Freedom System (SDOF).

Since this method requires the analytical solution of the modal equations of motion in the time domain, we use here the definition given in (20) as an example of an excitation signal which represent the analytical model of Tuned Discrete Gust (TDG) of an aero structure. However the methodology is applicable for any forcing function where a closed form solution exists.

$$p(t) = 1 - \cos(\omega t) \quad (20)$$

where  $\omega$  is the forcing frequency.

The analytical solution in the time domain for an undamped SDOF system subjected to a unitary pulse, as shown in (20), is given by:

$$D_i = \begin{cases} \frac{1}{\omega_i^2} (1 - \cos(\omega_i t)) - \frac{2}{\omega^2 - \omega_i^2} \sin\left(\frac{(\omega_i + \omega)t}{2}\right) \sin\left(\frac{(\omega_i - \omega)t}{2}\right) & 0 \leq t \leq \tau \\ \frac{1}{\omega_i^2} [\cos(\omega_i(t-\tau)) - \cos(\omega_i t)] + \frac{1}{2\omega_i(\omega - \omega_i)} [\cos((\omega - \omega_i)\tau + \omega_i t) - \cos(\omega_i t)] - \frac{1}{2\omega_i(\omega + \omega_i)} [\cos((\omega + \omega_i)\tau - \omega_i t) - \cos(\omega_i t)] & \tau \leq t \end{cases} \quad (21)$$

Where  $\tau$  is the pulse length. From the classical theory of shock, the maximum response will occur during the application of the pulse whenever the forcing frequency is smaller than twice the natural frequency of the system [13]. Thus, the solution for the maximum amplitude of the dominant elastic mode and the time  $t_1^{\max}$  at which it occurs can be estimated by differentiating (21) with respect to time during the application of the pulse and finding the roots of the derivative; alternatively, computing the complete time response of the dominant mode using (21) and extracting the peak values.

Then, the rest of the dynamic responses can be estimated by computing (20) at  $t_1^{\max}$ , that is:

$$D_i^{\max} = D_i(t_1^{\max}) \quad (22)$$

The transient response II participation fraction is defined similar to equations (17) and (19) as:

$$L_i^{tsII} = \frac{|\Gamma_i D_i^{\max}|}{\sum_i^N |\Gamma_i D_i^{\max}|} \quad (23)$$

### D. Internal load Participation Factor

For point loads, the element internal forces are computed as the product of the element stiffness matrix  $K_e$  and the corresponding displacement vector  $U_e(t)$  of the nodes that conform the element in the global coordinate system.

When the element and global coordinate systems do not coincide a rotation matrix  $C^T$  is necessary to ensure that the

internal forces computed,  $N_e(t)$ , are expressed in the element coordinate system as:

$$N_e(t) = C^T K_e U_e(t) \quad (24)$$

Where  $K_e$  and  $U_e(t)$  are the element stiffness matrix and the vector of nodal displacements in the global coordinate system., respectively.

We can expand equation (24) into its modal components as:

$$N_e(t) = C^T K_e \Phi_e q(t) = C^T K_e \Phi_e \Gamma D(t) \quad (25)$$

Equation (23) gives an important insight into the variables that affect the internal loads sustained by each element. The term  $\Gamma$  is constant for a given loading conditions and its magnitude depends on the matrix of eigenvectors. On the other hand, the magnitude of  $D(t)$  is strongly dependent on the initial conditions and the ration between the forcing and the natural frequencies of the system. The magnitude of  $\Gamma D(t)$ , thus, determines the dominance of a mode in the solution, whereas the product  $\Sigma_e = C^T K_e \Phi_e$  determines the impact of such mode in the r component of the element load where  $r \in \{1:6\}$ . A participation factor can then be defined as:

$$L_{r,i}^{\text{load}} = \frac{|\sum_{e_r,i} \Gamma_i D_i|}{\sum_{i=1}^N |\sum_{e_r,i} \Gamma_i D_i|} \quad (26)$$

### IV. CASE STUDY

An aircraft stick model based on a Bombardier Aircraft platform was created to assess the performance of each of the methods described herein. The model is excited by a forcing vector  $f$  with a linear distribution of a 1000 N on the wing root and 480 N on the wing tip of the form given in equation (20). The modal responses were calculated in MSC Nastran [14] and the normalized results are displayed in Figure 2.

Figure 1. Case study: airplane stick model.

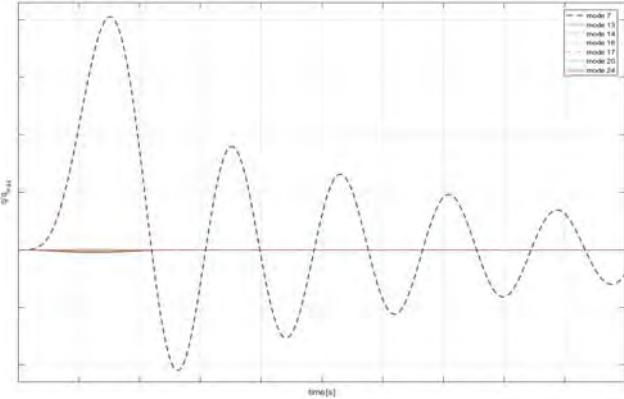

Figure 2. Normalized modal responses.

The modal participation factors of the free-free airplane model were computed using (17), (19) and (23) and the results are presented in Table I.

The results are well in agreement with the transient response of Figure 1; the first elastic mode dominates entirely the response, followed by the elastic modes 7, 8 and 10. The peak out of plane bending moment of the wing root was estimated also in MSC Nastran, and approximated using (25) with (17), (19) and (23). The percentage of error is shown in figure 3.

TABLE I. MODAL PARTICIPATION FACTORS

Modal Participation Fractions			
Elastic mode	$L_i^{ts}$	$L_i^{tsII}$	$L_i^{st}$
1	94.67%	95.41%	95.93%
2	0.00%	0.00%	0.00%
3	0.00%	0.00%	0.00%
4	0.00%	0.00%	0.00%
5	0.00%	0.00%	0.00%
6	0.00%	0.00%	0.00%
7	0.21%	0.18%	0.16%
8	0.27%	0.22%	0.20%
9	0.00%	0.00%	0.00%
10	0.31%	0.27%	0.24%

Both of the transient approximations present better results than that of the steady-state participation factor, which has an error of 32%. This result is expected since the modal amplitude computed using (17) treats the excitation as a periodic function.

That is, even though the participation factor obtained using  $L_i^{st}$  is well in agreement with Figure 1, the actual magnitude of the modal response is not. This large variation is reflected in the large error of the estimated out of plane bending moment.

The static modal participation factor  $L_i^{ts}$  was computed using the time domain solution of the modal response extracted from

Nastran; its associated error is due an implicit assumption of equation (18): the modal responses are considered to be in phase. This means that the recovered amplitudes are not time consistent, thus the method tends to either over or underestimate the value of the internal load, even when the exact solution is known.

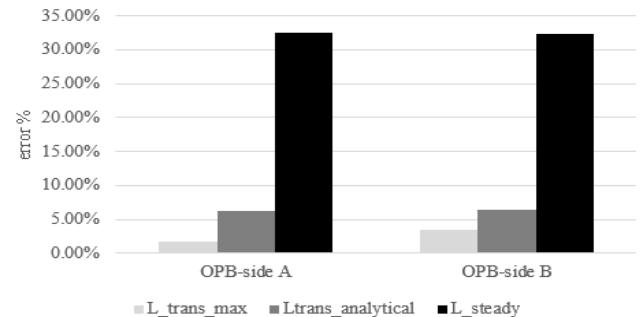

Figure 3. Normalized modal responses.

In the case of  $L_i^{tsII}$  the approximation could be improve by considering modal damping in the derivation of the analytical solution (23).

Finally, the modal participation fraction of the out of plane bending moment at the wing root were computed using (26) with (17), (19) and (23). The results are shown and compared in Table II.

TABLE II. ELEMENT INTERNAL LOAD MODAL PARTICIPATION FACTORS

Out of Plane Bending Moment at wing root contribution fractions			
Elastic mode	$L_i^{ts}$	$L_i^{tsII}$	$L_i^{st}$
1	92.449%	93.444%	94.263%
2	0.000%	0.000%	0.000%
3	0.000%	0.000%	0.000%
4	0.000%	0.000%	0.000%
5	0.000%	0.000%	0.000%
6	0.000%	0.000%	0.000%
7	0.196%	0.168%	0.152%
8	0.195%	0.159%	0.150%
9	0.000%	0.000%	0.000%
10	0.056%	0.049%	0.043%

Once again, the first elastic mode dominates entirely the response. However, it is noticed that the participation of the modes shown in Table II decrease. This means that term  $\Sigma_e$  from equation (25) increased the participation of higher order modes.

## V. CONCLUSIONS AND FUTURE WORK

Static modal participation factors have the potential to be used as response tracking mechanisms during structural design optimization, since they are inexpensive to compute and allow

to estimate the peak internal load of the elements. Thus, large design spaces could be easily updated without the need to run any dynamic analysis.

The methodology presented herein is applicable for systems with concentrated nodal forces, however, in aerospace applications we mostly encounter distributed loads such as aerodynamic and inertia loads. The extension of this methodology for aeroelastic response analysis is of particular interest and will be addressed in our future work.

**Abstract**—A higher order theory for beams based on expansion of the two dimensional (2-D) equations of elasticity into Legendre's polynomials series has been developed. The 2-D equations of elasticity have been expanded into Legendre's polynomials series in terms of a thickness coordinate.. Cases of the first and second approximations have been considered in details. For obtained boundary-value problems, a finite element method (FEM) has been used and numerical calculations have been done with MATLAB. Developed theory has been applied for study stress-strain state of the electrostatically and thermally actuated MEMS/NEM.

**Keywords-** *higher order beam theory; MEMS; NEMS; actuators*

## I. INTRODUCTION

Micro-Electro-Mechanical Systems (MEMS) are microscale devices or miniature embedded systems involving one or more components that enable higher-level functionality. MEMS have a characteristic length scale between 1 mm and 1  $\mu\text{m}$ . Similarly Nano-Electro-Mechanical Systems (NEMS) nanoscale devices. NEMS have a characteristic length scale between 1 nm and 100  $\mu\text{m}$  [3]. The MEMS and NEMS are widely used in engineering industries, communications, defense systems, health care, information technology, environmental monitoring, etc. [3]. Fabrication of the MEMS and NEMS rapidly increase from year to year. Therefore modeling, simulation and mathematical analysis are very important for optimizing process of their fabrication and further safety exploration.

Many MEMS and NEMS structures and devices can be considered as thin-walled structures that are exposed to mechanical loading, high temperature and electromagnetic fields and are in mechanical and thermal contact with other structural elements and massive bases through thin heat conducting layers. Often in the analysis and simulation of such devices classic models based in Euler-Bernoulli or Timoshenko hypothesis give an inaccurate result [1]. For accurate analysis and simulation of such structures and devices higher order theories may be more preferable. These theories

are based on expansion of the stress-strain and temperature field components into polynomial Legendre's series in term of thickness [5]. Such an approach has significant advantages because of Legendre's polynomials are orthogonal and as result obtained equations are simpler. This approach was extended and applied to thermally actuated MEMS and NEMS in [6, 7].

In this presentation high order, models of beams based on nonlocal theory of elasticity have been developed and applied for MEMS and NEMS modeling and computer simulations.

## II. 2-D NONLOCAL THEORY OF ELASTICITY

We consider a curved elastic rod in a 2-D Euclidian space, which occupies the domain  $V = \Omega \times [-h, h]$  with a smooth boundary  $\partial V$ . Here  $2h$  is thickness,  $\Omega = [-l, l]$  is the middle line of the rod and  $2l$  is its length. The boundary of the rod  $\partial V$  can be presented in the form  $\partial V = S \cup \Omega^+ \cup \Omega^-$ , where  $\Omega^+$  and  $\Omega^-$  are the upper and lower sides and  $S$  denotes lateral sides.

According to the theory of nonlocal elasticity [2], the basic equations for linear, homogeneous, isotropic, nonlocal elastic solid are given in the form of the following system of differential equations.

The equations of motion have the form

$$\nabla \cdot \boldsymbol{\sigma} + \mathbf{b} = \rho \ddot{\mathbf{u}} \quad (1)$$

Here  $\mathbf{b}$  is a vector of body forces,  $\rho$  is a density of material,  $\ddot{\mathbf{u}}$  is the acceleration vector.

Kinematic relations simplify and have the form

$$\boldsymbol{\epsilon} = (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) \quad (2)$$

Here  $\mathbf{u}$  is a displacements vector and  $\boldsymbol{\epsilon}$  is a tensor of small deformations.

According to Eringen's nonlocal elasticity theory [1] the stress at a point  $\mathbf{x}$  in a body is functional of the strain field at every point of the body. In differential form nonlocal constitutive relations are presented as

$$(1 - (e_0 a)^2 \nabla^2) \boldsymbol{\sigma} = \bar{\lambda} (tr \boldsymbol{\epsilon}) \mathbf{I} \delta_{ij} + 2\mu \boldsymbol{\epsilon} \quad (3)$$

Here  $\bar{\lambda} = \lambda \frac{2\mu}{\lambda + 2\mu}$ ,  $\lambda$  and  $\mu$  are Lamé constants of classical elasticity,  $e_0$  is the constant of material,  $a$  is a parameter describes internal characteristic length.

The differential equations of motion in the form of displacements can be represented as the following

$$\mathbf{L}_u \cdot \mathbf{u} + (1 - (e_0 a)^2 \nabla^2)(\mathbf{b} - \rho \mathbf{I}_u \cdot \ddot{\mathbf{u}}) = 0 \quad (4)$$

where  $\mathbf{I}_u$  is the matrix operator that has on the main diagonal elements equal to one and

$$\mathbf{L}_u \cdot \mathbf{u} = \mu \nabla^2 \mathbf{u} + (\bar{\lambda} + \mu) \nabla (\nabla \cdot \mathbf{u}) \quad (5)$$

Differential operator of Hamilton and its combinations in orthogonal system of coordinates related to the middle line of the beam are presented in [5].

### III. 1-D FORMULATION

In order to reduce the 2-D problem for the couple stress theory of elastic curved beams to a 1-D one, we expand the physical parameters, that describe the stress-strain state of the beam into the Legendre polynomials series along the coordinate  $x_2$ . Then any continuous function  $f(p)$  can be represented by Legendre's polynomial series according to formula

$$f(x_2) = \sum_{k=0}^{\infty} a_k P_k(\varpi), a_n = \frac{2k+1}{2} \int_{-h}^h f(\varpi) P_k(\varpi) dx_2 \quad (6)$$

where  $\varpi = x_2 / h$ .

By expanding all functions contained in the equations (1)-(3) in the Legendre's polynomial series one can obtain differential equations of motion for Legendre's polynomial series coefficients of the displacements in the form (4).

For the first order approximation theory we have

$$\begin{aligned} u_\alpha(x_1, x_2) &= u_\alpha^0(x_1) P_0(\varpi) + u_\alpha^1(x_1) P_1(\varpi), \\ \varepsilon_{\alpha\beta}(x_1, x_2) &= \varepsilon_{\alpha\beta}^0(x_1) P_0(\varpi) + \varepsilon_{\alpha\beta}^1(x_1) P_1(\varpi) \\ \sigma_{\alpha\beta}(x_1, x_2) &= \sigma_{\alpha\beta}^0(x_1) P_0(\varpi) + \sigma_{\alpha\beta}^1(x_1) P_1(\varpi) \end{aligned} \quad (7)$$

The matrix differential operator  $\mathbf{L}_u$  vectors of displacements and body forces have the form

$$\mathbf{L}_u = \begin{vmatrix} L_{11}^{00} & L_{12}^{00} & L_{11}^{01} & L_{12}^{01} \\ L_{21}^{00} & L_{22}^{00} & L_{21}^{01} & L_{22}^{01} \\ L_{11}^{10} & L_{12}^{10} & L_{11}^{11} & L_{12}^{11} \\ L_{21}^{10} & L_{22}^{10} & L_{21}^{11} & L_{22}^{11} \end{vmatrix}, \quad \mathbf{u} = \begin{vmatrix} u_1^0 \\ u_2^0 \\ u_1^1 \\ u_2^1 \end{vmatrix}, \quad \mathbf{b} = \begin{vmatrix} b_1^0 \\ b_2^0 \\ b_1^1 \\ b_2^1 \end{vmatrix} \quad (8)$$

For the second order approximation theory we have

$$\begin{aligned} u_\alpha(x_1, x_2) &= u_\alpha^0(x_1) P_0(\varpi) + u_\alpha^1(x_1) P_1(\varpi) + u_\alpha^2(x_1) P_2(\varpi), \\ \varepsilon_{\alpha\beta}(x_1, x_2) &= \varepsilon_{\alpha\beta}^0(x_1) P_0(\varpi) + \varepsilon_{\alpha\beta}^1(x_1) P_1(\varpi) + \varepsilon_{\alpha\beta}^2(x_1) P_2(\varpi), \\ \sigma_{\alpha\beta}(x_1, x_2) &= \sigma_{\alpha\beta}^0(x_1) P_0(\varpi) + \sigma_{\alpha\beta}^1(x_1) P_1(\varpi) + \sigma_{\alpha\beta}^2(x_1) P_2(\varpi). \end{aligned} \quad (9)$$

The matrix differential operator  $\mathbf{L}_u$  vectors of displacements and body forces have the form

$$\mathbf{L}_u = \begin{vmatrix} L_{11}^{00} & L_{12}^{00} & L_{11}^{01} & L_{12}^{01} & L_{11}^{02} & L_{12}^{02} \\ L_{21}^{00} & L_{22}^{00} & L_{21}^{01} & L_{22}^{01} & L_{21}^{02} & L_{22}^{02} \\ L_{11}^{10} & L_{12}^{10} & L_{11}^{11} & L_{12}^{11} & L_{11}^{12} & L_{12}^{12} \\ L_{21}^{10} & L_{22}^{10} & L_{21}^{11} & L_{22}^{11} & L_{21}^{12} & L_{22}^{12} \\ L_{11}^{20} & L_{12}^{20} & L_{11}^{21} & L_{12}^{21} & L_{11}^{22} & L_{12}^{22} \\ L_{21}^{20} & L_{22}^{20} & L_{21}^{21} & L_{22}^{21} & L_{21}^{22} & L_{22}^{22} \end{vmatrix}, \quad \mathbf{u} = \begin{vmatrix} u_1^0 \\ u_2^0 \\ u_1^1 \\ u_2^1 \\ u_1^2 \\ u_2^2 \end{vmatrix}, \quad \mathbf{f} = \begin{vmatrix} f_1^0 \\ f_2^0 \\ f_1^1 \\ f_2^1 \\ f_1^2 \\ f_2^2 \end{vmatrix} \quad (10)$$

Explicit expressions for differential operators in the matrix differential operators (8) for the beams are presented in [3].

The equations presented here can be used for modeling and stress-strain calculations of the beams by considering nonlocal effects at micro- and nanoscales

### IV. APPLICATION TO MODELING OF THE ELECTROSTATICALLY ACTUATED MICRO AND NANO BEAMS

Let us consider an elastic beam of the length  $l$ , width  $b$  and thickness  $2h$  which is suspended above the rigid foundation with an initial gap  $h_0$  in the electromagnetic field. The beam and foundation are perfect conductors and separated by a dielectric medium of permittivity  $\varepsilon_0 \varepsilon_r$ , where  $\varepsilon_0 = 8.854 \cdot 10^{-12} F/m$  is the vacuum permittivity and  $\varepsilon_r$  is the relative permittivity. A positive potential difference  $V$  between the two conductors causes the beam to electrostatically deflect downwards. We assume that the gap  $h_0$  is commensurable with the beam displacements which are assumed to be small. There is an electro conducting medium in the gap between the foundation and the beam, which does not resist the beam deformation.

From an electrical point of view, the system behaves as a variable gap capacitor. We do not consider fringing fields in the present work. Therefore a distributed force on the deformable beam due to the electric field depends on the potential difference between the two conductors and on their geometries. Because of we consider that  $h_0/l \ll 1$ , it is reasonable to assume that at every point the electrostatic force per unit length depends only on the local deflection and equals the force per unit length acting on an infinitely long straight beam separated by a distance  $h_0 + u_2(x_1)$  from a ground plane. Then the magnitude of the electrostatic force  $F_e$  acting on the deformable electrode along its normal is given by

$$F_e = \frac{\varepsilon_0 V^2}{2(h_0 - u_2)^2} \quad (11)$$

Thus the expression for the electrostatic force at a point on the plate depends only on the local gap  $h_0$  and the validity of the analysis is limited to those variable gap capacitors which are locally parallel to each other.

For convenience we introduce the nondimensional parameters of the beam deformation  $\hat{u}_\alpha^k = u_\alpha^k / h_0$  and the nondimensional coordinate  $\hat{x}_1 = x_1 / l$ . Then the electrostatic force (11) can be presented in the form

$$F_e = \frac{\alpha V^2}{(1 - \hat{u}_2)^2}, \quad \alpha = \frac{3\varepsilon_0 l^2}{4\mu b h^2 h_0^2} \quad (12)$$

An applied direct current (DC) voltage  $V$  between the beam and foundation results in the deflection of the beam and a consequent change in the system capacitance. The applied voltage has an upper limit beyond which the electrostatic force is not balanced by the elastic restoring force in the deformable conductor. Beyond this critical voltage the deformable conductor snaps and touches the lower rigid foundation. As it was mentioned in introduction, this phenomenon is called pull-in instability. We study static response of beam till pull-in instability using high order models developed here for fixed-fixed and simply supported beams.

For solution of the system of differential equation (4) with operators (8) we used simple iterative algorithm as it have been proposed in [4]. Algorithm consists in the following. We start from the initial value of  $\mathbf{u}^0(x_1)$ , for example and calculate next value form the equation

$$\mathbf{u}^{n+1} = \mathbf{T} \cdot \mathbf{u}^n \quad (13)$$

where is the operator that act in the Banach space, which properties depend on used model. In our case it is the operator inverse to (8).

Algorithm (13) is not always convergent, and for its convergence operator  $\mathbf{T}$  has to be a contraction in corresponding Banach space. In that case  $\mathbf{T}$  has a fixed point which is a solution of the system of differential equations (4) and can be obtained from the initial value  $\mathbf{u}^0(x_1)$  using iterative algorithm (13), as the limit of the iterative sequence. We do not study here conditions for convergence of the algorithm, it can be done mathematically using methods of functional analysis.

This approach we explore for investigation of the pull-in instability of the beams using first order and second order theories developed here. On each step of iteration we calculate displacements using differential equations (4) with differential operators (8)for first and second order theories respectively. Corresponding differential equations we solve numerically using finite element method (FEM). All calculations and post processing analysis have been done using commercial software MATLAB. We performed finite element analysis with MATLAB. We used PDE mode with coefficient form impute module. The differential equations (4)are presented in the form convenient for MATLAB input. In 1-D PDE coefficient module are used finite elements of Lagrange type from linear to quantic order. Also in MATLAB there is option for mesh refinement. For details we refer to the corresponding

software manuals. Our numerical experiments show that for the problem under consideration FEM has good convergence and use quadratic elements with one mesh refinement gives accurate results.

We calculated dimensionless vertical displacements of the beam using first order and second order and Euler-Bernoulli theories. Calculations have been done using iteration algorithm (13) defined above. The algorithm demonstrates good convergence for  $V < V_{in}$ , where  $V_{in}$  is the critical value of the applied voltage  $V$ , that corresponds to pull-in instability of the beam and called pull-in voltage. In the vicinity of  $V_{in}$  convergence of the algorithm becomes worse and worse and finally is broken down for value of  $V$  close to  $V_{in}$ . We define approximate value of  $V_{in}$  using that convergence property of the algorithm. For fixed-fixed beam all considered theories give the same result  $V_{in} \approx 81$  V. Results of calculation of the displacements at the middle point  $x_1 = l/2$  for various values of the applied voltage  $V$ , up to point of pull-in instability are presented. The results obtained using different theories are in a good correspondence.

## V. APPLICATION TO MODELING OF THE THERMALLY ACTUATED MICRO AND NANO BEAMS

Let us consider an elastic beam of the length  $l$ , width  $b$  and thickness  $2h$ , which is settled above the rigid foundation with an initial gap  $h_0$  in the thermal field. There is a heat-conducting medium in the gap between the foundation and the beam. The medium does not resist the beam deformation, and heat exchange between the foundation and the beam is due to the thermal conductivity of the medium. We assume that the gap  $h_0$  is commensurable with the beam displacements which are assumed to be small.

With taking into account temperature field the 1-D differential equations of thermoelasticity and head conductivity of the beam can be presented in the form

$$\begin{aligned} \mathbf{L}_u \cdot \mathbf{u} + \mathbf{L}_\theta \cdot \boldsymbol{\theta} + \mathbf{f} &= 0, \\ \mathbf{L}_{\theta\theta} \cdot \boldsymbol{\theta} + \mathbf{Q} + \boldsymbol{\chi} &= 0 \end{aligned} \quad (14)$$

The matrix differential operator  $\mathbf{L}_u$  and vectors  $\mathbf{u}$  and  $\mathbf{f}$  have the forms (8) and (10) for first and second order approximations, respectively. The differential operators  $\mathbf{L}_{\theta\theta}$  and  $\mathbf{L}_\theta$  and vectors  $\boldsymbol{\theta}$ ,  $\mathbf{Q}$ , and  $\boldsymbol{\chi}$  can be presented in the following forms.

For the first order approximation theory

$$\begin{aligned} \theta_i(\mathbf{x}) &= \theta_i^0(x_1)P_0(\omega) + \theta_i^1(x_1)P_1(\omega), \\ \chi_i(\mathbf{x}) &= \chi_i^0(x_1)P_0(\omega) + \chi_i^1(x_1)P_1(\omega) \end{aligned} \quad (15)$$

$$\mathbf{L}_\theta = \mathbf{E} \cdot \begin{vmatrix} L_1^0 \\ L_2^0 \\ L_1^1 \\ L_2^1 \end{vmatrix}, \boldsymbol{\theta} = \begin{vmatrix} \theta_1^0 \\ \theta_2^0 \\ \theta_1^1 \\ \theta_2^1 \end{vmatrix}, \mathbf{L}_{\theta\theta} = \begin{vmatrix} L^0 & 0 \\ 0 & L^1 \end{vmatrix}, \mathbf{Q} = \begin{vmatrix} Q_2^0 \\ Q_2^1 \end{vmatrix}, \boldsymbol{\chi} = \begin{vmatrix} \bar{\chi}^0 \\ \bar{\chi}^1 \end{vmatrix} \quad (16)$$

For the second order approximation theory

$$\begin{aligned} \theta_i(\mathbf{x}) &= \theta_i^0(x_1)P_0(\omega) + \theta_i^1(x_1)P_1(\omega) + \theta_i^2(x_1)P_2(\omega), \\ \chi_i(\mathbf{x}) &= \chi_i^0(x_1)P_0(\omega) + \chi_i^1(x_1)P_1(\omega) + \chi_i^2(x_1)P_2(\omega) \end{aligned} \quad (17)$$

$$\mathbf{L}_\theta = \mathbf{E} \cdot \begin{vmatrix} L_1^0 \\ L_2^0 \\ L_1^1 \\ L_2^1 \\ L_1^2 \\ L_2^2 \end{vmatrix}, \boldsymbol{\theta} = \begin{vmatrix} \theta_1^0 \\ \theta_2^0 \\ \theta_1^1 \\ \theta_2^1 \\ \theta_1^2 \\ \theta_2^2 \end{vmatrix}, \mathbf{L}_{\theta\theta} = \begin{vmatrix} L^0 & 0 & 0 \\ 0 & L^1 & 0 \\ 0 & 0 & L^2 \end{vmatrix}, \mathbf{Q} = \begin{vmatrix} Q_2^0 \\ Q_2^1 \\ Q_2^2 \end{vmatrix}, \boldsymbol{\chi} = \begin{vmatrix} \bar{\chi}^0 \\ \bar{\chi}^1 \\ \bar{\chi}^2 \end{vmatrix} \quad (18)$$

In some cases under action of mechanical load and temperature filed lower side  $\Omega^-$  of the beam can be in unilateral mechanical contact with the rigid foundation. In this case the area of close mechanical contact  $\partial V_e$  and contact forces are not known in advance. Therefore unilateral mechanical contact conditions have the form of inequalities

$$u_n \geq h_0, q_n \geq 0, (u_n - h_0)q_n = 0, \quad \forall \mathbf{x} \in \partial V_e \quad (19)$$

For the case if temperature set on upper side of the beam  $\theta^+(x_1)$  and on the foundation  $\theta^-(x_1)$  respectively, then contact conditions through heat conduction layer we have

$$T_k = \frac{\lambda_T(h_0 - u_2)(3\theta^+ + 6\theta^0 - 10\theta^1) + \lambda_T^* h \theta^-}{9\lambda_T(h_0 - u_2) + \lambda_T^* h} \quad (20)$$

Here  $u_2(x_1)$  is calculated using representation (7) and (9) for the first and second order approximation theories, respectively.

It is important to mention, that systems of differential equations of thermoelasticity and heat conductivity (14) are coupled. Their connectedness is not the one usually related to dynamical thermoelasticity. We consider stationary problem and here the connectedness of the corresponding equations caused by change of the heat conducting conditions during the microbeam deformations. One can see that in the equations of heat is presented function  $u_2(x_1)$  that is deflection of the beam. Presence of the function  $u_2(x_1)$  in the equation (20) turns the problem into nonlinear one.

For solution of the problem we use iterative algorithm developed in [51, 53]. In the first step of iteration we assume that deflection of the beam  $u_2(x_1) = 0$ . In this case we have traditional uncoupled problem of thermoelasticity and heat

conductivity. For that uncoupled problem any analytical or numerical method can be used and corresponding equations of thermoelasticity and heat conductivity can be solved independently. We refer below to this case as uncoupled or traditional formulation. In the next steps of iterations we substitute in (20) deflection  $u_2(x_1)$  obtained from the solution of the problem in previous step of iteration. Our previous and fulfilled here researches show that in the problems under consideration algorithm is convergent and convergence is fast enough.

In this study the differential equations of thermoelasticity and heat conductivity (14) we solve numerically using finite element method (FEM). All calculations and post processing analysis have been done using commercial software MATLAB and COMSOL Multiphysics. We performed finite element analysis with COMSOL Multiphysics. We used PDE mode with coefficient form impute module. The differential equations (14) are presented in the form convenient for MATLAB input. In 1-D PDE coefficient module are used finite elements of Lagrange type from linear to quartic order. Also in MATLAB there is option for mesh refinement. For details we refer to the corresponding software manuals. Our numerical experiments show that for the problem under consideration FEM has good convergence and use quadratic elements with one mesh refinement gives accurate results. Obtained with MATLAB results of the finite element analysis then have been further analyzed and compared with results obtained by Euler-Bernoulli theory.

#### ACKNOWLEDGMENT

This work was partly supported by the Committee of Science and Technology of Mexico (CONACYT) by the Research Grants (Ciencia Basica, Reference No 256458), which is gratefully acknowledged. The grants provided by Lassonde School of Engineering and NSERC Quanser Chair in Design Engineering are also acknowledged.

**Abstract**—This paper studies the dynamic characteristics of an electric solar wind propulsion system. To study the coupled interaction of the orbital and self-spinning motions of an electric solar wind propulsion system, a high-fidelity model is built up by using the nodal position finite element method, where the axial elastic and transverse dynamic motions of tether with the electric effects are considered. The coupling effects between the orbital and self-spinning motions are identified and explained, its results show that they have a significant impact on the system dynamics.

## I. INTRODUCTION

The electric solar wind sail (E-sail) is an innovative propulsion system to extract momentum from the high-speed plasma streams in the solar wind [1, 2]. The E-sail consists of a main spacecraft connected with a multiple of long and thin conductive tethers that are positively charged by a solar-powered electron gun on the spacecraft. Each tether contains a remote unit at its end, which comprises a small gas or ion thruster to control the main tether's angular velocity [3, 4].

The precise dynamics of E-sail requires a high-fidelity model of the tethers. Since the length of main tethers is several orders of magnitude larger than dimension of the main spacecraft/remote units, the attitude dynamics of the main spacecraft and remote the units can be safely omitted. Thus, the E-sail model consists of inter-connected tethers with lumped masses at the center of E-sail and the tips of main tethers. Many efforts have been devoted to the modelling of E-sail [3]. Initially, the E-sail was simplified as a spherical rigid pendulum model to investigate dynamic behavior of the sailplane attitude dynamics subjected to the tether voltage [5, 6]. The complicated dynamic behavior of E-sail caused by the tether dynamics is completely omitted. Then, the initial study was expanded by modeling each main tether as a rigid bar to study the coupled orbital-attitude dynamics of E-sail in a heliocentric transfer mission [6-8]. However, the rigid bar model ignores the influence of spring effect of tether on the

configuration and attitude of E-sail, which is critical for its application in space exploration. To address the challenge, the main tethers are modeled by elastic catenary theory, and the shape of the main tether is parameterized by the ratios of the E-sail force over the centrifugal force and the spin plane orientation over the solar wind direction [9]. Although effective, both the rigid bar and elastic catenary models cannot describe the slack phenomenon of tethers that may happen dynamically. Furthermore, the analytical solution of elastic catenary model exists in very limited cases, which is problem specific. To address the problem, the discretized model of tether has been proposed. A typical approach is to discretize tethers into a series of lumped mass connected by massless springs and dampers [4, 10]. It transforms the nonlinear partial differential equations of a tether into a set of ordinary differential equations, and it is actually a special case of the finite element method [11]. The finite element method is probably the most appealing technique among all numerical methods. It discretizes the continuous tether into a finite number of elements to approximate the solution within each element. The main advantage of the finite element method over the lumped method is its capability to handle the complex geometries with different tether properties along the tether length in an algorithmic fashion [11, 12].

Once the high-fidelity model of the E-sail is developed, the coupled dynamics of the E-sail should be investigated, such as the coupling effect between the orbital motion and the self-spinning motion around the principal axis of the E-sail [9, 10]

## II. FINITE ELEMENT FORMULATION OF ELECTRIC SOLAR WIND SAIL

### A. Coordinate Systems

Consider an E-sail as shown in Fig. 1, where the main and auxiliary tethers are divided into finite number of elements. Each element is assumed to resist tensile load only. Both main spacecraft and remote units are modeled as lumped masses without attitude dynamics. The dynamic motion of the E-sail can be described by three generalized coordinate systems: the global heliocentric-ecliptic inertial coordinate system

( $O_g X_g Y_g Z_g$ ) and the orbital coordinate system ( $O_o X_o Y_o Z_o$ ) as shown in Fig.1. The origin of the heliocentric-ecliptic inertial coordinate system  $O_g$  is at the center of the Sun, where the positive  $X_g$ -axis points in the vernal equinox direction, the positive  $Y_g$ -axis is along the normal direction of the ecliptic plane, and the positive  $Z_g$ -axis completes a right-hand coordinate system. The origin of the orbital coordinate system  $O_o$  is at the center of mass (CM) of the E-sail, where the positive  $Z_o$ -axis points from the Sun to the CM of E-sail, the positive  $X_o$ -axis is perpendicular to the  $Z_g$ -axis and  $Z_o$ -axis, and the positive  $Y_o$ -axis completes a right-hand coordinate system.

### B. Modeling of E-sail by the nodal position coordinates formulation

The nodal position finite element method is applied to model the complex E-sail due to its advantages in handling large rigid-body motion coupled with small elastic deformation in a simple and accurate formulation.

Considering a two-node straight element in the global heliocentric-ecliptic coordinate system. Taking the  $k$ -th element as an example, an arbitrary position inside the element can be expressed as,

$$\mathbf{X} = \mathbf{N}_k \cdot \mathbf{X}_{e,k} \quad (1)$$

where  $\mathbf{X} = (X, Y, Z)^T$  is the position vector inside the element in the global inertial coordinate system, and  $\mathbf{X}_{e,k} = (X_k, Y_k, Z_k, X_{k+1}, Y_{k+1}, Z_{k+1})^T$  is the nodal coordinate vector with subscripts referring to the node numbers of the  $k$ -th element,  $N_k$  is the shape function matrix defined in [11, 12]

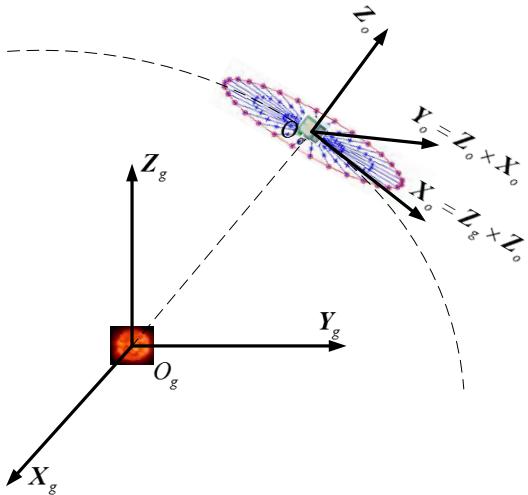

Figure. 1 Coordinate systems for E-sail

From the Hooke's law, the elastic stress of  $k$ -th element can be written as,

$$\sigma_k = E_k \varepsilon_{l,k} = E_k \left( \frac{L_{e,k} - L_{e0,k}}{L_{e0,k}} \right) = E_k \mathbf{B}_{e,k} \mathbf{X}_{e,k} - E_k \quad (2)$$

where the subscript  $k$  denotes  $k$ -th element,  $\varepsilon_{l,k}$  is the longitudinal strain of element,  $L_{e0,k}$  is the unstretched length of the element.  $E_k$  is the Young's modulus of tether material, and  $\mathbf{B}_{e,k}$  is the element strain matrix defined in [11, 12].

The element mass matrix  $\mathbf{M}_{e,k}$  can be derived from the kinetic energy, such as,

$$T_{e,k} = \frac{1}{2} \int_0^{L_{e,k}} \rho_k A_k \dot{\mathbf{X}}_{e,k}^T \dot{\mathbf{X}}_{e,k} ds = \frac{1}{2} \dot{\mathbf{X}}_{e,k}^T \mathbf{M}_{e,k} \dot{\mathbf{X}}_{e,k} \quad (3)$$

where  $\rho_k$  and  $A_k$  are the material density and cross-section area of the tether with the subscript  $k$  indicating the  $k$ -th element.

The symbol  $(\cdot)$  denotes the first order derivative with respect to time, and element mass matrix  $\mathbf{M}_{e,k}$  is given in. It should be noted that the mass matrix is constant in the global inertial coordinate system.

The strain energy due to the longitudinal deformation can be written as,

$$U_{e,k} = \frac{1}{2} \int_0^{L_{e,k}} E_k A_k \varepsilon_{l,k}^2 ds = \frac{1}{2} \mathbf{X}_{e,k}^T \mathbf{K}_{e,k} \mathbf{X}_{e,k} - \mathbf{X}_{e,k}^T \mathbf{F}_{k,k} + \frac{1}{2} E_k A_k L_{e,k} \quad (4)$$

where  $\mathbf{K}_{e,k}$  is the nonlinear element stiffness matrix and  $\mathbf{F}_{k,k}$  is the generalized nodal force vector resulting from the elasticity of element in the global inertial coordinate system[11, 12].

The virtual work done by external forces including the gravitational and Coulomb forces can be written as,

$$\delta W_{g,k} = \int_0^{L_{e,k}} \delta \mathbf{X}^T \rho_k \mathbf{g}_c A_k ds = \delta \mathbf{X}_{e,k}^T \mathbf{F}_{g,k} \quad (5)$$

$$\delta W_{c,k} = \int_0^{L_{e,k}} \delta \mathbf{X}^T \mathbf{f}_c ds = \delta \mathbf{X}_{e,k}^T \mathbf{F}_{c,k} \quad (6)$$

where  $\mathbf{F}_{g,k}$  and  $\mathbf{F}_{c,k}$  are the vectors of equivalent nodal gravitational and Coulomb forces, respectively.

Accordingly, the Hamilton's principle for the E-sail from  $t_1$  to  $t_2$  can be obtained as,

$$\delta \Pi = \int_{t_1}^{t_2} (\delta T_{e,k} - \delta U_{e,k} + \delta W_{g,k} + \delta W_{c,k}) dt = 0 \quad (7)$$

Equation (7) yields the dynamic equation as,

$$\frac{d}{dt} \left( \frac{\partial T_{e,k}}{\partial \dot{\mathbf{X}}_{e,k}^T} \right) - \frac{\partial T_{e,k}}{\partial \mathbf{X}_{e,k}^T} + \frac{\partial U_{e,k}}{\partial \mathbf{X}_{e,k}^T} = \mathbf{F}_{g,k} + \mathbf{F}_{c,k} \quad (8)$$

Substituting Eqs. (3) and (4) into Eq. (8) and rearranging them into the matrix form yield the following dynamic equation for the  $k$ -th element,

$$\mathbf{M}_{e,k} \ddot{\mathbf{X}}_{e,k} + \mathbf{K}_{e,k} \mathbf{X}_{e,k} = \mathbf{F}_{k,k} + \mathbf{F}_{g,k} + \mathbf{F}_{c,k} \quad (9)$$

The dynamic equations of E-sail can be obtained by assembling Eq. (9) with the standard assembly procedure in the finite element method [12, 13]. It is worth pointing out that the primary variables in the NPFEM are the nodal position coordinates instead of the nodal displacements in the conventional finite element method. It should be noted the internal damping of the tether is not considered in the flight dynamics due to the lack of experimental data in space. Nonetheless, the damping effect generally stabilizes the disturbance to the E-sail system. Thus, the neglect of damping will not affect the validation of current investigation.

### III. RESULTS AND DISCUSSION

In the current paper, the E-sail is assumed fully deployed and spinning. The dynamic equations of the E-sail are solved numerically by an implicit 4th order Runge-Kutta Gaussian-Legendre scheme with a Symplectic property that is suitable for the long-term numerical integration [12]. The maximum iteration number and error tolerance of each iteration step are set to 10 and 10<sup>-9</sup>, respectively. The physical properties of the E-sail are listed in Table I.

TABLE I. PHYSICAL PROPERTIES OF E-SAIL

Parameters	Values
Mass of main satellite (kg)	100
Number of main tethers (auxiliary tethers)	10
Length of each main tether (km)	10
Material type of main/auxiliary tether	Aluminum/Kapton
Material density of main tether ( $\text{kg}/\text{m}^3$ )	2700
Material density of auxiliary tether ( $\text{kg}/\text{m}^3$ )	1420
Elastic modulus of main tether ( $10^9 \text{N}/\text{m}^2$ )	70
Diameter of main tether (m)	$7.3810^{-5}$
Elastic modulus of the auxiliary tether ( $10^9 \text{N}/\text{m}^2$ )	2.5
Width of auxiliary tether (m)	0.03

#### A. The steady state of self-spinning E-sail

The initial equilibrium conditions, such as the tension of tether, for the given initial position and velocity of E-sail are unknown. Consequently, a special start-up procedure is developed with very small numerical damping to damp out the initial transient oscillation until the steady state of spinning E-sail is obtained. In this case, the main and auxiliary tethers of E-sail are modeled by one truss element respectively. The tethers are assumed spinning and subjected to a central gravitational field, but the center of E-sail is stationary in the space. The numerical damping is removed after 500 s and then

the simulation continued for another 5,900 s. The results of the steady state of a spinning E-sail are shown in Fig. 5. As shown in Fig. 2(a), the numerical damping successfully damps out the transient oscillation in the first 500 s. Then, the system state maintains constant as expected. The same phenomenon can be observed in the tensions of the main and auxiliary tethers, and the angular velocities of the remote units, seen in Figs. 2(b)-2(c).

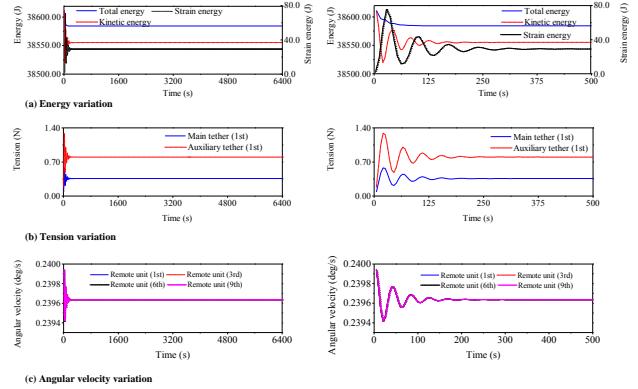

Figure 2. Steady state of a self-spinning E-sail (a) energy (b) tension in main and auxiliary tethers (c) angular velocity of remote unit.

#### B. The coupled orbital and attitude dynamics of E-sail

The coupling effect between the orbital and spinning motions of E-sail is investigated. The E-sail is temporally assumed to move in a circular orbit with a radius of  $R = 1 \text{ AU}$ . Accordingly, the orbital angular velocity  $\Omega$  of E-sail can be calculated by  $\Omega = \sqrt{\mu_s/R^3}$ , where  $\mu_s$  and  $R$  are the gravitational constant and orbital radius, respectively. In this case, the main and auxiliary tethers are modeled with one truss element respectively. The initial spin rate  $\omega$  and the time step in the simulation are set as 0.24 deg/s and 0.01 s, respectively.

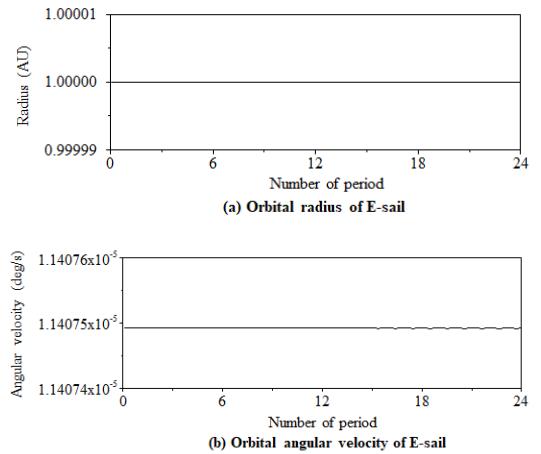

Figure 3. The results of the orbital dynamic motion of E-sail

The characteristics of the coupled motion between the orbital and spinning motions of E-sail is analyzed for a period of 36,000 s. The simulation results are shown in Figs. 3 to 4, where the time scale is changed from seconds to the number of

period of self-spinning,  $\omega_0 t / (2\pi)$ . First, it can be found in Fig. 3 that the orbital radius and angular velocity of E-sail subject to the gravity are constant as expected. It shows that the assumption of constant orbital radius  $R$  and orbital angular velocity  $\Omega$  is reasonable. Second, Fig. 4 shows that the spin rate, the length of main tether, and the tension in the main and auxiliary tethers change periodically at the frequency of spin rate of E-sail, which is corresponding to the term of  $(\mathbf{L} \cdot \boldsymbol{\Omega})\boldsymbol{\omega}$  for the spin rate. Fig. 4(a-b) shows the variations of main tether length and its rate vs the time. They are all very small. Thus, the induced Coriolis effects  $2\boldsymbol{\omega} \times \dot{\mathbf{L}}$  and  $2\boldsymbol{\Omega} \times \dot{\mathbf{L}}$  are negligible in the short term. Fig. 4(c) shows the spin rate changes from the maximum to minimum in every period. This phenomenon is caused by the coupling between the orbital and spinning motions of E-sail as presented in section 2.3. Moreover, it is seen that the tension variation in the auxiliary tether is in phase with the spin rate, while it is out of phase with the tension in the main tether, see Fig. 4(d). The reason is that the periodic motion of the spin rate induces the periodic motion of the auxiliary tether and remote unit within one period. Furthermore, the centrifugal force  $(\boldsymbol{\omega} \cdot \boldsymbol{\omega})\mathbf{L}$  causes periodical variation of tension in the main tether. Finally, three conclusions can be drawn from the above results: (i) the coupling effect between the orbital and spinning motions of E-sail will induce a periodic oscillation of the spin rate. Then, the oscillation of spin rate induces the oscillation of tension in the main and auxiliary tethers. This phenomenon is not observed in previous references [5, 10]. (ii) for the short-term analysis, the assumption of constant value of orbital radius and angular velocity is reasonable. (iii) the Coriolis effects  $2\boldsymbol{\omega} \times \dot{\mathbf{L}}$  and  $2\boldsymbol{\Omega} \times \dot{\mathbf{L}}$  are the long-term effect [5].

## CONCLUSION

A high-fidelity model of an electric solar wind sail is developed by using the nodal position finite element method. The coupling effects between the orbital and self-spinning motion are analyzed when the system subjects to the gravitational force only, and major coupling terms are identified and examined. The numerical simulations show that the coupling effect between the orbital and self-spinning motions causes a periodic variation of the spin rate and tension in the tethers.

**Abstract**— This is the first of two companion papers that examine the elastic buckling and post-buckling behavior of thin unsymmetric cross-ply laminates. When cured in a flat mold these panels possess two cylindrical equilibrium configurations. From stability perspective this problem is identified as a bifurcation buckling problem. As explained in literature thermal mismatch between plies and existing geometric imperfections triggered this behavior. Therefore, and according to Koiter it is necessary to measure and account for these geometric imperfections to accurately predict the cured shapes. Since imperfection measurement is challenging and cannot be possible in the stage of design. This work applies a unified finite element methodology based on Koiter's theory to predict the cured shapes. This methodology is consistently applied in commonly used finite element computer codes, ABAQUS, ANSYS and LS-DYNA, and their predictions are compared.

## I. INTRODUCTION

When thin unsymmetric composite laminate is cured in a press or an autoclave, it will develop out-of-plane deformations at room temperature. These deformations are due to mismatch in thermal expansion behavior and elastic properties of laminae within the laminate. Hyer [1] reported the shapes of several families of unsymmetric laminates and observed that the room-temperature shapes do not always conform to the predictions of classical lamination theory. To justify this mismatch Hamamoto and Hyer [2] measured the cured laminate and reported its lack of thickness uniformity, i.e., thicker in the middle than it is near the edges. The reason for such non-uniform thickness was explained to be caused by resin flow during curing resulting in differences in fiber volume fraction from one location to the next within the laminate. Some other factors were also suggested to be responsible for geometric imperfections, such as the hand-layup technique in which it is impossible to precisely orient or stack different laminae.

Several solutions reported in literature focused on predicting the cured shapes of unsymmetric cross-ply laminates [3]. The

first solution among these was developed by Hyer [4] presenting the extended classical lamination (ECLT) theory based on the Principal of Minimum Total Potential Energy (PMTPE). Predictions obtained from ECLT was limited to unsymmetric square laminates with straight edges. The first finite element solution was originally proposed by Schlecht and Schulte [5] in which they added a subroutine in finite element (FE) code MARC applying so-called backward method to obtain the cured shapes of unsymmetric square cross-ply laminates. Their finite element analysis (FEA) predictions agreed with Hyer's measurements and analysis [1, 4]. The first analytically correct FEA methodology using Abaqus finite element code was initially presented then published by Tawfik et al. [6, 7]. Their methodology was based on Koiter's theory [8] and their predictions of room temperature cured shapes were in good agreement with Hyer's measurements and analysis [1, 4]. Giddings et al. [8] developed an improved FE model in ANSYS V11.0 to predict the cured shapes of thin unsymmetric laminates. They developed two FE models, the first model was based on 'idealised' nominal ply-thickness which required a temporary force during the initial curing simulation to allow convergence. While the second 'improved model' used optical microscopy, data obtained post curing to account for resin rich areas in the FE simulation. Giddings et al. [8] reported excellent predictions using the 'improved model' and acceptable predictions by the model based on idealised ply-thickness. In summary, to enable FEA to accurately predict the cured shapes of thin unsymmetric laminates one must account for deviations in geometry such as resin rich areas. Meanwhile measuring the specific to certain laminate deviation may not be possible prior to manufacturing. Therefore, an analytical solution based on Koiter's theory provides the potential for accurate predictions prior to manufacturing, e.g. during the design stages.

To this end the current work aimed at providing a general applicability of the proposed methodology of Tawfik et al. [6, 7]. Their proposed methodology which they developed in Abaqus was consistently applied in Ansys and LS-Dyna. Cured shapes of thin unsymmetric laminated as predicted by all FE codes, ABAQUS, ANSYS and LS-DYNA were compared, and conclusions were provided.

TABLE II. ELEMENT TYPES IN DIFFERENT FE CODES

## II. METHODOLOGY

### A. Problem definition

Tawfik [10] and Tawfik et al. [6, 7, 11] were pioneers in investigating the shapes of unsymmetric cross-ply laminate under thermal curing stresses using FEA. Based Koiter's theory [8], considering the effect of the geometric imperfections, they developed a FE based methodology for predicting such cured shapes.

Tawfik et al. [6, 7, 11] implemented their FE methodology in ABAQUS and proved that without geometric imperfection cured shape of an unsymmetric laminate cannot be predicted by FEA accurately. They did an extensive study regarding shape prediction using their FE methodology and finally came up with two distinct useful relations which they named as the temperature-curvature relationship and the design curve.

This current work is focused on presenting a generalized FE based methodology to predict the shapes of unsymmetric cross-ply laminates under thermal curing load by replicating Tawfik's ABAQUS model in two other commercial FE codes, ANSYS and LS-DYNA, and finally comparing the ANSYS and LS-DYNA results with the ABAQUS results.

### B. Description of basic FEA model

The cross-ply unsymmetric laminate used in this model has square geometric configuration and it is a [0<sub>n</sub>/90<sub>n</sub>] laminate of Hexcel IM7/8551-7 graphite/epoxy prepreg with mechanical properties provided in Table I.

Tawfik [10] conducted the convergence study with all the shell elements available in Abaqus element library and ended with the selection of S4R as the element type and 20 × 20 as the mesh size for optimal modeling of this problem in ABAQUS.

For the present work uses shell elements and 20 × 20 mesh for modeling. Table II documents the details about the element types used in three different FE codes.

The centre point of the laminate geometry is fixed in all degrees of freedom during the curing cycle. The applied load during curing cycle is a temperature drop with a magnitude of 156 °C. Fig. 1 shows the basic ABAQUS model used for this curing cycle problem.

TABLE I. MECHANICAL PROPERTIES OF MATERIAL AS REPORTED BY TAWFIK [10]

Material	$E_{11}$ (GPa)	$E_{22}$ (GPa)	$G_{12}$ (GPa)	$v_{12}$	$\alpha_1$ ( $10^{-6}/^\circ\text{C}$ )	$\alpha_2$ ( $10^{-6}/^\circ\text{C}$ )	$t$ (μm)
IM7/8551-7 graphite/epoxy prepreg	141.18	7.20	4.45	0.30	0.30	30.98	138.75

FE code	Element name	Element type	Number of DOF*	Description
ABAQUS [12]	S4R	Shell element	6	A four-node general-purpose finite-membrane-strain shell with reduced integration for hourglass control
ANSYS [13]	Shell 181	Shell element	6	A four-node thin to moderately-thick shell with both full and reduced integration schemes
LS-DYNA [14]	Type 16	Shell element	6	A four-node fully integrated thin shell with assumed strain interpolation and available hourglass control option

### C. Equation and curves presented by Tawfik and Tawfik et al.

#### 1) The temperature-curvature relationship

Utilizing the concept of geometric imperfection, Tawfik et al. [6, 7, 11] used their ABAQUS model to predict the bifurcation point or the tendency of retaining cylindrical-like. Two curvatures of two adjacent sides of the square unsymmetric cross-ply laminate were plotted in a temperature vs. curvature graph, keeping the cure cycle relative temperature along the abscissas and curvatures along the ordinates. The point from which the two curvatures start deviating from each other is the bifurcation point and the graph was named as temperature-curvature relationship. This deviation of two curvatures of two adjacent sides indicates the tendency of a unsymmetric cross-ply laminate to retain two different curvatures with bistable behavior while curing. Their ABAQUS analysis predicted the bifurcation point to occur at a relative temperature of 140.60 °C with a laminate curvature of 0.290 m<sup>-1</sup>. Curvatures were approximate using (1).

$$\kappa = \frac{1}{R} \cong \frac{8d}{C^2 + 4d^2} \quad (1)$$

where  $\kappa$  is the approximated curvature,  $R$  is the radius,  $d$  is the out-of-plane displacement and  $C$  is the chord length as shown in Fig. 2.

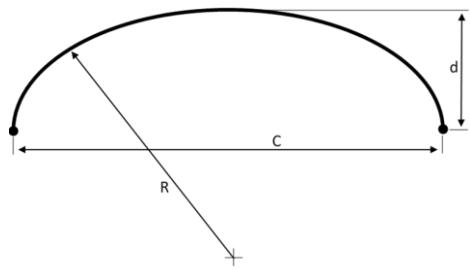

Figure 2. Curvature of laminate

## 2) The design curve

Tawfik [10] and Tawfik et al. [6, 7, 11] predicted the out-of-plane deformation and expressed it as the effect of laminate side length-to-thickness ratio. This relationship was named as the design curve while keeping the non-dimensional curvature along the abscissas and non-dimensional side length along the ordinates. This design curve shows that the relative side length-to-thickness ratio is one of the parameters controlling the panel's bistable behavior and there is a critical value of side length in units of thickness that makes the laminate to have cylindrical-like shape. This non-dimensional critical side length for square  $[0_n/90_n]$  laminate was documented as  $L_C^* = 82.8$ , below which the cured panel assumes a saddle shape and above it the panel is bistable with cylindrical-like equilibrium shapes. They defined the non-dimensional side length and non-dimensional curvature as respectively (2) and (3).

$$L^* = \frac{L}{t} \quad (2)$$

$$\kappa^* = \kappa \times L \times \frac{180}{\pi} \quad (3)$$

where  $L^*$  and  $\kappa^*$  are non-dimensional side length and non-dimensional curvature respectively. While  $L$ ,  $t$  and  $\kappa$  are the side length, thickness and curvature of the laminate respectively.

## D. Modelling curing cycle in ABAQUS

Tawfik [10] and Tawfik et al. [6, 7, 11] presented, in ABAQUS the cylindrical-like cured shapes of an unsymmetric laminate can be easily obtained through three major steps as follows

- Eigenvalue buckling analysis of the perfect geometry using the \*BUCKLE option which is also known as buckling analysis.
- Introducing geometric imperfections as a linear superposition of buckling eigenmodes of the perfect geometry using \*IMPERFECTION option.
- A geometrically non-linear load-displacement analysis of the imperfect structure using the \*STATIC, STABILIZE method which is one kind of post buckling analysis.

Tawfik [10] and Tawfik et al. [6, 7, 11] stated, one of the major step of their methodology is accounting for geometric imperfection. So, they studied the influence of imperfection size on predicting the bifurcation point and figured out that imperfection in a must for predicting cylindrical-like cured shape and the most suitable imperfection size for this problem is one tenth of the laminate thickness. This current work will also use the same size of imperfection.

Tawfik [10] mentioned about two different procedures available in ABAQUS for solving non-linear systems of equations and among those two, the one which can introduce an artificial damping into the solution is more suitable for problems with local instability and hence enables to capture the cylindrical shape during the curing cycle and in ABAQUS it is available in the name of STABILIZE.

Further for modeling the curing cycle in LS-DYNA and ANSYS Tawfik's three-step methodology will be followed as guideline.

## E. Modelling curing cycle in LS-DYNA

With LS-DYNA cylindrical-like cured shapes of an unsymmetric laminate can be predicted as follows.

- Eigenvalue buckling analysis of the perfect geometry using the \*CONTROL\_IMPLICIT\_EIGENVALUE [14] option.
- Introducing geometric imperfection as a linear superposition of buckling eigenmodes of the perfect geometry using \*PERTURBATION\_NODE [14] option.
- A geometrically non-linear load-displacement analysis of the imperfect structure using the \*CONTROL\_IMPLICIT\_STABILIZATION [14] option.

ABAQUS creates the buckling results in normalized form but in LS-DYNA eigen buckling analysis results are not normalized. So, this should be taken into consideration while selecting the value of the scale factor.

## F. Modelling curing cycle in ANSYS

Unlike ABAQUS and LS-DYNA solving this current problem in ANSYS requires following four steps:

- Static analysis step to get an initial deformation that is going to be used in the Eigen buckling analysis.
- Eigen buckling analysis step is used to generate the Eigen modes for the model based on the applied thermal load in the static analysis step using any available eigen solver i.e.; SUBOPT [13].
- Based on extracted Eigen mode shapes the geometry of the model is to be perturbed using a required imperfection value. The command UPCOORD [13] is used by multiplying a scale factor of imperfections to a specified step results.
- The last step is to solve a non-linear analysis for the imperfect geometry obtained from the previous step using STABILIZE [13] command.

Like LS-DYNA eigen buckling analysis results in ANSYS are not normalized by default. So, this should be taken into consideration while selecting the value of the scale factor.

#### G. A unified Finite Element Analysis methodology

Curing of a laminate is a locally unstable nonlinear problem which is highly imperfection sensitive. So, modeling the curing cycle in FEA requires solving a linear perturbation associated with geometric imperfection and a nonlinear load-displacement analysis in a row [10]. Implementation of modeling technique proposed by Tawfik in these three FE codes can be summarized as:

Modeling a curing cycle in any FEA code requires three available options.

- An eigenvalue solver for buckling analysis to get the eigenmodes.
- An option to introduce a geometric imperfection into the structure.
- An implicit non-linear solver that can introduce an artificial damping into the solution to make this locally unstable problem to capture the cylindrical-like shape.

Tawfik [10] first came up with this three-step Finite Element Analysis methodology and can be used as a unified guideline for modelling curing cycle in any FEA as LS-DYNA and ANSYS.

### III. RESULTS AND DISCUSSION

Tawfik [10] did an extensive study to figure out the effect of geometric imperfection on predicting the cured shapes of unsymmetric laminates and proved using ABAQUS that without any imposed geometric imperfection FEA cannot capture the cylindrical-like shape and predicts the saddle shape. Fig. 3 is the predicted saddle shape by ABAQUS in absence of imperfection and Fig. 4 is the cylindrical-like shape in the presence of imperfection.

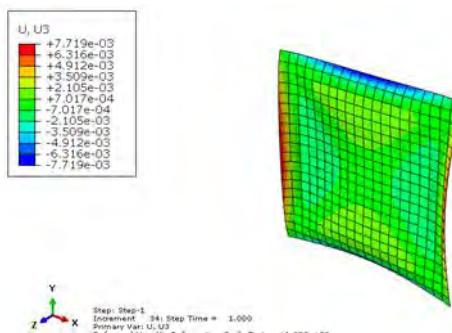

Figure 3. Saddle shape predicted by ABAQUS in absence of geometric imperfection

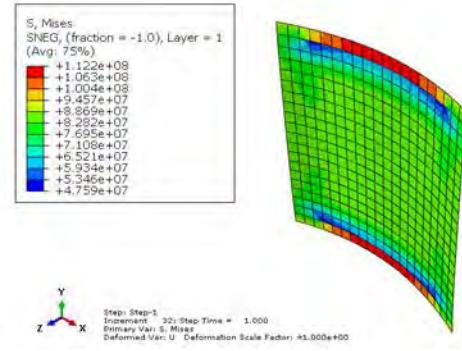

Figure 4. Cylindrical-like shape predicted by ABAQUS in presence of geometric imperfection

With the same size of imperfection suggested by Tawfik [10] and without imperfection LS-DYNA and ANSYS both predict cylindrical-like and saddle shape respectively as ABAQUS does. Fig. 5 is the predicted saddle shape by LS-DYNA in absence of imperfection and Fig. 6 is the predicted cylindrical-like shape in presence of imperfection. Fig. 7 and Fig. 8 respectively represents the saddle and cylindrical-like shape predicted by ANSYS.

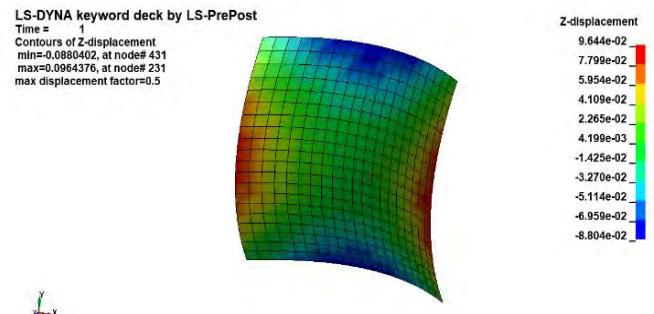

Figure 5. Saddle shape predicted by LS-DYNA in absence of geometric imperfection

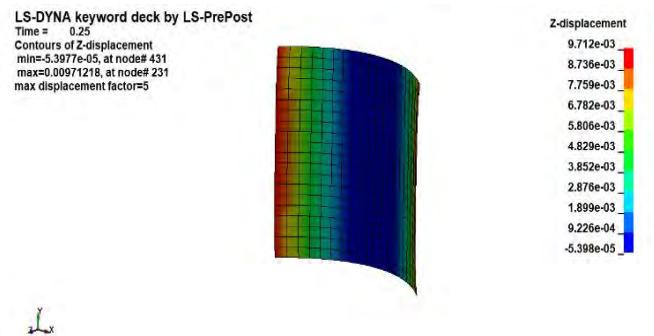

Figure 6. Cylindrical-like shape predicted by LS-DYNA in presence of geometric imperfection

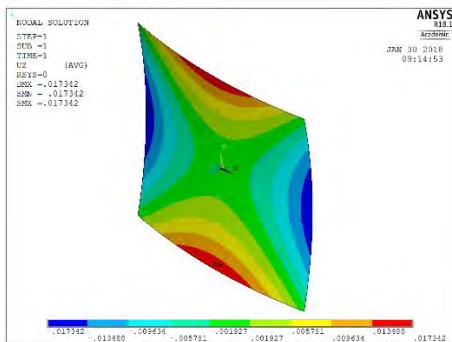

Figure 7. Saddle shape predicted by ANSYS in absence of geometric imperfection

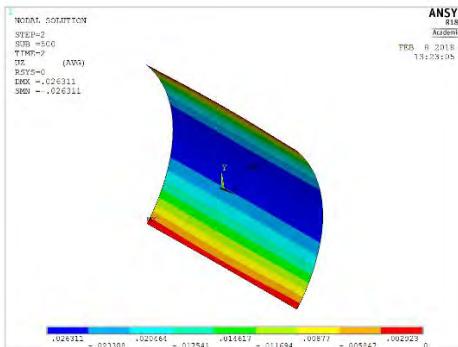

Figure 8. Cylindrical-like shape predicted by ANSYS in presence of geometric imperfection

To compare the ABAQUS, ANSYS and LS-DYNA results, both the temperature-curvature relationship and the design curve from these three codes have been plotted and compared with each other.

To plot the temperature-curvature relation Tawfik's [10] results in ABAQUS were reiterated in ABAQUS, ANSYS and LS-DYNA while recording curvatures of both sides and thermal load at every time increment. Fig. 9 shows the temperature curvature relation from ABAQUS, ANSYS and LS-DYNA for square  $[0_n/90_n]_T$  laminate of Hexcel IM7/8551-7 graphite/epoxy prepreg in the same graph. The figure also shows the results from ABAQUS, ANSYS and LS-DYNA are in an excellent agreement and the bifurcation temperature prediction from these three FE codes is almost the same.

To plot the design curve the side length of the square  $[0_n/90_n]_T$  laminates was varied from 0.01 m to 0.15 m keeping the laminate thickness and layup unchanged while recording the corresponding curvatures of the two sides of the laminate at the end of the curing cycle. Fig. 9 Shows the design curve from ABAQUS, ANSYS and LS-DYNA for square  $[0_n/90_n]_T$  laminate of Hexcel IM7/8551-7 graphite/epoxy prepreg in the same graph and it also shows the results from ABAQUS, ANSYS and LS-DYNA are in an excellent agreement and the critical side length prediction from these three FEA codes is almost the same.

A good agreement of ANSYS and LS-DYNA results with the ABAQUS result makes Tawfik's three-step FE based methodology unified.

#### IV. CONCLUSION

This work addressed the buckling behavior of thin unsymmetric laminates and their out-of-plane cured shapes. An analytically correct methodology is obtained from literature and applied in commonly used finite element computer codes, Abaqus, Ansys and LS-Dyna. Predicted out-of-plane cured shapes of thin unsymmetric cross-ply laminated were compared and results from all FE codes were found in excellent agreement. Therefore, the currently used analytically correct methodology proved its generality and applicability in commonly used FE software codes.

**Abstract**— This is the second of two companion papers that examine the elastic buckling and post buckling behavior of unsymmetric cross-ply laminates. The existence of geometric imperfection and thermal mismatch between plies result in these panels to retain two equilibrium configurations despite being cured in a flat mold. These equilibrium configurations conform to cylindrical shapes of orthogonal and opposite curvatures. Under externally applied load a panel undergoes snap-through behavior from one equilibrium shape to the other. The unified finite element methodology based on Koiter's theory and presented in the first companion paper is extended to predict the required force responsible for snap-through behavior. Accordingly, ABAQUS, ANSYS and LS-DYNA finite element codes are used to predict the critical snap-through forces and their predictions are compared.

**Keywords**-stability; bistable; snap-through; snap-back; finite element; post buckling

## II. INTRODUCTION

It was observed that a cured thin unsymmetric cross-ply laminate will possess two equilibrium configurations. These equilibrium configurations conform to two cylindrical shapes of equal and opposite curvatures which was initially reported by Hyer [1]. The cured panel when triggered it undergoes snap-through behavior from one equilibrium shape to the other, hence called bistable. A panel exhibit this post buckling response if it originally possessed large out-of-plane at room temperature caused by thermal stresses in its layers. The effect of thermal stresses and the existence was originally explained and documented by Hamamoto and Hyer [2].

Bistable panels found many applications in morphing and energy harvesting as discussed in Emam and Inman [3]. It is credited to Hyer to present the first analytical solution to predict the out of plane deformations of these panels [4]. Based on the Principal of Minimum Total Potential Energy PMTPE, Hyer developed the extended classical lamination theory (ECLT). Later Hyer's colleagues Dano [5] and Schultz [6] extended the ECLT to predict the requirements to trigger snap-through behavior using shape memory alloys (SMA) and piezoelectric

actuators, respectively. Tawfik [7] extended his ABAQUS finite element (FE) methodology to predict the force required to trigger snap-through behavior in panels with various planforms. This methodology was based on Koiter's theory [8] in accounting for geometric imperfections and originally proposed by Tawfik et al. [9, 10]. ABAQUS based FE predictions of snap-through loads and test results reported in [7] were in good agreement. Therefore, the proposed ABAQUS based FE methodology proved to be successful predicting post buckling behavior. As reported by Emam and Inman [3] many researchers worked on the same problem, i.e. triggering snap-through behavior in bistable panels. Meanwhile, the ABAQUS FE methodology proposed by Tawfik [7] proved successful application in predicting mechanical force or piezoelectric actuators requirements. Moreover, this methodology is analytically correct and do not require obtaining any measurement of actual imperfection in the manufactured panel. Therefore, this methodology possesses potential to be used during the design stages of morphing applications.

The current work targeted generalizing the proposed methodology of Tawfik [7] and investigating the applicability in wide variety of FE computer codes. Therefore, this proposed methodology was consistently applied in commonly used FE codes ANSYS and LS-DYNA. The force required to trigger snap-through behavior in thin unsymmetric cross-ply laminates was predicted by ABAQUS, ANSYS and LS-DYNA. Predictions obtained from FE analysis were compared with test values and proved to be consistent and in good agreement.

## III. METHODOLGY

### A. Problem definition

Tawfik [7] and Tawfik et al. [9, 10, 11] were the pioneer in investigating the stability of unsymmetric cross-ply laminates using Finite Element Analysis (FEA). Utilizing two back to back non-linear load-displacement analysis they developed a FE based methodology to examine the bistable characteristics of thin unsymmetric cross-ply laminates using ABAQUS, a commercial FE code, and presented their analysis outcome as a load-displacement curve to show that a cured unsymmetric

cross-ply laminate is stable in its both equilibrium positions which is termed as the bistable behavior. For different geometries, forces required to trigger snap-through of such bistable laminates were also predicted and compared with test measurements.

This current work is focused on presenting a generalized FE based methodology to capture the bistable characteristics of a unsymmetric cross-ply laminate under thermal load by replicating Tawfik's ABAQUS [9, 10] work in two other commercial FE codes, ANSYS and LS-DYNA, and finally comparing their results with Tawfik's ABAQUS and test results.

### B. Description of basic FEA model

The unsymmetric cross-ply laminate used in this problem has a square geometric configuration and it is a thin  $[0_2/90_2]_T$  laminate of Hexcel IM7/8551-7 graphite/epoxy prepreg with mechanical properties provided in Table I. Tawfik [7] conducted the convergence study with all the shell elements available in ABAQUS element library and ended with the selection of S4R as the element type and  $20 \times 20$  as the mesh size for optimal modeling of this problem in ABAQUS. This present work will use the same mesh size and the similar types of elements in two other FE codes. Table II documents the details about the element types used in three different FE codes.

Tawfik [7] mention that investigation of stability characteristics is a subsequent analysis of curing and in FEA bistable behavior of a thermally cured unsymmetric cross-ply laminate can easily be captured by performing an extra nonlinear load-displacement analysis right after the curing cycle. Only the boundary conditions and loading need to be changed during this extra step. During the first step, the curing cycle, center point of the laminate geometry is kept fixed in all degrees of freedom and the applied load is a temperature drop with a magnitude of  $156^\circ\text{C}$ . During the second step, for analyzing stability characteristics, temperature of the cured shape is kept constant at  $-156^\circ\text{C}$  and the center point of the cured shape is kept free only in z-direction while the four corners are kept free in all degrees other than the z-direction. A concentrated force,  $P$ , with a value higher than the snap-through load is applied along the z-direction at the center point as displayed in Fig. 1.

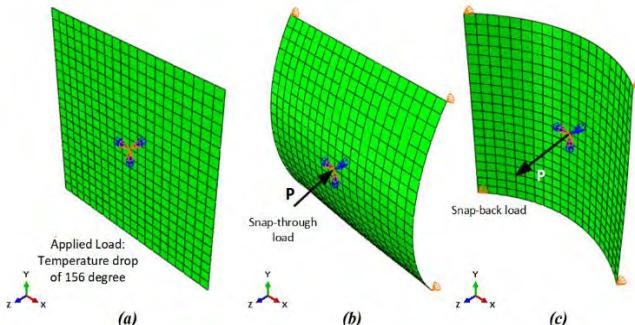

Figure 1. ABAQUS model at different stages of analysis showing the corresponding shapes, boundary conditions and applied load; a) at the beginning of first step b) at the beginning of the second step c) at the end of the second step.

TABLE II. ELEMENT TYPES IN FE CODES.

FEA code	Element name	Element type	Number of DOF*	Description
ABAQUS [13]	S4R	Shell element	6	A four-node general-purpose finite-membrane-strain shell with reduced integration for hourglass control
ANSYS [14]	Shell 181	Shell element	6	A four-node thin to moderately-thick shell with both full and reduced integration schemes
LS-DYNA [15]	Type 16	Shell element	6	A four-node fully integrated thin shell with assumed strain interpolation and available hourglass control option

\*Degrees of freedom

Fig. 1 shows the ABAQUS model and its geometric shapes at different stages of the stability analysis. It also illustrates the corresponding boundary conditions and applied loads associated with those stages.

### C. Notations used by Tawfik and Tawfik et al.

Tawfik [7] and Tawfik et al. [11] used some important notations to describe the stability characteristics of a thermally cured bistable unsymmetric cross-ply laminate.

- First equilibrium shape: Laminate's shape when the larger curvature is along the x-axis, Fig. 2a.
- Second equilibrium shape: Laminate's shape when the larger curvature is along the y-axis, Fig. 2b.
- Snap-through: Forcing a laminate to snap from first equilibrium shape to the second equilibrium shape, Fig. 2a.
- Snap-back: Forcing a laminate to snap from the second equilibrium shape to the first equilibrium shape, Fig. 2b.

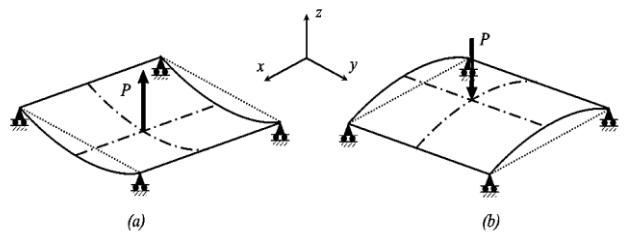

Figure 2. Triggering snap-through in cylindrical panel via concentrated force [7, 11].

#### D. Snap-through and snap-back analysis with ABAQUS

Tawfik [7] and Tawfik et al. [9, 10] showed that snap-through and snap-back can be captured in ABAQUS using following steps

- Eigenvalue buckling analysis of the perfect geometry using the \*BUCKLE keyword to get the eigenmodes.
- Introduce imperfections into the geometry using \*IMPERFECTION keyword.
- Non-linear load-displacement analysis of the imperfect geometry using the \*STATIC, STABILIZE keyword to get the cured shape.
- A second non-linear load displacement analysis of the cured shape using \*STATIC, STABILIZE keyword to capture the snap-through and snap-back.

Among these four steps, first three are for obtaining the cured shape while the fourth step is for snap-through and snap-back of that cured shape [7, 9, 10].

The second non-linear load-displacement analysis in Tawfik's [7, 9] two-step FE methodology was pursued by performing the following sub steps

- Boundary condition of the cured shape was reset such that the center point of the panel was free only in z-direction and the four corner points were free in all degrees other than the z-direction.
- A concentrated force, P, higher than the snap-through load was applied at the center point along the z-direction such that it tended to switch the curved laminate to its second equilibrium shape.
- As the laminate switched to its second equilibrium shape the applied load was removed to make sure that the retained shape was stable.
- After the second equilibrium position was found force, P, was applied again along the z-direction such that it tended to switch the panel to its first equilibrium shape. Boundary conditions were kept unchanged.
- As the laminate switched back to its first equilibrium shape the load was removed once again to make sure that this retained shape was stable.

Further, for modeling of the snap behavior in LS-DYNA and ANSYS Tawfik's two-step methodology will be followed as a guideline.

#### E. Snap-through and snap-back analysis with LS-DYNA

With LS-DYNA snap behavior of cured bistable unsymmetric laminate can easily be captured as follows

- Eigenvalue buckling analysis of the perfect geometry using the \*CONTROL\_IMPLICIT\_EIGENVALUE [15] keyword.
- Introduce imperfections into the geometry using \*PERTURBATION\_NODE [15] keyword.
- Non-linear load-displacement analysis of the imperfect geometry to capture the cured shape using the \*CONTROL\_IMPLICIT\_STABILIZATION [15] keyword.

- A second non-linear load displacement analysis of the cured shape to capture the snap-through and snap-back using \*CONTROL\_IMPLICIT\_STABILIZATION keyword.

Like ABAQUS the first three steps are for obtaining the cured shape and the fourth one is for snap-through and snap-back of that cured shape.

#### F. Snap-through and snap-back analysis with ANSYS

Unlike ABAQUS and LS-DYNA solving snap-through and snap-back in ANSYS require following steps

- Static analysis step to get an initial deformation that is going to be used in the Eigen buckling analysis.
- Following is the eigen buckling analysis to generate the 1<sup>st</sup> eigenmode under thermal loading using any available eigensolver.
- Based on extracted eigenmode shape, the geometry of the model is to be perturbed using a required imperfection size. The command UPCOORD [14] is used to introduce the imperfection.
- The next step is to solve a non-linear analysis of the imperfect geometry using STABILIZE [14] command to get the cured shape.
- A second non-linear load displacement analysis of that cured shape using STABILIZE [14] command.

First four steps are for obtaining the cured shape and the fifth one is for snap-through and snap-back of that cured shape.

#### G. A unified Finite Element Analysis methodology

Successful implementation of Tawfik's ABAQUS based FE methodology in ANSYS and LS-DYNA can be summarized as follows

Modeling snap-through and snap-back to investigate the stability characteristics of a bistable unsymmetric cross-ply laminate in any FE code requires two back to back analysis

- 1<sup>st</sup> analysis is for obtaining the cured shape of that unsymmetric cross-ply laminate.
- 2<sup>nd</sup> analysis is the non-linear load displacement analysis of that cured shape to obtain the snap-through and snap-back.

Tawfik [7] and Tawfik et al. [9, 10, 11] first came up with this two-step FE methodology and can be used as a unified guideline for studying stability characteristics of a bistable unsymmetric cross-ply laminate in any FE code, like LS-DYNA or ANSYS.

## IV. RESULTS AND DISCUSSION

Fig. 3 shows the comparison of load-displacement curves extracted from ABAQUS, ANSYS and LS-DYNA illustrating that they are in good agreement.

Fig. 4 shows the two equilibrium shapes of a bistable laminate extracted from ABAQUS, while Fig. 5 and Fig. 6 display the equilibrium shapes solved by ANSYS and LS-DYNA respectively.

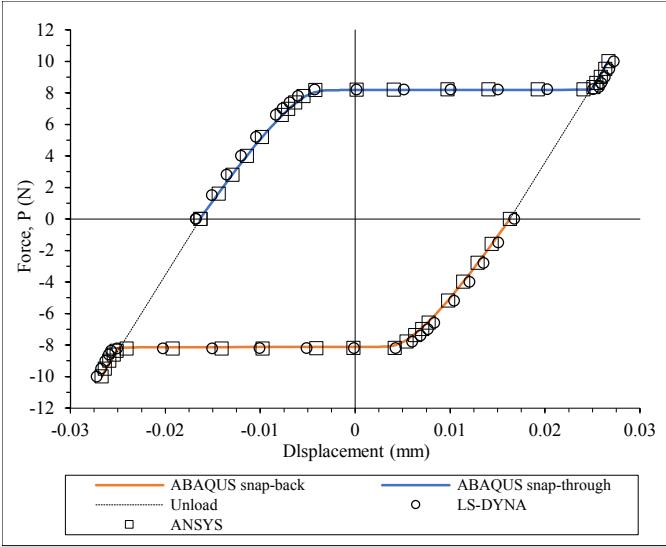

Figure 3. Load-displacement curve for a  $150 \times 150 \text{ mm}^2$  cured laminate made of Hexcel IM7/8551-7 graphite/epoxy prepreg with  $[0_2/90_2]_T$  stacking.

TABLE III. EXPERIMENTAL AND FE SNAP-THROUGH LOADS OF SQUARE SPECIMENS

Sidelength [7] (mm $\times$ mm)	Test [7] P (N)	ABAQUS [7]		LS-DYNA		ANSYS	
		P (N)	%	P (N)	%	P (N)	%
151 $\times$ 150	9.61	8.72	-9.29	8.69	-9.50	8.76	-8.84
123 $\times$ 125.5	8.90	8.15	-8.46	8.19	-7.87	8.06	-9.44
100 $\times$ 101	8.09	7.54	-6.76	7.49	-7.29	7.20	-11.00
87 $\times$ 88	5.11	4.93	-3.46	5.09	-0.21	4.82	-5.68
67 $\times$ 67	2.75	2.7	-1.81	2.69	-1.84	2.68	-2.55

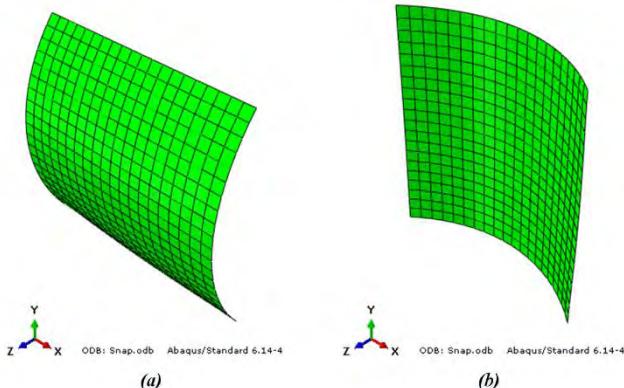

Figure 4. a) First equilibrium shape and b) Second equilibrium shape extracted from ABAQUS.

TABLE IV. EXPERIMENTAL AND FE SNAP-BACK LOADS OF SQUARE SPECIMENS

Sidelength [7] (mm $\times$ mm)	Test [7] P (N)	ABAQUS [7]		LS-DYNA		ANSYS	
		P (N)	%	P (N)	%	P (N)	%
151 $\times$ 150	10.39	9.42	-9.36	9.49	-8.63	9.48	-8.76
123 $\times$ 125.5	10.06	9.25	-8.02	9.29	-7.61	9.50	-5.57
100 $\times$ 101	8.27	7.75	-6.35	7.69	-6.89	7.68	-7.13
87 $\times$ 88	6.12	5.37	-12.27	5.53	-9.61	5.22	-14.71
67 $\times$ 67	4.45	2.97	-33.26	3.05	-31.37	2.78	-37.53

Tawfik [7] also studied the effect of geometry on the stability characteristics by changing the sidelength of thin  $[0_2/90_2]_T$  square laminate and documented the snap-through and snap-back loads comparing the ABAQUS predictions with the test measurements. Table III shows the snap-through loads predicted in this present work by LS-DYNA and ANSYS while table IV shows the snap-back loads. These two tables also illustrate the percentage differences in predictions from these three FE codes while compared with the test measurements, where all the test measurements and ABAQUS results are from Tawfik [7]. ABAQUS, ANSYS and LS-DYNA all are in good agreement with the test measurements which proves the generality of that two-step FE methodology developed by Tawfik [7] and Tawfik et al. [9, 10, 11].

## V. CONCLUSION

The current work addressed post buckling behavior in thin unsymmetric cross-ply laminates and stability characteristics. An analytically correct methodology is obtained from literature and applied in commonly used finite element computer codes, ABAQUS, ANSYS and LS-DYNA. Critical forces required to trigger snap-through behaviour in thin unsymmetric cross-ply laminated were compared with test measurement and found to be in good agreement. Therefore, the adopted analytically

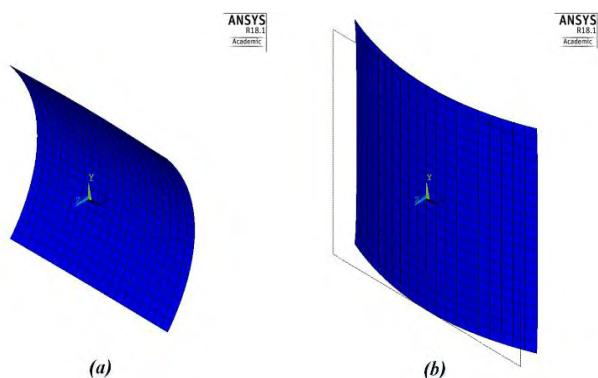

Figure 5. a) First equilibrium shape and b) Second equilibrium shape extracted from ANSYS.

correct methodology proved generality and recommended for analysis and design of unsymmetric composites morphing applications.

**Abstract**— The Equations of Motion (EoM) software, developed by University of Windsor Vehicle Dynamics and Control Research Group, can be used to generate linear or linearized equations of motion for mechanical systems, and is particularly well suited to vehicle dynamics. This paper describes an effort to extend its capability to include the effects of wings on the motion of multibody systems.

**Keywords-** *multibody dynamics; aerodynamics; equations of motion; stability; eigenvalues; open source software*

## I. INTRODUCTION

This paper discusses the Equations of Motion (EoM) multibody dynamics software developed by University of Windsor Vehicle Dynamics and Control Research Group, and an attempt to extend its capability to include the effects of wings on the motion of multibody systems.

The EoM software can be used to generate linear or linearized equations of motion for multibody mechanical systems. The software is entirely open source and runs within the MATLAB® framework, or in the syntax compatible open source alternative, Octave. It has also recently been ported to Julia, a new open source high performance programming language optimized for numerical computing. It is freely available online at the software hosting site [www.github.com](http://www.github.com).

The input of the software is a simple function file describing the system in question, and the output is the state space form of the equations, and optionally, a report tabulating the results of a linear analysis in a .pdf format, and animations of the mode shapes that can be viewed using any virtual reality modelling language (VRML) viewer.

When analyzing a multibody system, EoM will first read the information from the input data, and build the necessary stiffness and constraint Jacobian matrices required to find all the preload and constraint forces. Once these are known, the stiffness matrices are updated with the tangent stiffness terms. The kinematic differential equations relating position and velocity

are then combined with the Newton-Euler equations of motion, reduced to a minimal coordinate set, and cast in the following form:

$$\begin{bmatrix} \mathbf{E} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{x}} \\ \mathbf{y} \end{Bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} \begin{Bmatrix} \mathbf{x} \\ \mathbf{u} \end{Bmatrix} \quad (1)$$

A careful examination will show that this system, known as the descriptor form of the state space, can be further reduced to standard state space form, if the  $\mathbf{E}$  matrix is non-singular. If it is singular, then the system becomes a set of differential-algebraic equations. Nevertheless, a singular value decomposition approach can be used to reduce the system to an equivalent lower dimensional standard state space form. From this state matrix form, EoM will perform a number of linear analyses, e.g., calculate the eigenvalue of each mode to determine the stability, compute the frequency response between any inputs or outputs that have been defined, and determine the minimal realization (the minimum dimensional system with equivalent input-output behaviour).

## II. EXTENSION TO INCLUDE AERODYNAMIC EFFECTS

The intention of the work described in this paper is to extend the capabilities of the EoM software to include aerodynamic effects. The EoM software is primarily used to model vehicle dynamics; there are many cases where aerodynamic effects could have significant influence on vehicle behaviour. The addition of aerodynamic items to EoM would enable automated construction of multibody dynamic models of a number of systems, e.g. a vehicle ride (bounce-pitch) model with front and rear wings, a motorcycle with an aerodynamic fairing, or an aircraft with discrete flexible model elements (e.g. a torsionally flexible fuselage). More elaborate examples might include an aircraft during lift-off or landing, where both the tires and the aero surfaces are contributing to the motion, or an aircraft towing a second aircraft with a cable, as is commonly used when launching gliders.

### A. Basic wing example

To illustrate the inclusion of aero effects on a dynamic vibrating system, consider the equations of motion for the

<sup>†</sup>corresponding author

spring mass system, with a single wing attached, as depicted in Fig. 1. The development begins with the breakdown of the net aerodynamic force into lift and drag. The equations for lift force  $L$  and drag force  $D$  are written as a function of the dynamic pressure  $q$ , where  $\rho$  represents the air density,  $V$  the airstream velocity, and  $S$  the wing area.

$$q = \frac{1}{2} \rho V^2 \quad (2)$$

$$L = q S C_L \quad (3)$$

$$D = q S C_D \quad (4)$$

The nondimensional coefficients of lift and drag are  $C_L$  and  $C_D$ , respectively.

Note that the lift and drag forces are assumed to remain parallel and perpendicular to the airflow direction respectively, *measured in a reference frame that moves with the wing*. If the wing is moving vertically downward, the airflow appears to have an upward velocity component, quantified by the *angle of attack*. The angle of attack can be written in terms of the vertical speed of the wing, and simplified by assuming small angles.

$$\alpha \approx \alpha_0 - \frac{\dot{z}}{V} \quad (5)$$

In effect, the directions of the aero forces as defined above change relative to the ground fixed reference frame. Taking the vertical component of the aero forces gives:

$$Z = L \cos(\alpha - \alpha_0) + D \sin(\alpha - \alpha_0) \quad (6)$$

To linearize, a truncated Taylor series is used.

$$Z \approx Z_0 + \left. \frac{\partial Z}{\partial \alpha} \right|_{\alpha=\alpha_0} (\alpha - \alpha_0) \quad (7)$$

The lift and drag coefficients are assumed to be functions of the angle of attack.

$$\begin{aligned} \frac{\partial Z}{\partial \alpha} &= \frac{\partial L}{\partial \alpha} \cos(\alpha - \alpha_0) - L \sin(\alpha - \alpha_0) \\ &\quad + \frac{\partial D}{\partial \alpha} \sin(\alpha - \alpha_0) + D \cos(\alpha - \alpha_0) \end{aligned} \quad (8)$$

$$\left. \frac{\partial Z}{\partial \alpha} \right|_{\alpha=\alpha_0} = \frac{\partial L}{\partial \alpha} + D = q S \left( \frac{\partial c_L}{\partial \alpha} + c_D \right) \quad (9)$$

As a result:

$$Z = Z_0 + q S \left( \frac{\partial c_L}{\partial \alpha} + c_D \right) (\alpha - \alpha_0) \quad (10)$$

Noting that  $\alpha - \alpha_0 = -\dot{z}/V$

$$Z = Z_0 - \frac{q S}{V} \left( \frac{\partial c_L}{\partial \alpha} + c_D \right) \dot{z} \quad (11)$$

Combining the sum of the aerodynamic and spring forces, and equating to mass times acceleration gives the familiar

second order linear differential equation of motion. Note that the deflection  $z$  is measured from equilibrium, where any static lift forces  $Z_0$  are offset by the spring preload  $k z_0$ , (weight force is neglected, but would have no effect in this example).

$$m \ddot{z} = Z - k(z + z_0) = Z_0 - \frac{1}{V} \frac{\partial Z}{\partial \alpha} \dot{z} - k(z + z_0) \quad (12)$$

Simplifying:

$$m \ddot{z} + \frac{q S}{V} (c_L \alpha + c_D) \dot{z} + kz = 0 \quad (13)$$

The dynamic pressure  $q$  is parabolic in  $V$ , so the wing behaves effectively as a damper whose coefficient increases linearly with airspeed. This is noteworthy in a vehicle dynamics context, as it is in contrast to a typical slip-based tire model, where the tire is effectively a damper whose coefficient varies as the inverse of forward speed.

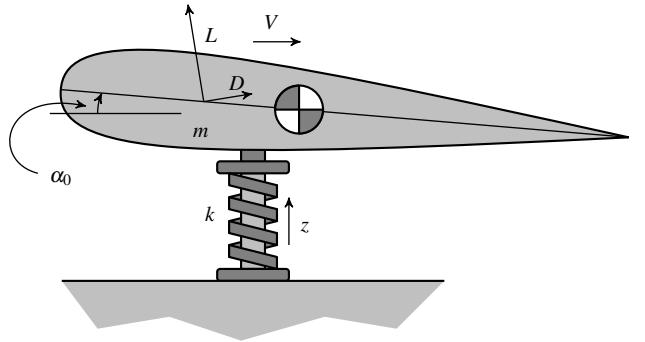

Figure 1. Spring mass wing model. Note that the lift and drag forces are assumed to remain parallel and perpendicular to the airflow direction respectively, measured in a reference frame that moves with the wing.

While the example illustrates the development of the equation of motion for a simple system, in fully three dimensional motion, the effective damping term becomes a full  $6 \times 6$  matrix, where the three forces and three moments are written as linear functions of linear and angular speed. A typical vehicle based coordinate system is used, where the  $x$  axis is the vehicle's direction of travel, and the  $z$  axis is vertical. Symmetry in the  $xz$  plane is assumed; the effect is that fully half of the 36 damping terms go to zero. In this notation, the components of force in the three coordinate axes are  $X$ ,  $Y$ ,  $Z$ , while  $L$ ,  $M$ ,  $N$  are the corresponding moments. The linear and angular velocities are represented as  $u$ ,  $v$ ,  $w$ , and  $p$ ,  $q$ ,  $r$ , respectively. The wingspan is denoted as  $b$ , and  $c$  is the chord (i.e.,  $S = bc$  for a rectangular planform wing). These  $6 \times 6$  matrices can be easily incorporated into the EoM generated equations of motion.

The full equation is written as:

$$\begin{Bmatrix} X \\ Y \\ Z \\ L/b \\ M/c \\ N/b \end{Bmatrix} = -\frac{qS}{V} \begin{bmatrix} C_{Xu} & 0 & C_{Xw} & 0 & C_{Xq} & 0 \\ 0 & C_{Yv} & 0 & C_{Yp} & 0 & C_{Yr} \\ C_{Zu} & 0 & C_{Zw} & 0 & C_{Zq} & 0 \\ 0 & C_{Lv} & 0 & C_{Lp} & 0 & C_{Lr} \\ C_{Mu} & 0 & C_{Mw} & 0 & C_{Mq} & 0 \\ 0 & C_{Nv} & 0 & C_{Np} & 0 & C_{Nr} \end{bmatrix} \begin{Bmatrix} u \\ v \\ w \\ \frac{b}{2}p \\ \frac{c}{2}q \\ \frac{b}{2}r \end{Bmatrix} \quad (14)$$

or:

$$\begin{Bmatrix} X \\ Y \\ Z \\ L \\ M \\ N \end{Bmatrix} = [\mathbf{L}] \begin{Bmatrix} u \\ v \\ w \\ p \\ q \\ r \end{Bmatrix} \quad (15)$$

where:

$$\mathbf{L} = -\frac{qS}{V} \begin{bmatrix} C_{Xu} & 0 & C_{Xw} & 0 & \frac{1}{2}cC_{Xq} & 0 \\ 0 & C_{Yv} & 0 & \frac{1}{2}bC_{Yp} & 0 & \frac{1}{2}bC_{Yr} \\ C_{Zu} & 0 & C_{Zw} & 0 & \frac{1}{2}cC_{Zq} & 0 \\ 0 & bC_{Lv} & 0 & \frac{1}{2}b^2C_{Lp} & 0 & \frac{1}{2}b^2C_{Lr} \\ cC_{Mu} & 0 & cC_{Mw} & 0 & \frac{1}{2}c^2C_{Mq} & 0 \\ 0 & bC_{Nv} & 0 & \frac{1}{2}b^2C_{Np} & 0 & \frac{1}{2}b^2C_{Nr} \end{bmatrix} \quad (16)$$

### B. EoM system elements

In EoM, each component of a system is defined as an ‘item’. The most basic type of item is a ‘body’, which defines a rigid body. The other types of items define either rigid or flexible connectors that are attached to one or more rigid bodies. All the available types of items are listed in Table I.

TABLE I. Types of items in EoM

Type of item	Definition
body	a rigid body
spring	a two point elastic spring, with linear or torsional stiffness and damping, non-zero free length
link	a two point massless rigid link
rigid_point	a generic point constraint with a variable number of constraint forces and moments
flex_point	a point spring with translational and/or rotational stiffness and damping
nh_point	a non-holonomic constraint to prevent velocity but not displacement
beam	a zero mass beam spring with bi-directional bending and shear stiffness
load	constant forces or moments applied to the system
actuator	applied force or moment, proportional to an input signal
sensor	used to measure displacement, velocity, or acceleration

A typical vehicle model in EoM will consist of rigid bodies, both rigid and flexible connectors, and other items like static loads (to include the effect of preloads), actuators to apply time varying forces, and sensors to measure the resulting motion. Joints constrain bodies together while allowing certain degrees of freedom; ball joints (spherical joints) and hinges

(revolute joints) are both typical. Both are modelled in EoM as ‘rigid\_point’ type items, where the appropriate number of constraints can be specified in each case, along with an axis to define the associated directions. Suspension springs and shock absorbers are modelled as uni-directional two-point springs, and tires as ‘flex\_point’ items, i.e., springs with zero free length.

As the aerodynamic forces described above are expressed using a linear dependency on the velocities, they are included as a special case of the ‘flex\_point’ item, where the full  $6 \times 6$  matrix is supplied, as opposed to a typical point spring damper where a single coefficient and a direction vector suffice. It is noteworthy that the terms generated by traditional mechanical damper will always result in a symmetric damping matrix. Because the wing behaviour requires a potentially asymmetric matrix, there is no possible combination of dampers that would provide an equivalent motion response. In order to properly capture the wing behaviour, the full matrix must be supplied.

### III. FORMULATION OF THE EQUATIONS OF MOTION

The linearized equations of motion of the model are automatically generated by EoM. A detailed description of the method is given in Minaker and Rieveley[1], and expanded in Minaker[2]. The set of differential equations are written as

$$\begin{bmatrix} \mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{M} & -\mathbf{G} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{p}} \\ \dot{\mathbf{w}} \\ \dot{\mathbf{u}} \end{Bmatrix} + \begin{bmatrix} \mathbf{V} & -\mathbf{I} & \mathbf{0} \\ \mathbf{K} & \mathbf{L} & -\mathbf{F} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{Bmatrix} \mathbf{p} \\ \mathbf{w} \\ \mathbf{u} \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{f}_c \\ \mathbf{u} \end{Bmatrix} \quad (17)$$

where the mass matrix  $\mathbf{M}$  results from the Newton-Euler equations, and is tri-diagonal as is typical. The stiffness matrix  $\mathbf{K}$  is the sum of terms resulting from deflection of elastic elements, and additional tangent stiffness matrix terms resulting from preload in the connectors. The  $\mathbf{L}$  matrix contains the traditional viscous damping matrix, plus terms due to the inertia forces, i.e., centripetal forces and gyroscopic moments. It is in this  $\mathbf{L}$  matrix that the aero terms are included. The  $\mathbf{V}$  matrix results from the linearization of the kinematic differential equations, and is non-zero only in the event of a non-zero velocity reference condition.

The  $\mathbf{F}$  and  $\mathbf{G}$  matrices are used to allow the inclusion of rate dependency in the input forces, i.e., the applied forces are written as

$$\mathbf{f}_a = \mathbf{F}\mathbf{u} + \mathbf{G}\dot{\mathbf{u}}$$

where  $\mathbf{u}$  is the input. The  $\mathbf{p}$  vector represents the global locations and small angle orientations, and the  $\mathbf{w}$  vector represents the body fixed linear and angular velocities. The constraint forces  $\mathbf{f}_c$  are still present in the intermediate formulation, but are eliminated through a coordinate reduction process. The linearized constraint equations are written as

$$\begin{bmatrix} \mathbf{J}_h & \mathbf{0} & \mathbf{0} \\ -\mathbf{J}_h \mathbf{V} & \mathbf{J}_h & \mathbf{0} \\ \mathbf{0} & \mathbf{J}_{nh} & \mathbf{0} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{p}} & \mathbf{p} \\ \dot{\mathbf{w}} & \mathbf{w} \\ \dot{\mathbf{u}} & \mathbf{u} \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{Bmatrix} \quad (18)$$

where the  $\mathbf{J}_h$  and  $\mathbf{J}_{nh}$  matrices represent holonomic and non-holonomic constraint equations, respectively. An orthogonal

complement of the Jacobian is used to reduce the number of coordinates.

#### IV. WING ANALYSIS

In order to generate the wing properties used to fill the associated damping matrix, a numerical approach is required. Luckily, a well-developed solution already exists.

##### A. Athena Vortex Lattice

Athena Vortex Lattice (AVL) is an open source software tool developed at MIT by Mark Drela and Harold Youngren[3]. It has numerous capabilities related to the flight-dynamic analysis of rigid aircraft of arbitrary configuration. While AVL can already produce a linearized aerodynamic model to predict aircraft stability, its models are limited to treating the aircraft as a single rigid body.

However, individual lifting and control surfaces can also be modelled in AVL (rather than full aircraft), and the full aerodynamic properties can be output in a format suitable for inclusion in other codes, such as EoM.

The relevant functionality of AVL for this paper is its ability to produce stability derivatives (the elements of the system matrix relating state derivatives to the state values) at any flight condition. By definition, vortex lattice codes work in three dimensions; it is not possible to carry out two-dimensional analysis using AVL. AVL can be expected to produce accurate results when the lifting surfaces are thin and angles of attack (and sideslip) are small ( $\ll 1$  rad). In a vortex lattice code, the surfaces and the wakes that trail them downstream are represented with vortex sheets of infinitesimal thickness. By discretizing the aerodynamic surface(s) of interest with horseshoe vortices distributed along the span and chord, a numerical solution for the aerodynamic forces and moments along the surface(s) can be obtained. A full description of vortex lattice methods is beyond the scope of this paper, but see for example Lan[4], Lamar and Gloss[5], and Miranda, Elliot, and Baker[6] for the foundational work that underpins AVL. An important limitation of AVL is the assumption of quasi-steady flow[3]. This means that oscillatory motions must be sufficiently slow so that the period of oscillation is long compared to the time it takes for the flow to travel the length of the wing chord. This can be quantified using the reduced frequency  $\beta$ , where

$$\beta = \frac{\omega c}{V} \ll 1 \quad (19)$$

For typical aircraft in flight this is almost always true, but in alternative applications of AVL for use in EoM such as ground vehicles, this condition should be checked. Finally, the angular velocities (roll, pitch, and yaw rates) must be slow enough to ensure that small angle assumptions continue to hold.

Quantitatively, this means:

$$|pb/2V| < 0.10 \quad (20)$$

$$|qc/2V| < 0.03 \quad (21)$$

$$|rb/2V| < 0.25 \quad (22)$$

Again, while this is normally not an issue for aircraft, if AVL analysis is used for other applications, these should be checked to ensure solution validity.

#### V. EXAMPLE PROBLEM

In order to demonstrate the capabilities of the combined EoM/AVL software tool, a test model was developed. It is an expansion of the swivel wheel problem, as presented by Schwab and Meijaard[7], and before them by Den Hartog[8]. The model is used to predict the shimmy phenomenon, as sometimes observed in aircraft nose wheel landing gear, or more commonly on the front wheels of a grocery cart. The model consists of a single rigid body, constrained to planar motion, and travelling at a fixed forward speed. The motion of the body is reacted by a lateral spring placed at the front, to represent the lateral stiffness of the wheel carrier or support, and a no-slip tire (modelled as a nonholonomic constraint) at the rear. The wheel shimmy problem is noteworthy, as it can predict unstable behaviour. The response is strongly dependent on the location of the mass centre; when it is near the midway point between the tire and the lateral spring, the system is stable, while locations near either end result in an unstable motion. The instability is oscillatory; the amplitude grows with time.

In this example, the shimmy problem is repeated with an aerodynamic surface added to the model. A symmetric generic thin surface model is used for the airfoil. The reference point of the airfoil is taken at one quarter of the chord from the leading edge. The wing is fixed such that its reference point is located at the front of the body at the same location where the lateral stiffness acts. It is noteworthy that shifting the longitudinal location of the wing does have an effect on its influence. As the wing is moved closer to the zero-slip tire, its angle of attack is reduced. In fact, the tire constraint forces the angle of attack to be zero at that point, minimizing the influence of the wing on the overall motion. A schematic diagram of the problem is shown in Figure 2.

In order to establish a baseline result, the model is run first with no wing present. The default properties of the mechanical system are:  $m = 5.0$  kg,  $l = 1.0$  m,  $I_z = 1.05$  kg m<sup>2</sup>,  $k = 1.5$  N/m, and  $u = 10.0$  m/s. The location of the mass centre is varied from the front to the rear of the model. The results are then repeated with the wing present. The resulting aerodynamic properties are:  $L_{2,2} = 7.59895$  Ns/m,  $L_{2,6} = -2.05293$  Ns/rad,  $L_{6,2} = 0.153319$  Ns,  $L_{6,6} = 0.224167$  Nms/rad,  $b = 1.0$  m, and  $c = 0.5$  m.

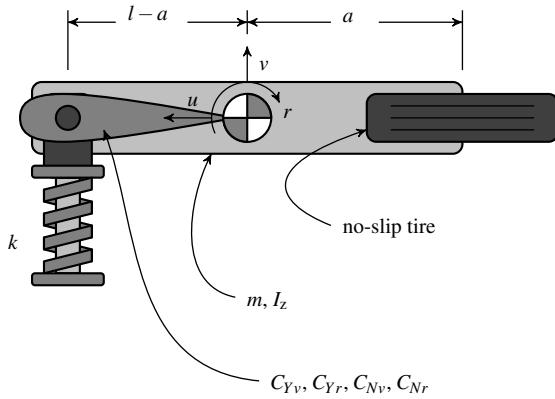

Figure 2. Swivel wheel example problem, with added aerodynamic effect. The swivel wheel exhibits the shimmy phenomenon, with potential instability, as a function of the location of the mass centre.

### A. Results

Once the EoM software has generated the equations of motion, a number of linear analyses are automatically conducted. By analyzing the eigenvalues, the stability and natural frequencies of the motion can be found. The resulting eigenvalues govern the form of the motion. The eigenvalue can be expressed in the form of  $s = a \pm bi$ , i.e., it is frequently a complex number. If the real part is positive, the motion will be unstable; if the real part is negative, the motion is stable as it gradually approaches zero with time. The imaginary part controls the oscillatory frequency of the motion. If the imaginary part is equal to zero, there will be no oscillation in the unforced motion.

The results are plotted in Figures 3 and 4. Figure 3 shows both eigenvalues. Note that the slow eigenvalue is complex, while the fast eigenvalue, i.e., the more negative, is real. Figure 4 shows the real part of the slow eigenvalue, which is unstable in some cases, with a much tighter zoom, to better illustrate the zero crossings. Note that if the centre of mass is located in the range  $0.3l < a < 0.7l$ , then the system without the wing is stable. When the wing is added, the stability range increases to  $0.12l < a < 0.88l$ .

## VI. CONCLUSIONS

The paper outlines the development of an open source multibody code for the analysis of the dynamics of mechanical systems, including aerodynamic effects. An example illustrates how mechanical system behaviour can be influenced by the addition of aerodynamic effects. The example shown is relatively simple in scope when compared to the type of problems that could be analyzed using the combined EoM and AVL software, but serves to illustrate the concept. Future work will expand this approach to more extensive applications, such as ground vehicles with multiple aerodynamic surfaces or flexible aircraft.

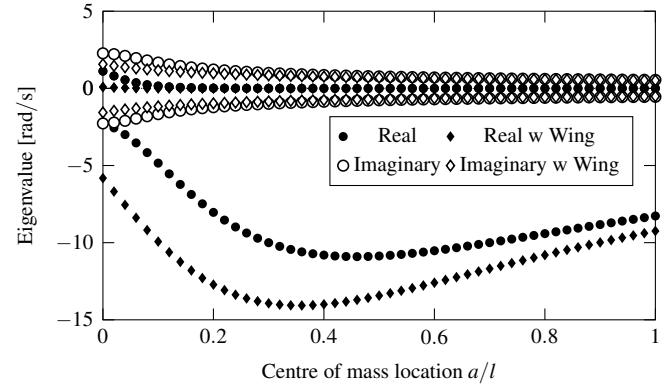

Figure 3. Eigenvalues vs centre of mass location. The effect of the addition of the wing on the eigenvalues is a significant increase in stability, and decrease in the shimmy frequency in the cases where the centre of mass is shifted rearward.

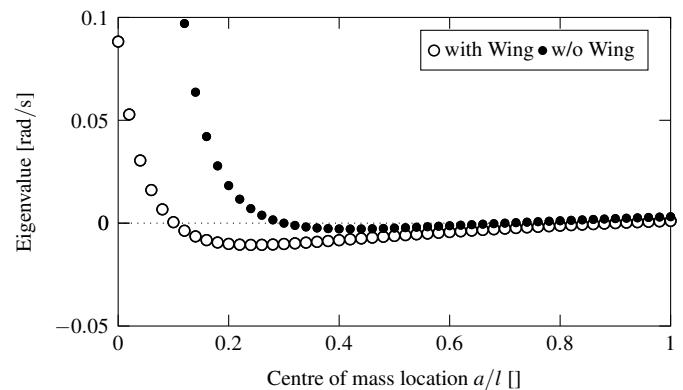

Figure 4. Slow eigenvalues vs centre of mass location, zoomed. Note that if the centre of mass is located in the range  $0.3l < a < 0.7l$  then the system without the wing is stable. When the wing is added the range is expanded.

# Numerical Study of Inlet Gas Velocity Effects on Droplet Behaviors in Microchannel

Mengcheng Jiang, Biao Zhou<sup>1</sup>

Department of Mechanical, Automotive and Materials Engineering  
University of Windsor  
Windsor, ON, Canada, N9B 3P4

**Abstract**—In this study, the numerical simulation of liquid water behaviors inside a single straight microchannel is conducted using Volume of fluid (VOF) method and dynamic contact angle (DCA) model. Two different gas inlet velocities are considered in the simulation to investigate the gas velocity effects on the droplet behaviors. The general process of the liquid water evolvement inside the channel are presented and discussed. The results indicate that the water droplet will form into long slug flow under lower gas inlet velocity and thin film flow under higher gas inlet velocity.

**Keywords-droplet behaviors; microchannel; volume of fluid method; dynamic contact angle.**

## I. INTRODUCTION

Proton exchange membrane fuel cells (PEMFCs) are energy conversion devices that can produce electrical power from hydrogen and air, releasing only water and heat. PEMFC is one of the promising energy power sources for next-generation vehicles and distributed power applications, mainly because of their advantages such as zero-emission, low operation temperature, high power density and quietness.

However, water management is still one of the most critical challenges for fuel cell commercialization. Thoroughly understanding the gas-liquid dynamics inside PEMFCs will help researchers to optimize the PEMFC designs. Numerical simulation using volume of fluid (VOF) method has been recognized as an effective approach to investigate the liquid water behaviors inside the gas channels. So far, for PEMFC-related simulations, the static contact angle (SCA) model is generally used [1-7] while the dynamic contact angle (SCA) model is still under development. Recently, several researchers have applied DCA model to simulate the droplet dynamics and evolvement [8-11] and it is indicated that DCA model is more applicable than SCA model in the prediction of droplet behaviors. Zhou's group proposed the AR-DCA model [12] implemented with Hoffman function [13], which is able to simulate both advancing and receding dynamic contact angles. This AR-DCA model has been successfully validated against a series of experiments for droplet impact on horizontal and inclined surfaces from Sikalo et al. [14, 15], showing its potential to be applied in the simulation of gas-liquid two-phase in microchannels.

<sup>1</sup> Corresponding Author and Principal Investigator: Dr. Biao Zhou, [bzhou@uwindsor.ca](mailto:bzhou@uwindsor.ca), 1-519-253-3000 ext. 2630

However, only a few of the researchers reported the simulations of droplet behaviors in microchannels using DCA model: Fang et al. [16] employed a contact angle hysteresis model to simulate gas-liquid flows and the results showed that the contact angle distribution in the microchannel will significantly affect the slug elongation and instability; Miller [17] and Wu [18] implemented DCA model with Hoffman function to simulate the liquid water transport and behaviors in gas channel, and it is indicated that the dynamic contact line treatment is very crucial in the simulation of gas-liquid dynamics.

In this study, as one part of the progress for the DCA model development, we further extend our research to the simulation of droplet behaviors in a single straight microchannel. The numerical results under different gas inlet velocity will be presented and discussed.

## II. NUMERICAL MODEL DESCRIPTION

### A. Computational Domain

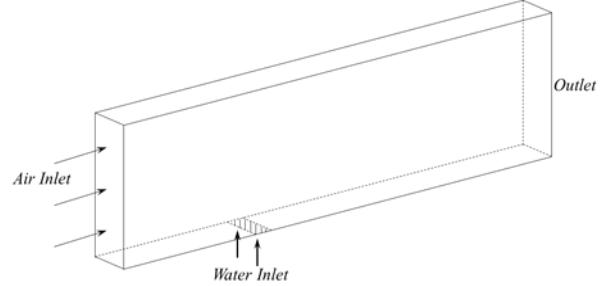

Figure 1. Schematic of computational domain in this study.

In this study, a three-dimensional single straight channel with rectangular cross section is built up as the computational domain. The dimensions of the channel are 0.05 mm in depth, 0.5 mm in width and 5 mm in length. The liquid water enters into the channel through a 0.02 mm rectangular slot on the bottom wall, which is located at 1.65 mm away from the inlet boundary.

### B. Computational Methodology

In the simulation, the VOF method is used to track the gas-liquid flow interface. The governing equations are as follows:

The mass conservation equation:

$$\frac{\partial(\rho)}{\partial t} + \nabla \cdot (\rho \vec{u}) = 0 \quad (1)$$

The mixture density and viscosity in each computational cell can be calculated by:

$$\rho = s_l \rho_l + s_g \rho_g \quad (2)$$

$$\mu = s_l \mu_l + s_g \mu_g \quad (3)$$

where  $s_l$  and  $s_g$  are the liquid and gas volume fraction respectively, and the sum of the volume fraction is:

$$s_l + s_g = 1 \quad (4)$$

Then the continuity equation for the liquid phase can be expressed as the following form:

$$\frac{\partial(s_l \rho_l)}{\partial t} + \nabla \cdot (s_l \rho_l \vec{u}) = 0 \quad (5)$$

The momentum equation is:

$$\frac{\partial}{\partial t} (\rho \vec{u}) + \nabla \cdot (\rho \vec{u} \vec{u}) = -\nabla p + \nabla \cdot [\mu (\nabla \vec{u} + \nabla \vec{u}^T)] + S_m \quad (6)$$

The surface normal  $\hat{n}$  is determined by:

$$\hat{n} = \hat{n}_w \cos \theta_d + \hat{t}_w \sin \theta_d \quad (7)$$

where  $\hat{n}_w$  and  $\hat{t}_w$  represent the unit vectors normal and tangential to the wall respectively. Dynamic contact angle  $\theta_d$  is applied at the wall boundaries through a user defined function (UDF) code. The methodology to calculate and implement  $\theta_d$  has been reported in our previous work [12] and more details can be found in [12].

### C. Boundary Conditions and Mesh Set Up

In the numerical simulation, the no-slip boundary condition is applied at channel walls. The DCA is considered on both side wall and bottom wall. The initial contact angle (i.e., SCA) for all the boundary walls is  $108^\circ$ . The volume flow rate of liquid water is set as  $50 \mu\text{L}/\text{min}$ ; the gas inlet velocities  $V_{inlet}$  are set as  $4.8 \text{ m/s}$  and  $21.9 \text{ m/s}$  respectively to investigate the effects of different gas inlet velocities on the droplet behaviors and evolvement.

The whole computational domain is meshed by approximately 125500 cells, with minimum cell volume of  $2 \times 10^{-7} \text{ mm}^3$  and maximum cell volume of  $1.4 \times 10^{-6} \text{ mm}^3$ . The grid size is approximately  $0.01 \text{ mm}$  in X-, Y- and Z- direction with a grid refinement applied near the bottom wall.

### III. RESULTS AND DISCUSSION

Fig. 2 presents the water droplet evolvement process in the single straight microchannel under relative low velocity ( $V_{inlet} = 4.8 \text{ m/s}$ ), with the liquid water volume fraction contours. The dark blue area represents the gas phase while the red area represents the liquid water. From this series of figure under selected time instances, the main process of droplet evolvement can be described as follows:

- 1) At the very beginning, the water enters into the channel with a constant volume flow rate, as shown in Fig. 2(a).
- 2) The liquid water continues to emerge and form the droplet with time (from  $t = 0.2 \text{ ms}$  to  $10 \text{ ms}$ , as shown in Fig. 2(b-c)).
- 3) When it comes to about  $16.4 \text{ ms}$ , the droplet almost blocks the channel (Fig. 2(d)) and reaches a critical point; then the droplet is blown away towards the outlet direction due to the force exerted at the windward side from the inlet gas, as shown in Fig. 2(e).
- 4) From  $t = 16.6 \text{ ms}$  to  $18.0 \text{ ms}$  (Fig. 2(e-g)), the droplet significantly deforms from “tall-standing” shaped slug to “long-lying” shaped slug, mainly due to the continuous pressure from the inlet gas and the interactions among the pressure, surface tension and shear stress.
- 5) After  $18.0 \text{ ms}$ , the deformation and evolvement of the water slug become stable, as shown in Fig. 2(g-h).

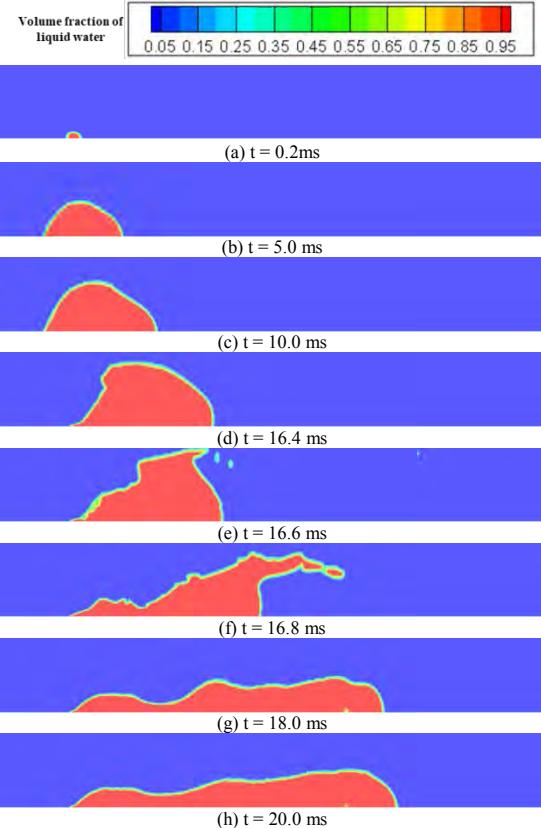

Figure 2. Liquid water droplet evolvement under  $V_{inlet} = 4.8 \text{ m/s}$ .

When the air inlet velocity is increased to  $21.9 \text{ m/s}$ , the remarkably different phenomena for the droplet behaviors and evolvement can be observed, as shown in Fig. 3.

- 1) At the beginning of the simulation, the water enters into the channel with a constant volume flow rate, as shown in Fig. 3(a).

- 2) From  $t = 2.0$  ms to  $4.4$  ms, the droplet continues to grow in the microchannel. Due to the higher gas inlet velocity, the droplet starts to deform at the early stage and tends to form small liquid film at the trailing side, as shown in Fig. 3(c).
- 3) From  $t = 4.4$  ms, when the deformation reaches a critical point, the upper part of the droplet is blown away, as shown in Fig. 3(d-e).
- 4) After  $4.6$  ms, the water droplet deforms into film flow and moves along the bottom wall. Some small splashed water droplet can also be observed in the channel, as shown in Fig. 3(f). This is mainly caused by the high pressure and strong air flow between the upper wall and the top side of droplet.
- 5) With time, the water accumulates at the leading side and forms a new droplet, as shown in Fig. 3(g), and the rest remains in the regime of film flow.
- 6) As shown in Fig. 3(h), the droplet further elongates and forms a long, thin and continuous film flow with waves. The liquid water will also drain out through the outlet.

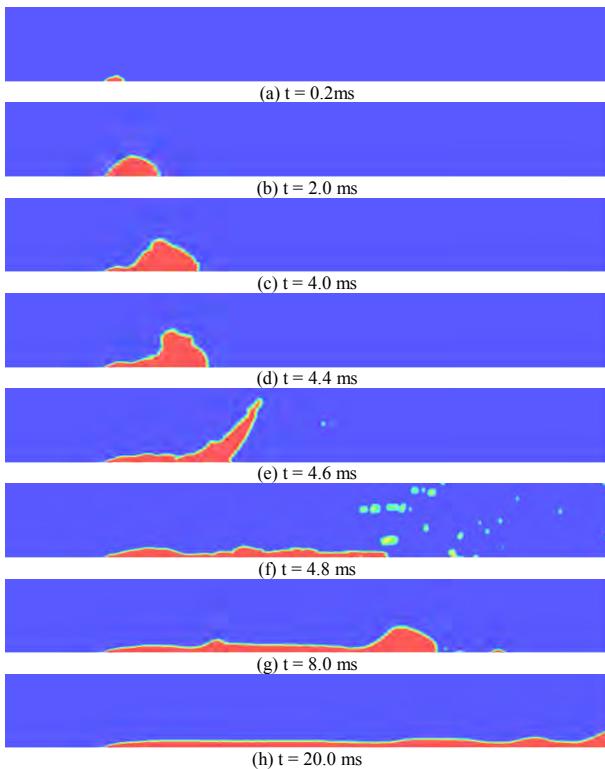

Figure 3. Liquid water droplet evolvement under  $V_{inlet} = 21.9$  m/s.

#### IV. CONCLUSIONS

This paper presents the numerical study of droplet behavior and evolvement in a single straight microchannel. The effects of gas inlet velocity are investigated by considering two different conditions (4.8 m/s and 21.9 m/s).

Dynamic contact angle is considered as one of the wall boundary conditions instead of static contact angle.

From the numerical results, it can be found that the two cases in this study (one with lower gas inlet velocity and another with higher velocity) share some similar droplet evolvement phenomena: the droplet first emerge and grow inside the channel near the liquid inlet area; with time, the droplet will reach a critical point and then be blown away towards the channel outlet side.

Also, several significantly different phenomena can also be captured: under lower gas inlet velocity (4.8 m/s), the liquid water can remain in a droplet much longer than that of the higher inlet velocity condition (21.9 m/s); within the same time period (20 ms), the liquid water will form into long slug flow under lower inlet velocity, while the continuous long film flow can be observed under higher inlet velocity. It can be concluded that the gas inlet velocity has remarkable effects on the droplet deformation and evolvement in the microchannel, mainly reflected in the flow regime.

#### ACKNOWLEDGMENT

The authors are grateful for the support from the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Windsor. The authors also would like to thank Compute Canada and Sharcnet for the support of computing resource.

# Using Visco-Plastic Lubrication for Suspension Transportation

Saeed Garmeh, Ali Dolatabadi and Ida Karimfazli

Department of Mechanical, Industrial and Aerospace Engineering  
Concordia University  
Montreal, Canada

**Abstract**—This study focuses on a common problem in suspension plasma spraying called clogging. Different mechanisms causing that issue are described and a technique called visco-plastic lubrication is introduced as a solution to this problem. Numerical modelling has been done using mentioned technique and effect of viscosity ratio of the fluids on the flow are investigated.

**Keywords:** *clogging; suspension plasma spraying; visco-plastic lubrication; numerical modelling*

## I. INTRODUCTION AND BACKGROUND

Coating plays an important role in surface engineering industries. The aim of coating is to enhance physical and mechanical properties of the material surface [1]. Among different spraying processes, suspension plasma spraying (SPS) is common and popular. In SPS, suspension which carries the material particles that we desire to coat them on top of a substrate, is injected into a plasma torch. These particles melt and stick to the substrate and then they are solidified and adhered to the surface.

Typical suspensions used in SPS have concentration of about 20 %wt. which means only 20 % of the mass of the suspension is composed of particles. This relatively low concentration consumes a lot of energy and time in spraying. One way to reduce the spraying time is to increase the concentration of the particles. For instance, if we use 50 %wt. suspension instead of 20%wt., we save time and energy with a factor of 2.5 which is significant. However, the chance of agglomeration and clogging that is a common issue in SPS is also raised.

Different ways of clogging occurrence are investigated and a technique called visco-plastic lubrication is introduced and modelled numerically as a solution to the clogging issue. In suspensions, when the concentration of particles is increased, the interaction between particles and the tube wall grows. There are two general ways that cause clogging.

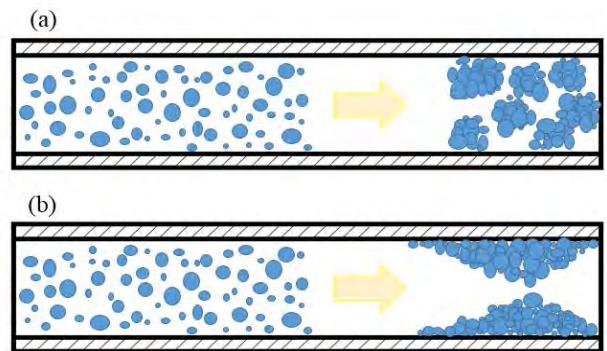

Fig. 1 Schematic of (a) Particle-Particle interactions and (b) Particle-Wall interactions for high concentration suspension inside the tube

Firstly, when the solid particles in the suspension interact with each other, they may adhere together and make bigger agglomerates. These agglomerated parts can be trapped in the carrying tube or injector and cause clogging. A visual representation of this phenomena is shown in Fig. 1(a).

Secondly, when these particles interact with the tube wall and injector, they can be attached to the tube and decrease the passing area gradually to a point that suspension couldn't flow through the tube and clogging would be the result. Fig. 1(b) shows this phenomena schematically.

For clarifying the problem, possibility of clogging due to the particle-particle interaction was focused. Suspensions of Titanium Dioxide ( $TiO_2$ ) with different concentrations of 20, 30, 40 and 50 %wt. were made and analyzed using laser diffraction system (Malvern Spraytec, UK). Measurement tests presented in Fig. 3 and Table 1 show no considerable difference. If the suspension is prepared properly, for concentration up to 50%, there will be no significant change in particle size distribution. The test indicates the main reason behind the clogging is interaction of particles with the tube wall which is shown in Fig 1(b). This conclusion motivates us to implement a technique for preventing contact of suspension with the tube wall.

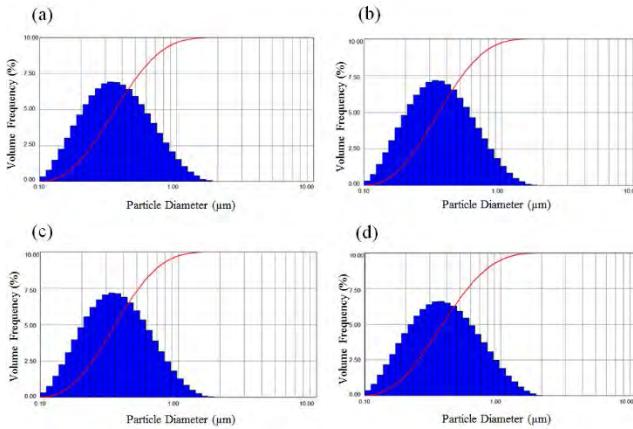

Fig. 2 Particle size distribution for TiO<sub>2</sub> suspensions with concentrations of (a) 20%wt. (b) 30%wt. (c) 40%wt. and (d) 50 %wt.

Table 1. Distribution parameters of suspended particles

	D (10) μm	D (50) μm	D (90) μm
20%	0.1793	0.3549	0.7391
30%	0.1784	0.3512	0.7266
40%	0.1782	0.3503	0.7243
50%	0.1798	0.3736	0.8196

Proposed solution to this problem is visco-plastic lubrication. In this technique, we have a core annular flow where the core fluid is high concentration suspension and it is lubricated with a yield stress fluid. The outstanding character of yield stress fluids is that they are able to flow only if they are submitted to a stress above a critical value called yield stress of the material. Otherwise they deform like solids [2]. Utilizing yield stress fluid prevents the core fluid to get in contact with the tube wall by preserving an unyielded plug around the core fluid [3]. Fig. 3 shows a schematic of visco-plastic lubrication.

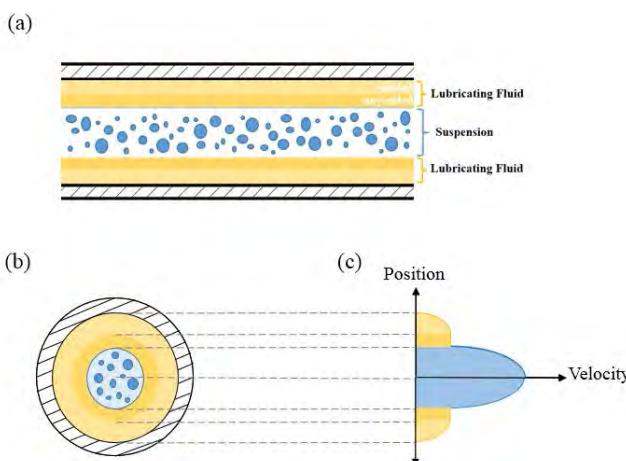

Fig. 3 Schematic of visco-plastic lubrication of suspension in (a) side view, (b) front view and (c) velocity profile of the flow

In this research, 0.3% Carbomer gel used as lubricating fluid which is a yield stress fluid. Result of the rheology test on the gel and the fitted curves are shown in Fig. 4. The curves generated using MATLAB Curve Fitting tool and the equations of the curves are as follows:

Herschel-Bulkley Model:

$$\tau = 44.18 + 13.84 \times \dot{\gamma}^{0.2986} \quad (1)$$

Bingham Model:

$$\tau = 55.12 + 0.80 \times \dot{\gamma} \quad (2)$$

Where  $\tau$  is the stress and  $\dot{\gamma}$  is strain rate. According to (1) and (2), the yield stresses predicted by Herschel-Bulkley and Bingham models are 44.18 Pa and 55.12 Pa, respectively. As it can be understood from Fig. 4, the Herschel-Bulkley model can predict the behavior of the yield stress fluid more accurately. For calculation of effective viscosity, slope of predicted curve by Bingham model is used when the flow begins [4]. Therefore, 0.80 Pa.s considered as the effective viscosity of the 0.3% Carbomer Gel.

## II. MECTHODOLOGY:

### A. Numerical model

All simulations were performed by ANSYS Fluent package. For modelling the multiphase flow, the mixture model was used. This model can be used to model multiphase flows where the phases move at different velocities. The mixture model can model n phases by solving the momentum, continuity, volume fraction equations for the secondary phases, and algebraic expressions for the relative velocities [5]. The governing equations are as follow:

#### 1) Continuity Equation

$$\frac{\partial(\rho_m)}{\partial t} + \nabla \cdot (\rho_m \vec{v}_m) = 0 \quad (3)$$

Where  $\rho_m$  is the mixture density according to (4) and  $\vec{v}_m$  is the mass-averaged velocity according to (5):

$$\rho_m = \sum_{k=1}^n \alpha_k \rho_k \quad (4)$$

$$\vec{v}_m = \frac{\sum_{k=1}^n \alpha_k \rho_k \vec{v}_k}{\rho_m} \quad (5)$$

Where n is number of phases. Current numerical study is for a flow of 2 phases.  $\alpha_k$ ,  $\rho_k$  and  $\vec{v}_k$  are volume fraction, density and velocity of phase k, respectively. k=1 is representing the lubricating fluid and k=2 is the core fluid.

#### 2) Momentum Equation

$$\frac{\partial}{\partial t} (\rho_m \vec{v}_m) + \nabla \cdot (\rho_m \vec{v}_m \vec{v}_m) = -\nabla P + \nabla \cdot [\mu_m (\nabla \vec{v}_m + \vec{v}_m^T)] + \rho_m \vec{g} + \vec{F} + \nabla \cdot (\sum_{k=1}^n \alpha_k \rho_k \vec{v}_{dr,k} \vec{v}_{dr,k}) \quad (6)$$

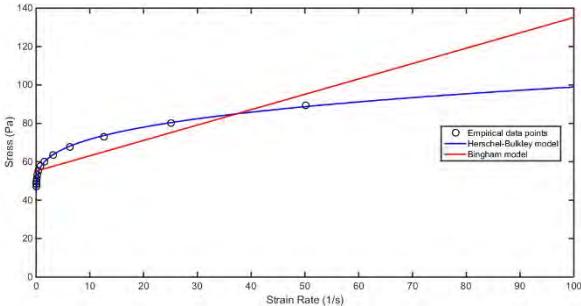

Fig. 4 Flow curve of 0.3% Carbomer Gel and fitted curves of Bingham and Herschel-Bulkley models

Where  $\vec{F}$  is the body force, and  $\mu_m$  is the viscosity of the mixture:

$$\mu_m = \sum_{k=1}^n \alpha_k \mu_k \quad (7)$$

And  $\vec{v}_{dr,k}$  is the drift velocity for secondary phase  $k$ :

$$\vec{v}_{dr,k} = \vec{v}_k - \vec{v}_m \quad (8)$$

### 3) Volume Fraction Equation for the Secondary Phase

From the continuity equation for secondary phase ( $k=2$ ), the volume fraction equation for secondary phase 2 can be obtained:

$$\begin{aligned} & \frac{\partial}{\partial t} (\alpha_2 \rho_2) + \nabla \cdot (\alpha_2 \rho_2 \vec{v}_m) \\ &= -\nabla \cdot (\alpha_2 \rho_2 \vec{v}_{dr,2}) + (\dot{m}_{12} - \dot{m}_{21}) \end{aligned} \quad (9)$$

Where  $\dot{m}_{12}$  is the mass transfer from phase 1 to phase 2 and  $\dot{m}_{21}$  is the mass transfer from phase 2 to phase 1.

### B. Dimensional analysis

According to The Buckingham Pi theorem, groups of dimensionless numbers are presented in Table 2. This study concentrates on investigating the effect of viscosity ratio of core fluid to lubricating fluid on the flow.

Core fluid and lubricating fluid have viscosities of  $\mu_{core}$  and  $\mu_{lub}$ , densities of  $\rho_{core}$  and  $\rho_{lub}$  and average velocities of  $V_{core}$  and  $V_{lub}$ , respectively.  $L$  and  $D$  are the length and diameter of the tube and  $d_i$  is the interface diameter of developed flow.  $\tau_y$  is the yield stress for lubricating fluid and  $\Delta P$  is the pressure drop alongside the tube.

Table 2. Dimensionless groups

$\Pi_1 = \frac{\rho_{core} V_{core} d_i}{\mu_{core}}$	$\Pi_2 = \frac{\tau_y D}{V_{lub} \mu_{lub}}$	$\Pi_3 = \frac{\Delta P}{\rho_{core} V_{core}^2}$	$\Pi_4 = \frac{\mu_{core}}{\mu_{lub}}$
$\Pi_5 = \frac{V_{core}}{V_{lub}}$	$\Pi_6 = \frac{\rho_{core}}{\rho_{lub}}$	$\Pi_7 = \frac{L}{D}$	$\Pi_8 = \frac{d_i}{D}$

According to table 2,  $\Pi_1$  is the Reynolds number based on the core fluid properties.  $\Pi_2$  is the Bingham number for lubricating fluid which is the ratio of yield stress to a typical viscous stress of the flow [4].  $\Pi_3$  is dimensionless pressure drop based on the core fluid properties,  $\Pi_4$ ,  $\Pi_5$  and  $\Pi_6$  are the ratios of core fluid to lubricating fluid properties.  $\Pi_7$  and  $\Pi_8$  are groups of the normalized length and interface diameter.

### C. Geometry and computational domain

The domain inside the tube that is modeled is a cylinder with diameter of  $D$  and length of  $L$ . The grid is made up of quadrilateral cells. ICEM CFD 14.0 was used for generating the mesh. Number of cells used in this study is 211,167 and a grid dependency study has been done to ensure the results are independent from the mesh.

### D. Boundary Conditions:

This study aims to reveal the relation of viscosity ratio to the flow parameters. Both fluids are injected co-axially to the domain. The velocity inlet boundary condition is assigned for inlets of core and lubricating fluids. Core fluid is injected from the center of cylinder. Pressure outlet used as the boundary condition at the exit of the flow. The wall boundary condition with no-slip is assigned to the tube wall.

In the modelling, the flow rate of each fluid kept at a constant value which results a stable core annular flow. Then, different values were set to the viscosity of the core fluid. By keeping the lubricating fluid parameters constant in all the simulations and just changing the viscosity of the core fluid, different viscosity ratios obtained and simulation repeated for each of those ratios.

### E. Simulation results

Effects of changing the viscosity ratio over dimensionless groups are demonstrated in Fig. 6. Velocity profiles of the flow are also presented in Fig. 7. Note that the velocity and position are normalized by average velocity of lubricating fluid ( $V_{lub}$ ) and diameter of the pipe ( $D$ ), respectively.

Contours of volume fraction of core fluid in a cut plane alongside the modelled tube for different viscosity ratios are shown in Fig. 8. The tube is long enough to ensure the flow is fully developed.

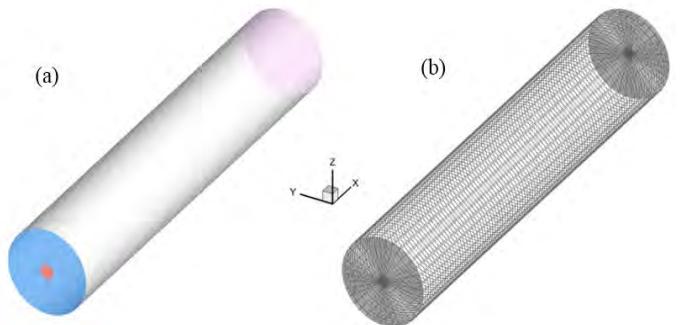

Fig. 5 (a) Geometry and (b) Generated grid

### III. SUMMARY AND CONCLUSION

The simulation results showed that using the visco-plastic lubrication technique can prevent suspension to get in contact with the tube wall by forming a solid-like annulus around the core fluid which in fact it can solve the clogging issue. Investigating different viscosity ratios of core fluid to lubricating fluid showed us as the ratio increases, the interface diameter rises which means there is more core fluid in each cross section of the tube.

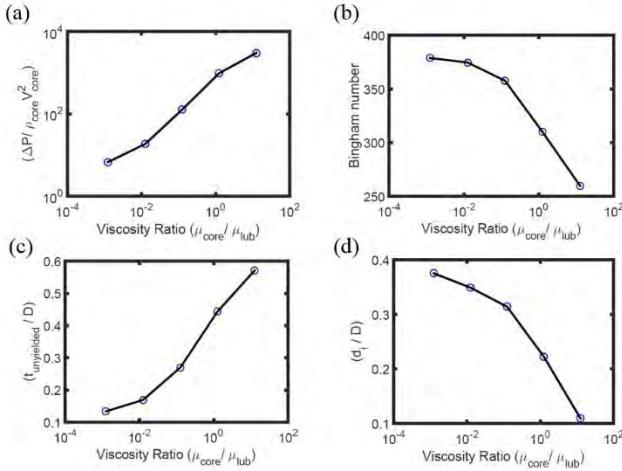

Fig. 6 Effects of changing the viscosity ratio on (a) dimensionless pressure drop (b) Bingham number, (c) normalized thickness of unyielded plug ( $t_{unyielded}/D$ ) around the core fluid and (d) normalized interface diameter ( $d/D$ ) for  $L=200$  mm,  $D=38.1$  mm and Reynolds number of 1392, 110, 6.9, 0.41, 0.03 for viscosity ratio of 0.00125, 0.0125, 0.125, 1.25 and 12.5, respectively.

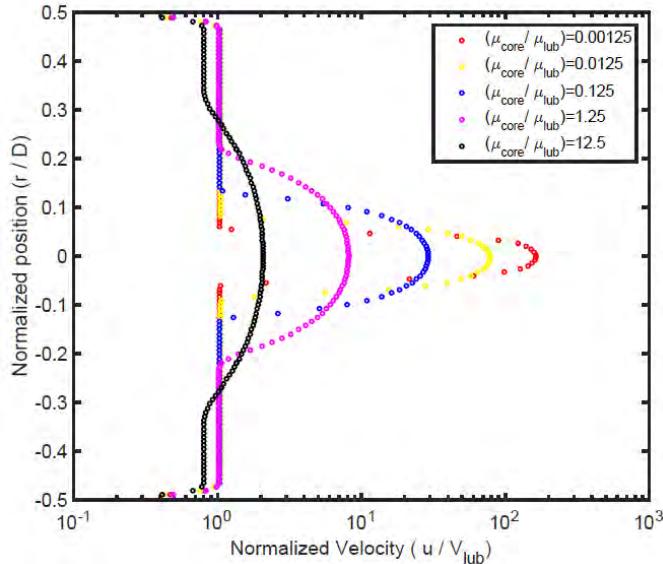

Fig. 7 Velocity profiles for different viscosity ratios

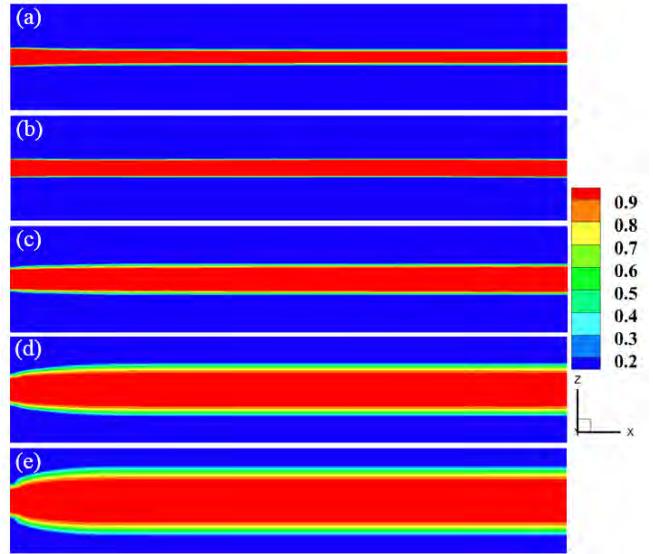

Fig. 8 Contours of volume fraction of core fluid for viscosity ratio of (a) 0.00125, (b) 0.0125, (c) 0.125, (d) 1.25, (e) 12.5

In all the cases, an unyielded plug was formed around the core suspension. When the viscosity ratio increased, reduction in the thickness of the plug was observed. As long as there is an annulus plug around the core, the interfacial instabilities cannot grow which means the flow is stable. Similar to our expectation, increasing the viscosity of the core fluid resulted in increasing the dimensionless pressure drop ( $\Pi_3$ ). In addition, increasing the viscosity ratio caused reduction of Bingham number.

Since we are interested in maximizing the flow rate ratio of core fluid to lubricating fluid, the future work of this study will focus on assigning different flow rates for each fluid in order to obtain maximum possible flow rate ratio. In addition, performing experiment in parallel is planned to confirm the simulation results.

**Abstract**—This work presents a finite element model of a cable-sheave system constructed to model cable vibrations due to vortex shedding in low-tension cases. The study assesses the potential for vortex shedding to lead to detachment of the cable from the sheave. The absolute nodal coordinate formulation is utilized to define the cable structural dynamics. Vortex shedding forces are incorporated by coupling the cable's equations of motion to a Van der Pol equation, also known as a wake-oscillator and the cable-sheave interaction is described using a contact penalty method. The study examines the contribution of vortex shedding occurring at the cable's natural frequency to the cable motion. For the cases studied the model demonstrates that vortex shedding alone results in very small vibration amplitudes and thus is unlikely to result in cable detachment.

**Keywords**—finite element method; absolute nodal coordinate formulation; cable-sheave interaction; vortex-induced vibration

## I. INTRODUCTION

Cable-sheave systems are commonly used in marine applications for towing and lifting. The cable is subjected to highly dynamic loading due to the ship motion, hydrodynamic forces and wind loading which can result in the cable falling off the sheave. Cables exposed to external fluid flow experience vortex induced vibrations (VIV) resulting from the periodic shedding of vortices in the cables wake. The vortex shedding produces oscillating lifting and drag forces on the cable, which can excite a resonance response in the cable if the shedding frequency matches the fundamental frequency of the cable. Excessive cable vibrations can result in wear of both the cable and the sheave and possible detachment of the cable from a sheave. It is thus useful to quantify the vibration amplitudes due to wind loading using a dynamic model and assess the potential for vortex shedding to lead to cable detachment.

Gabbai and Benaroya [1] give an overview of the various modeling approaches used to predict the response of cylinders

to the vortex shedding forces. One modelling approach known as a wake-oscillator model utilizes a second order differential equation, such as the Van der Pol equation, to represent the flow in the wake. The oscillator is coupled with the structural dynamics of the cable using forcing terms in both equations. This modelling approach does not require numerical modeling of the flow field and can be easily incorporated into existing dynamic cable models. Existing studies of cable vibrations using wake oscillator models typically utilize continuous equations to represent the cable structural dynamics. The contribution of the current research is the coupling of a wake-oscillator model and a finite element cable model, which has not been extensively studied.

This paper presents the construction of a finite element model using the absolute nodal coordinate formulation (ANCF). The model, used for a planar cable-pulley system in the researchers previous work [2], has been extended to include three dimension contact with the sheave grooves. Additionally, oscillating lift and drag forces using an existing wake-oscillator model [3] have been incorporated. Cases of low cable tension are considered as cable detachment is more likely to occur when the cable is slack. High sustained wind velocities are neglected in the study and only the contribution of vortex shedding at the cable's natural frequency is considered. Section 2 of the paper describes the cable model and the formulation of the external forces. Case studies examining the potential for VIV to lead to cable detachment are presented in Section 3. The paper ends with concluding remarks in Section 4.

## II. FINITE ELEMENT AND EXTERNAL LOAD MODEL

The finite element model is comprised of  $N$  two node cable elements. Each node has 6 degrees of freedom consisting of a position vector and a vector tangent to the cable centerline. All degrees of freedom are defined in the absolute coordinate frame. An additional parameter  $p \in [0, l]$  is used to interpolate

between nodes. The absolute coordinates  $\mathbf{r}$  of a point on the cable is defined using a vector of generalized coordinate  $\mathbf{q}$  and a cubic shape function  $\mathbf{S}(p)$  which interpolates between the nodes of each element:

$$\mathbf{r}(p) = \mathbf{S}(p)\mathbf{q} = [x \ y \ z]^T. \quad (1)$$

For a fully parameterized ANCF beam element of unstretched length  $l$ , the generalized coordinates consist of the Cartesian coordinates  $\mathbf{r}$  and the parametric slopes  $\partial\mathbf{r}/\partial p$  at each node:

$$\mathbf{q} = [\mathbf{r}_1^T \ (\partial\mathbf{r}/\partial p)_1^T \ \mathbf{r}_2^T \ (\partial\mathbf{r}/\partial p)_2^T]^T \quad (2)$$

where subscripts 1 and 2 represent the respective nodes of the element or parameter values of  $p = 0$  and  $p = l$ , respectively. The shape function representing a cubic spline is

$$\mathbf{S}(p) = \begin{bmatrix} (1 - 3(p/l)^2 + 2(p/l)^3) \mathbf{I} \\ ((p/l) - 2(p/l)^2 + (p/l)^3) \mathbf{I} \\ (3(p/l)^2 - 2(p/l)^3) \mathbf{I} \\ ((p/l)^2 - (p/l)^3) \mathbf{I} \end{bmatrix} \quad (3)$$

where  $\mathbf{I}$  is a  $3 \times 3$  identity matrix.

The standard form of the Newton-Euler equations are given for a single element as

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{K}\mathbf{q} + \mathbf{C}\dot{\mathbf{q}} - \mathbf{Q} = 0, \quad (4)$$

where  $\mathbf{M}$  is the mass matrix,  $\mathbf{K}$  is the elastic stiffness matrix,  $\mathbf{C}$  is the damping matrix,  $\mathbf{Q}$  is an external force vector, and  $\mathbf{q}$  is the vector of generalized coordinates defined in Equation 2. The equations of motion for the full system are formulated from Equation 4 using the embedding technique described in [4]. The Newton-Euler equations are solved using a numerical ODE integrator to determine the cable motion over time. The matrices  $\mathbf{M}$ ,  $\mathbf{K}$  and  $\mathbf{C}$  and force vector  $\mathbf{Q}$  will be defined in the following sections.

#### A. Mass Matrix

Using a variational mass lumping approach the mass matrix is derived directly from the element kinetic energy [5] and is given by

$$\mathbf{M} = \frac{\partial^2 E_T}{\partial \dot{\mathbf{q}} \partial \dot{\mathbf{q}}} = \int_0^l \rho A \mathbf{S}(\mathbf{p})^T \mathbf{S}(\mathbf{p}) dp \quad (5)$$

where  $E_T$  is the kinetic energy of the element,  $\rho$  is the cable density and  $A$  is the cable cross-sectional area.

#### B. Stiffness

Similarly, the stiffness matrix is derived from the strain energy  $E_S$  of the element given by [6]:

$$E_S = \frac{1}{2} \int_0^l [EA\epsilon_l^2(p) + EI\kappa^2(p)] dp \quad (6)$$

where  $E$  is the Young's modulus of the cable material,  $A$  is the cross-sectional area,  $I$  is the second moment of area,  $\epsilon_l$  is

the longitudinal strain, and  $\kappa$  is the curvature of the element. The internal stiffness force is then given by the derivative of the strain energy with respect to the coordinate vector  $\mathbf{q}$ . The force vector can be separated into longitudinal and transverse components,  $\mathbf{Q}_l$  and  $\mathbf{Q}_t$ . In order to simplify the computation of these forces it is assumed that the longitudinal strain  $\epsilon_l$  is small and also constant throughout the element. The forces can then be derived as shown by Berzeri et al. [6]:

$$\mathbf{Q}_l = \left[ EA\epsilon_l \int_0^l \mathbf{S}'^T \mathbf{S}' dp \right] \mathbf{q} \quad (7)$$

where  $\mathbf{S}'$  is the derivative of  $\mathbf{S}$  with respect to the parameter  $p$ . The longitudinal strain is determined from the arc length  $s$  of the element [2]:

$$\epsilon_l(\mathbf{q}) = \frac{s(\mathbf{q}) - l}{l} \quad (8)$$

where  $s$  is the arc length and  $l$  is the unstretched element length. The arc length is defined by integrating the norm of  $\partial\mathbf{r}/\partial p$  with respect to  $p$  over the length of the element [7]. The arc length  $s$  is approximated using a numerical quadrature

$$s(\mathbf{q}) = \sum_{i=1}^{N_I} w_i \sqrt{\mathbf{r}'(p_i)^T \mathbf{r}'(p_i)} \frac{l}{N_I} \quad (9)$$

where  $i$  denotes the integration point,  $N_I$  is the total number of integration points,  $w_i$  is the quadrature weight. The trapezoidal rule is used with quadrature weights defined

$$w_i = \begin{cases} 0.5, & i = 1, N_I \\ 1, & i = 2, 3, \dots, N_I - 1 \end{cases} \quad (10)$$

The transverse stiffness force  $\mathbf{Q}_t$  is defined [6]

$$\mathbf{Q}_t = \left[ \int_0^l EI S''^T S'' dp \right] \mathbf{q} \quad (11)$$

where  $I$  is the second moment of area. The general stiffness matrix  $\mathbf{K}$  from Equation 4 is then given by

$$\mathbf{K} = \int_0^l EI S''^T S'' dp + \epsilon_l(\mathbf{q}) EA \int_0^l \mathbf{S}'^T \mathbf{S}' dp. \quad (12)$$

#### C. Damping

The damping matrix  $\mathbf{C}$  from Equation 4 serves both to include energy dissipation and attenuate high frequency vibrational modes. The cable model uses the Rayleigh-damping approach [8], wherein the damping matrix is defined as a linear combination of the mass and stiffness matrices:

$$\mathbf{C} = \alpha \mathbf{M} + \beta \mathbf{K} \quad (13)$$

where  $\alpha$  and  $\beta$  are scalar damping coefficients. The mass-proportional damping term represents external viscous damping while the stiffness-proportional damping term represents internal frictional damping. Since the external fluid damping

can be incorporated into the aerodynamic drag force, the mass-proportional term will be neglected by setting  $\alpha$  equal to zero.

Given a specified damping ratio  $\xi$ , the corresponding value of the remaining coefficient  $\beta$  is given by [9]

$$\beta = 2\xi \frac{1}{\omega_n} \quad (14)$$

where  $\omega_n$  is the natural frequency of the cable.

#### D. External Forces

The vector of external forces  $\mathbf{Q}$  includes the gravitational body force, the normal contact forces along the sheave surfaces and the aerodynamic loading. The formulation of the forces is provided in the following sections.

1) *Contact Force*: In order to model the cable-sheave interaction, a contact penalty is used. The cable is allowed to “penetrate” the sheave surface and the normal force  $\mathbf{f}_N$  is defined as a function of the relative penetration  $\delta$ . The normal force per unit length  $\mathbf{f}_N$  acting at a single point on the element is defined using the Hunt-Crossley model [10], which represents the surface as a non-linear spring-damper:

$$\mathbf{f}_N = k_N \delta^n (1 + D\dot{\delta}) \mathbf{u}_n \quad (15)$$

where  $\mathbf{u}_n$  is the unit vector normal to the sheave surface at the point of contact,  $k_N$  is the contact stiffness,  $\delta$  is the relative “penetration” of the node into the surface,  $D$  is a damping coefficient and  $n$  is a positive constant with a value between 1 and 1.5 from the Hertz contact theory [11]. In the present analysis, a contact stiffness of  $1.5 \times 10^7$  N/m and a value of  $n$  of 1.5 is used based on the values used by Bulin et al [12] and the researchers’ previous work [2].

The radius of curvature of the groove is assumed to be equal to the radius of the cable. Two surfaces are defined that are parallel to the straight walls of the sheave groove and intersect at the center of curvature of the groove. In the cross-section shown in Figure 1, the two surfaces are straight solid lines and the sheave groove is a dotted line. If the cable centerline lies below either of the solid lines, a penalty force is produced proportional to the penetration of the cable node into the surface. If the cable node lies above both lines, no normal force is applied. The contact penalty is illustrated in Figure 1. The normal force per unit length is evaluated at  $N_I$  discrete points per element. The distributed force in the element coordinates is then calculated from the discrete force distribution that will be discussed in Section II-D4.

2) *Drag Force*: The drag force per unit length acting at a given point on the cable is given by [13]

$$f_D = -\frac{1}{2} C_D \rho_w d |\mathbf{V}_n| \mathbf{V}_n \quad (16)$$

where  $C_D$  is the drag coefficient,  $d$  is the cable diameter,  $\mathbf{V}_n$  is the normal component of the relative velocity  $V$ , and  $\mu$  is the dynamic viscosity of the fluid. The relative velocity and its normal component are calculated as follows:

$$\mathbf{V} = \dot{\mathbf{r}} - \mathbf{U} \quad (17a)$$

$$\mathbf{V}_t = (\mathbf{V} \cdot \mathbf{u}_t) \mathbf{u}_t \quad (17b)$$

$$\mathbf{V}_n = \mathbf{V} - \mathbf{V}_t \quad (17c)$$

where  $\mathbf{U}$  is the velocity of the free stream,  $\dot{\mathbf{r}}$  is the velocity of the point on cable centerline. The unit vector tangent to the cable centerline  $\mathbf{u}_t$  is equivalent to  $\frac{\dot{\mathbf{r}}'}{|\dot{\mathbf{r}}'|}$ . The drag coefficient  $C_D$  is given by

$$C_D = 1.1 + 4Re^{0.8}, \quad 30 < Re < 10^5 \quad (18)$$

where  $Re$  is the Reynolds number.

3) *Wake Oscillator Model*: A two-degree of freedom wake-oscillator developed by Bai and Qin [3] is used to describe the vortex shedding forces on the cable. The variable  $w(t)$  is introduced, with the function  $d^2\dot{w}(t)$ , where  $d$  is the cable diameter, corresponding to the vortex strength of the wake. The evolution of  $w$  over time satisfies a van der Pol equation of the form

$$\ddot{w} + a_1 \omega_{st} \left[ 1 - \frac{a_2(\dot{w})^2}{\omega_{st}^2} \right] \dot{w} + \omega_{st} w = \frac{a_3 \omega_{st}}{d} \dot{Y} \quad (19)$$

where  $a_1, a_2$  and  $a_3$  are empirical parameters,  $\omega_{st}$  is the Strouhal frequency in rad/s, and  $Y$  is the displacement of the cable in the cross-flow direction. Typical values for  $a_1, a_2$  and  $a_3$ , proposed by Facchinetto [14] and Bai and Qin [3] are 0.3, 0.2 and 12, respectively.

The forces acting on the structure due to the vortex shedding are then evaluated:

$$f_{SW} = -\frac{C_{D0} \rho d^4}{32\pi^3 St^3 U} \dot{w} \ddot{w} \quad (20a)$$

$$f_{CF} = \frac{C_{L0} \rho U d^2}{8\pi St} \dot{w} \quad (20b)$$

where  $f_{SW}$  is the force per unit length acting in the stream-wise direction,  $f_{CF}$  is the force per unit length acting in the cross-flow direction,  $C_{D0}$  and  $C_{L0}$  are the drag and lift coefficients associated with the vortex shedding, with assumed values of 0.2 and 0.3, respectively. In the absolute coordinate frame, the cross-flow direction corresponds to the  $y$ -axis, while the stream-wise direction corresponds to the  $z$ -axis.

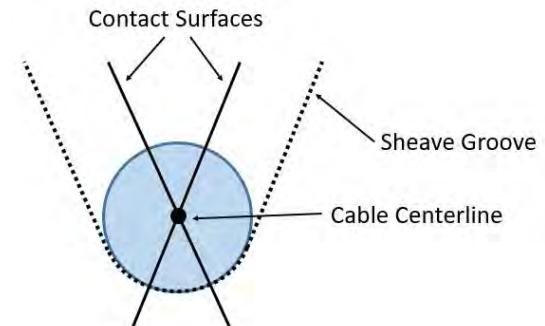

Fig. 1: Sheave Groove Cross-Section

For each node on the cable exposed to the wind, a degree of freedom representing the wake variable  $w$  is added to the system equations of motion. The wake coefficients are interpolated linearly to provide the discrete force distributions along each element.

*4) Total Distributed Force:* The force distributions determined for the normal contact, stationary drag and oscillating drag and lift are added together to give the total force distribution  $\mathbf{f}$ . The force acting on the element in the element coordinates  $\mathbf{Q}$  is then found by integrating over the length of the cable element:

$$\mathbf{Q} = \int_0^l \mathbf{S}(p)^T \mathbf{f} dp. \quad (21)$$

Again, a numerical quadrature is used to approximate the integral:

$$\mathbf{Q} = \sum_{i=1}^{N_I} w_i \mathbf{S}(p)^T \mathbf{f}_i \frac{l}{N_I} \quad (22)$$

where  $i$  denotes the integration point,  $N_I$  is the total number of integration points and  $w_i$  is the quadrature weight. Ten integration points per element were used for all simulations described in this report.

The gravitational body forces are defined similarly with  $\mathbf{f} = [0 \ -\rho Ag \ 0]^T$  where  $\rho$  is the cable density and  $g$  is the acceleration due to gravity. Since the gravitational force is constant, the integration can be performed symbolically using Equation 21 prior to the simulation.

### III. CASE STUDIES

#### A. Model Parameters

The system consists of a cable suspended by two identical sheaves. Each cable end is attached to a point mass as shown in Fig. 2. The wind vector is aligned with the z-axis. Static drag and oscillating lift and drag are applied only to the portion of the cable suspended between the two sheaves. A number of case studies were performed. The system properties used for the simulations are listed in Table I. The cable properties used are for a wire rope with 6x37 construction, commonly used for marine lifting and hoisting applications [15]. The sheave diameters are calculated using the minimum recommended sheave-to-rope diameter ratio of 18 [15].

Values for the cable bending stiffness  $EI$  and damping ratio  $\xi$  are not readily available, thus conservative values were used. A minimum bending stiffness value can be calculated by neglecting the friction between individual wires and assuming the total bending stiffness is the sum of the bending stiffnesses of the individual wires [16]. Using the average diameter  $d_{avg}$  and assuming the lay angle  $\theta$  is small, the bending stiffness becomes

$$EI = E \sum \frac{\pi d_w^4}{64} \cos\theta = EN_w \frac{\pi d_{avg}^4}{64} \quad (23)$$

where  $N_w$  is the number of wires. Based on the parameters listed in Table I, the bending stiffness is estimated to be 0.73

TABLE I: Model parameters.

Cable diameter, $d$	20 mm
Cable mass per unit length, $\mu$	1.38 kg/m
Damping ratio, $\xi$	0.10
Cable elastic modulus, $E$	75.8 GPa
Cable bending stiffness, $EI$	0.73 Nm <sup>2</sup>
Cable metallic area, $A$	$1.64 \times 10^{-4}$ m <sup>2</sup>
Sheave radius at root, $R$	0.18 m
Sheave groove angle	30 degrees
Sheave groove depth	30 mm

TABLE II: Case study parameters.

Case	1	2	3	4
Span length (m)	2	5	5	5
Cable Tension (N)	200	200	500	1000
Natural frequency (rad/s)	19.9	7.57	12.0	16.9
Wind velocity (m/s)	0.302	0.121	0.190	0.269

Nm<sup>2</sup>. Damping ratios for wire ropes undergoing bending vary with cable tension and have been shown to be as high as 37% for slack cables [17]. A conservative damping ratio of 10% was used for the simulations.

The natural frequency of the catenary is estimated by treating the cable as a thin Euler-Bernoulli beam pinned at both ends and is given by [18]

$$\omega_n = \left(\frac{\pi}{L}\right)^2 \sqrt{\frac{EI}{m} \left[1 + \frac{T}{EI} \left(\frac{L}{\pi}\right)^2\right]} \quad (24)$$

where  $L$  is the beam length,  $m$  is the mass per unit length,  $T$  is the axial tension, and  $EI$  is the bending stiffness. The vortex shedding frequency can be calculated using the Strouhal relation [3]:

$$f_{st} = \frac{StU}{d} = \frac{\omega_{st}}{2\pi} \quad (25)$$

where  $St$  is the Strouhal number, assumed to have a value of 0.2 [14],  $U$  is the free stream velocity and  $d$  is the cable diameter.

Simulations were performed for three cases; the model parameters specific to each case are given in Table II. In each case, the wind velocity was chosen such that the shedding frequency matches the estimated natural frequency of the cable.

#### B. Mesh Convergence

Fig. 2 shows how the cable was divided into five segments: the two free cable ends with point masses, the two segments in contact with the sheaves and the catenary suspended between the sheaves. The wind load is applied only to the catenary, segment 3. Each segment was further divided into elements. A smaller element length is desirable for the elements in contact with the sheave as the curvature is greater. A mesh convergence was performed by allowing the system to reach

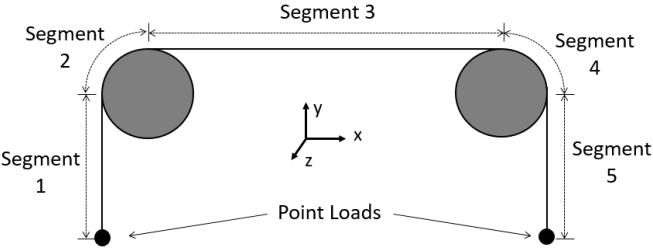

Fig. 2: Diagram of cable-sheave system. Air flow is along the z-axis.

equilibrium with no wind load applied and iteratively reducing the length of the elements in the contact arc and comparing the contact force at the top of the sheave. The number of elements was found to have a minimal effect on the contact force.

For segment 3, the convergence is determined by simulating 20 seconds of motion with the wind load applied. The maximum amplitudes of the motion at the mid-point of the span were compared. Convergence was considered to occur when the change in the output was less than 1%. Fig. 3 plots the mesh convergence for the vertical amplitudes of the 2 and 5m spans. For the final simulations, 5 elements were used for each of the contact segments while 12 and 16 elements were used for the 2 and 5 m cable spans. The free cable ends were assumed not to undergo significant transverse motion, thus only 2 elements were used for each.

### C. Results

For each case in Table II, the motion was simulated until a steady oscillation was obtained. Fig. 4 displays the vertical motion at midpoint of the span the for Case 4. The results for each test case are shown in Table III. The maximum amplitude at the midpoint of the span was  $4.5 \times 10^{-6}$  m for Case 4. At the sheave, the maximum amplitude was  $3.3 \times 10^{-6}$  m. The amplitude of the motion is much smaller than the 30 mm sheave groove depth.

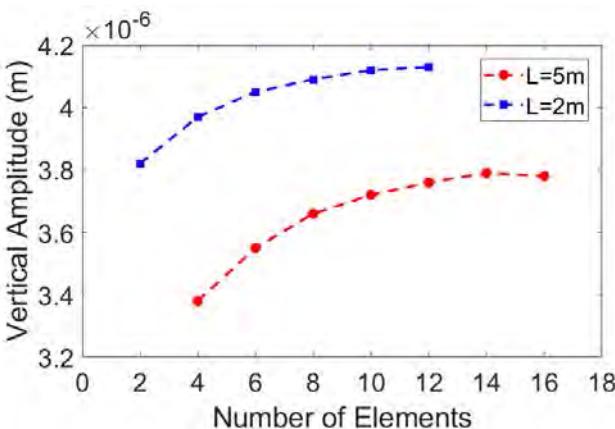

Fig. 3: Convergence curves for segment 3

TABLE III: Simulated vibration amplitudes.

Case	1	2	3	4
Vertical, Mid-span ( $10^{-6}$ m)	4.1	3.8	4.4	4.5
Streamwise, Mid-span ( $10^{-6}$ m)	0.30	0.35	0.30	0.30
Vertical, Sheave ( $10^{-6}$ m)	0.48	1.38	3.3	2.3

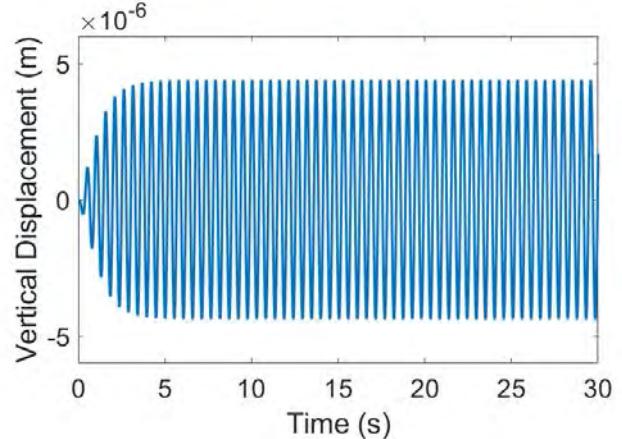

Fig. 4: Mid-span vertical displacement for Case 4

### IV. CONCLUSION

In this paper a dynamic finite element model of a low-tension cable sheave system was used to simulate the vortex-induced vibration of the cable due to wind loading and assess the potential for wind loading to lead to detachment of the cable from the sheave. The model, constructed using the absolute nodal coordinate formulation, utilized a wake-oscillator model to describe the vortex shedding forces. Also, three-dimensional contact with the sheave grooves was introduced. Several case studies were performed for systems of varying span length and cable tension with the wind velocity selected to excite the fundamental mode of the cable. The vibration amplitudes were determined to be small - the maximum amplitude observed at the sheave was only  $3.3 \times 10^{-6}$  m - thus wind loading alone is unlikely to lead to cable detachment. In future work, the wake-oscillator parameters can be tuned based on wind tunnel experiments. Scenarios where more severe vibrations are likely, such as cables with ice accretion, can also be examined in this manner. Further analysis can be performed to assess the effects of ship motion and higher sustained wind speeds on the response.

# Convergence Control for Topology Optimization

Dylan Bender and Ahmad Barari

Faculty of Engineering and Applied Science  
The University of Ontario Institute of Technology  
Oshawa, Canada  
Ahmad.Barari@uoit.ca

**Abstract**— Proportional-Integral-Derivative (PID) control theory is applied to the evolutionary rate of the Bi-Directional Evolutionary Structural Optimization (BESO) method to control aspects of the convergence such as the rise time, stability, and other convergence characteristics. When the PID controller is applied to the BESO topology optimization method, its behavior resembles that of a second order linear system and its response depends on whether it is an overdamped, critically damped or underdamped system. The new algorithm replaces the evolutionary rate control parameter with the three gain values of the controller, namely, the proportional gain, the integral gain and the derivative gain for further control the structure's evolution.

**Keywords** - *topology optimization; adaptive optimization; Proportional-Integral-Derivative; Bi-Directional Evolutionary Structural Optimization ; PID control*

## I. INTRODUCTION

Structural optimization consists of three main categories, which are size, shape and topology optimization. Size optimization aims to find an optimal design by optimizing variables such as cross-sectional dimensions or thicknesses. Shape optimization achieves structural optimization by changing pre-determined boundaries. Topology optimization, the concern of this paper, aims to determine the best locations and geometries of cavities within the design domain [1]. Fig. 1 shows a sample problem definition and resulting optimal structure of the Bi-Directional Evolutionary Structural Optimization method of topology optimization (BESO). Although the resulting structure has much less material and weight, but it maintain the required mechanical stiffness for the given loading and boundary condition. Reducing weigh of the components is highly desired in various applications, particularly in design and manufacturing of automotive and aerospace products.

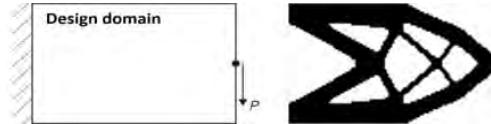

Figure 1. Sample topology optimization problem definition (left) and resulting structure (right)

Significant developments have been seen in topology optimization methodologies within the last two decades [2], the majority of which are based of Finite Element Analysis. However, applications of the developed topology optimization methods have been very limited due (i) the limitations in manufacturing and inspection of the complex topologies, and (ii) the computational complexity of the topology optimization algorithms. A successful design process needs to be conducted by considering the details of the manufacturing and inspection requirement [3]. Although the additive manufacturing processes are still not able to produce high surface qualities [4], they are highly flexible in producing the complex geometries resulting by the topology optimization methodologies [5]. Also. The advances in coordinate metrology algorithms allow relatively fast inspection of the complex topologies resulting by the topologically optimized designs [6].

The computational complexity is another limiting factor in implementation of the topology optimization algorithms. There is not that much control on the convergence of these algorithms and their computational efficiencies are not addressed well. This paper will focus on the convergence control of a typical topology optimization algorithm, Bi-directional Evolutionary Structural Optimization. BESO first introduced by [7]. The BESO method contains several control parameters including target volume fraction, penalty, minimum density, filter radius, mesh resolution, and the focus of this paper, the evolutionary rate. Traditionally, the evolutionary rate is taken to be a constant value, usually 1%, 2% or even as high as 4%, but there exists potential to use the evolutionary rate as a parameter of adaptive optimization in the form of a Proportional-Integral-Derivative controller in conjunction with closed-loop feedback.

Feedback is a very powerful idea. Its use has often had revolutionary consequences with drastic improvements in performance [8]. The usefulness of PID controls lies in their

general applicability to most control systems. In particular, when the mathematical model of the plant is not known and therefore analytical design methods cannot be used, PID controls prove to be most useful [9]. For this paper, the volumetric error signal is used to control the evolutionary rate of the BESO algorithm. The volumetric error is calculated as the difference in the targeted volume fraction and the current iterations volume fraction which can then be integrated and differentiated to produce the three inputs of the PID controller.

## II. BACKGROUND

### A. Bi-directional Evolutionary Structural Optimization

In the Bi-Directional Evolutionary Structural Optimization (BESO) method, the optimal topology is determined according to the relative ranking of the elemental sensitivity numbers. The sensitivity numbers of the elements are conceptualized to be the increase in the mean compliance,  $C$ , of a structure as a result of the removal of the  $i$ th element is equal to its elemental strain energy [1]. By this definition, the optimization problem is to find the most effective way to remove elements so that the increase in the compliance is minimal as shown in (1).

Minimize:

$$C = \frac{1}{2} \mathbf{f}^T \mathbf{u} \quad (1)$$

Where  $\mathbf{f}$  is the nodal DOF force vector and  $\mathbf{u}$  is the nodal displacement vector, both of which has the size  $2*(nely+1)*(nelx+1)$  where  $nelx$  and  $nely$  are the number of elements in the x- and y-dimensions respectively of the finite element mesh.

The study on the effect of element removal on the stiffness is referred to as the sensitivity analysis. Sensitivity numbers, which indicate the change in the overall stiffness (strain energy), have been formulated using information available from a static finite element analysis [10]. The sensitivity number of the  $i$ th element is calculated as:

$$\frac{\partial C}{\partial x_i} = -\frac{1}{2} p x_i^{p-1} u_i^T K_i^0 u_i \quad (2)$$

Each iteration of the topology optimization problem is subject to equation (3) and (4) where  $V^*$  is the prescribed target volume,  $V_i$  and  $x_i$  are the volume and density of each element respectively and  $N$  is the total number of elements.

$$V^* - \sum_{i=1}^N V_i x_i = 0 \quad (3)$$

$$x_i = x_{min} \text{ or } 1 \quad (4)$$

The target volume for the subsequent iteration ( $V_{i+1}$ ) or ( $V^*$ ) is determined based on the current structural volume,  $V_i$  the target structural volume,  $V_c$ , and the main focus of this paper, the evolutionary rate, ER. The subsequent target volume is calculated as follows:

$$V_{i+1} = \begin{cases} \max(V_i(1-ER), V_c) & \text{when } V_i > V_c \\ \max(V_i(1+ER), V_c) & \text{when } V_i \leq V_c \end{cases} \quad (5)$$

Convergence Criterion:

$$\text{error} = \frac{|\sum_{i=1}^N C_{k-i+1} - \sum_{i=1}^N C_{k-N-i+1}|}{\sum_{i=1}^N C_{k-i+1}} \leq \tau \quad (6)$$

The soft-kill BESO MATLAB code downloaded from the website [www.isg.rmit.edu.au](http://www.isg.rmit.edu.au) is used as a test platform for the methods proposed in this paper. The design domain is assumed to be rectangular and discretized using four node plane stress elements. Below, in fig. 2, a short cantilever is taken as an example of the resulting structure of the unmodified code (the graph was generated by the authors of this paper) with the input data being:  $nelx = 120$ ,  $nely = 60$ ,  $volfrac = 0.5$ ,  $ER = 0.02$ , and  $rmin = 3$ .

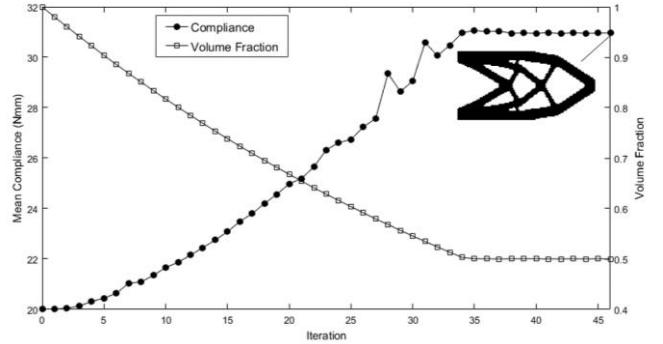

Figure 2: Results of a topology optimized short cantilever with optimization parameters:  $nelx = 120$ ,  $nely = 60$ ,  $volfrac = 0.5$ ,  $ER = 0.02$ ,  $rmin = 3$ ,  $p = 3$ . Resulting compliance: 30.96 Nmm.

### B. PID Control of a Second Order Linear System

A standard Proportional-Integral-Derivative controller, or PID controller for short is a form of a “three-term” controller whose transfer function is written as:

$$G(s) = K_p + K_I \frac{1}{s} + K_D s \quad (7)$$

The “three-term” functionalities are the proportional term, the integral term, and the derivative term. The proportional term provides an overall control action proportional to the error signal through the proportional gain factor. The integral term reduces steady-state errors through low-frequency compensation by an integrator and the derivative term improves the transient response through high-frequency compensation via a differentiator [8]. The effects of increasing these terms can be seen below in Table 1. Rise time refers to the number of iterations to reach the target volume for the first time, overshoot is the maximum peak value of the response curve (volumetric error curve) measured from target volume. Settling time refers the number of iterations for the response curve to reach and stay within a range of the final volume fraction. Steady state error refers to the difference between the final equilibrium and the target volume of the response curve.

Table 1. Effects of independent P, I, and D tuning [7]

Closed-Loop Response:	Rise Time	Overshoot	Settling Time	Steady State Error	Stability
Increasing $K_p$	Decrease	Increase	Small Increase	Decrease	Degrade
Increasing $K_i$	Small Decrease	Increase	Increase	Large Decrease	Degrade
Increasing $K_d$	Small Decrease	Decrease	Decrease	Minor Change	Improve

A family of unit-step response curves with various values of damping coefficients,  $\zeta$  is shown in fig. 3. In control theory, a system with a damping coefficient of  $\zeta = 0$  is considered marginally stable and results in a sinusoidal error signal. A damping coefficient of  $0 < \zeta < 1$ , results in a system known as underdamped where the error signal exhibits a damped sinusoidal oscillation and at steady state, no error exists between input (target volume) and output (actual volume). A damping coefficient of  $\zeta = 1$  is considered critically damped (often the ideal situation) which exhibits the fastest response. A coefficient of  $\zeta > 1$  is known as an overdamped system and is sluggish in responding to any inputs.

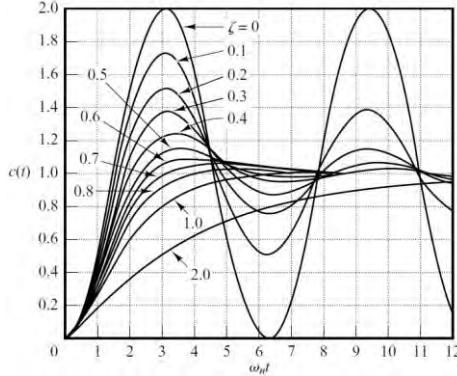

Figure 3. Unit-step response curves for a second order system with varying damping ratios [9]

### III. METHODOLOGY

It is expected that, the smaller the value of the element removal ratio used, the more accurate is the final design, at the expense of larger computation time [10]. This philosophy is based on elemental removal ratio strategy considered with respect to the current number of elements. The motivation behind the applied control theory is to allow for large amounts of material to be removed at the beginning of the optimization when there exists a lot of inefficient material and for small amounts of material to be removed towards the end of the optimization as the volumetric error approaches zero.

The plot of volume versus iteration number can be generalized as a nonlinear function which starts at some arbitrary initial volume, then approaches and eventually reaches the prescribed target volume. Note that the traditional constant evolutionary rate results in a volume graph that resembles a piecewise linear function as shown in fig. 2 but the

adaptive evolutionary rate results in a nonlinear graph as presented as seen in fig. 6.

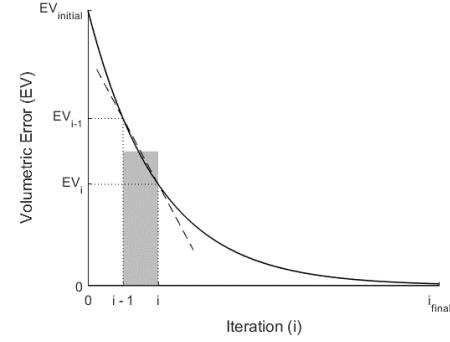

Figure 4. The volumetric error plot with a visualization of the volumetric error integral calculation (shaded grey box) and the volumetric error derivative (dashed line)

The volumetric error is calculated as the difference in the current structural volume and the target structural volume and demonstrated convergence is graphed in fig. 4. Volumetric Error ( $E_v$ ) is calculated as:

$$E_{v_i} = V_{target} - V_i \quad (8)$$

The volumetric integral error is calculated to be the integral of the volumetric error signal which may be visualized as the area under the volumetric error graph as demonstrated in fig. 4. Volumetric Integral Error ( $\int E_v$ ) is calculated as:

$$\int_0^i E_v \approx \int_0^{i-1} E_v + \frac{E_{v_{i-1}} + E_v}{2} (i - (i - 1)) \quad (9)$$

Where  $i$  denotes the current iteration number. Note that the  $(i - (i - 1))$  term of (8) evaluates to 1, and therefore may be omitted during implementation.

The volumetric error derivative is calculated as the rate of change of the volumetric error. This can be simplified to represent the slope of the line passing through two adjacent points of the volumetric error graph as shown in the right graph of fig. 4. Volumetric Error Derivative ( $E_v'$ ) is calculated as:

$$\frac{dE_{v_i}}{di} \approx \frac{E_{v_i} - E_{v_{i-1}}}{i - (i - 1)} \quad (10)$$

Similar to (9), the  $(i - (i - 1))$  term of equation (8) evaluates to 1, and therefore may be omitted during implementation.

Evolutionary Rate (ER):

$$ER_i = K_p E_{v_i} + K_I \int_0^i E_v + K_D E'_{v_i} \quad (11)$$

An alternative formula may be used for the next iterations target volume in lieu of (5). This method allows for the underdamped cases where the evolution's volume overshoots the target volume and returns to an equilibrium at the target volume.

$$V_{i+1} = \min(\max(V_i - ER, 0), 1) \quad (12)$$

Tuning a proportional-integral-derivative (PID) controller appears to be conceptually intuitive, but can be hard in practice, if multiple (and often conflicting) objectives such as short transient and high stability are to be achieved [11]. There exist many suggested methods for tuning a PID controller but the majority of them require increasing the proportional gain until the system becomes unstable or marginally unstable which breaks down the topology optimization algorithm when implemented.

For tuning the PID controller, the authors suggest starting with a derivative gain of zero and a very small value of the integral gain ( $0.0001 < k_I < 0.001$ ) slowly increasing the proportional gain until just after the algorithm has reached similar performance (e.g. similar compliance and settling time) as the standard algorithm. Then, the user should start increasing the derivative gain to make the volume convergence plot resemble that of a critically damped system. If the system seems to take too long to converge, the user should increase the integral gain slightly. The authors have found that the controller exhibits similar performance characteristics for varying mesh resolutions so it is suggested that the tuning be carried out on a low-resolution mesh then applied to the applicable high-resolution mesh.

#### IV. RESULTS AND DISCUSSION

The first sample topology optimization with the PID controller presented in fig. 5 is to demonstrate how closely its volumetric convergence resembles that of the response of a second order linear dynamic system. With the gain tuning values of  $K_P = 0.2$ ,  $K_D = 0.3$  and  $K_I = 0.04$ , it can be seen that at first the algorithm overshoots its target volume of 50% and reaches a volume fraction of 29%, then overshoots the target again on its way back up and reaches a volume fraction of 55% before eventually reaching its target and settling down. This behaviour resembles that of a system with a damping coefficient of 0.3.

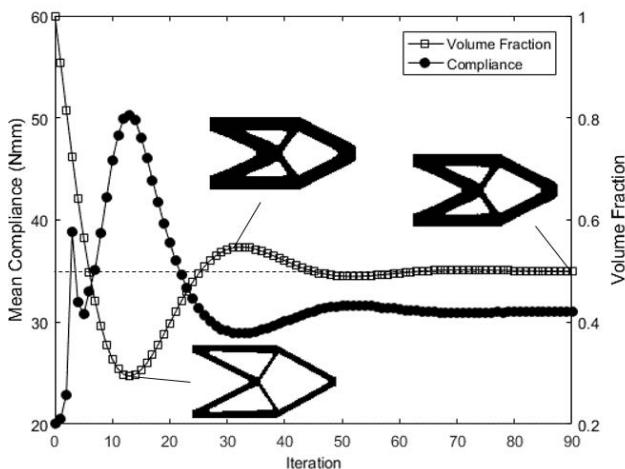

Figure 5. Topology optimization result with a PID tuning of  $k_P = 0.2$ ,  $k_D = 0.3$ ,  $k_I = 0.04$ , resulting in a final compliance of 31.06 Nmm

The second sample optimization run aims to demonstrate similar performance to that of the standard BESO algorithm but with improved convergence characteristics. The example also uses the standard volume calculation of (5) instead of the new proposed volume calculation of (12) like the previous example. It can be seen that with a controller tuning of  $k_P = 0.2$ ,  $k_D = 0.3$ ,  $k_I = 0.04$ , the optimization reaches a similar compliance within the same number of iterations. The volume convergence and incidentally the compliance make big changes at first when the volumetric error is the highest and small, gradual changes towards the end when the volumetric error is near zero.

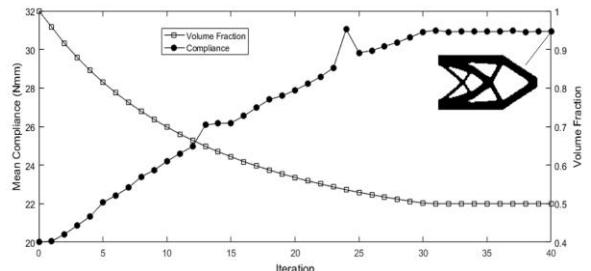

Figure 6. Topology optimization result with a PID tuning of:  $k_P = 0.125$ ,  $k_D = 0.35$ ,  $k_I = 0.002$ , resulting in a final compliance of 30.93 Nmm

The addition of the PID controller to the evolutionary rate of the BESO algorithm uses very little resources but provides the user with increased control on the algorithm's convergence as well as other surprising characteristics. The authors have found tunings that can achieve better compliance in less iterations than the standard BESO algorithm but the convergence plot is highly unstable. The authors have also found tunings that seem to provide length scale invariance regardless of the mesh resolution chosen. These intriguing cases will be explored further in a future publication as the goal of this paper was to just introduce the topic.

Additionally, the evolutionary rate plays the similar role as the move limit in mathematical programming and the step size in optimality criteria methods [10]. This fact could be used to extend the PID control of the evolutionary rate of the BESO method to the move limit of the SIMP or MMA methods and will also be explored in future publications.

#### V. CONCLUSION

This paper presents an approach to control the convergence of Bi-Directional Evolutionary Structural Optimization algorithm. It is shown the evolutionary rate is an effective control parameter for a closed-loop Proportional-Integral-Derivative controller in the Bi-Directional Evolutionary Structural Optimization method. The developed methodology provides the user with effective control of various convergence characteristics of the volumetric evolution during the topology optimization process.

# Incorporating asymmetric hardening behavior in modeling the Cold Expansion process of AZ31B Sheet

Sasan Faghih, Seyed Behzad Behravesh, Hamid Jahed

Mechanical and Mechatronics Engineering Department, University of Waterloo  
Waterloo, Ontario

**Abstract**—The Variable Material Properties (VMP) method of elastoplastic analysis for axisymmetric problems is extended to the applications of the cold expansion problem for magnesium sheets exhibiting asymmetric hardening behavior. To investigate the effect of hardening asymmetry in the stress-strain results, a detailed 3D finite element (FE) model with symmetric material properties was also generated for the cold expansion problem. Comparison between the results of the VMP and the FE model revealed the significant effect of hardening asymmetry.

**Keywords-** Asymmetric hardening; VMP; Cold expansion; Finite element

## I. INTRODUCTION

Lightweighting, as an effective approach to improve fuel efficiency and reduce greenhouse gasses emissions, has been a major strategy in the transportation industry [1]. Magnesium, as the lightest structural metal, has been a candidate for replacing the existing heavier materials in this industry. Magnesium application in the aerospace industry goes back to early aircraft development in 1930s, mostly for non-load bearing components, such as gearbox casing [2]. Recently, it has been considered also for structural components [3].

In aerospace structures, fastened joints are the most common assembly technique [4]. Rivet joints, causing stress concentration in structures, are highly susceptible to fatigue failure [5]. One of the approaches to improve the fatigue life is to create compressive residual stress around the hole by plastic expansion. There are several ways of expanding the hole, such as hole edge expansion, ball expansion and tapered mandrel. Due to the surface damage caused by these methods [4], they have been replaced by a more advanced method called split sleeve cold expansion. This method, which consists of pulling a tapered mandrel covered with split sleeve through the hole [6], is now widely used in aerospace industry as the fatigue life improvement technique [7]. From the design point of view, determination of the residual stress due to cold expansion is key to estimation of fatigue life. Such stresses have been shown to strictly depend on the stress-strain material model employed in the calculation/simulation [8]. Current calculation/simulation models for cold expansion process, either finite element models [9], [10] or analytical models [11], [12] are based on simple material models, which can only consider symmetric yield and

hardening behaviors. The variable material property (VMP), with capability of considering actual material behavior [13]–[15], is proven to be able to consider the asymmetric behavior ([16]).

Wrought magnesium alloys, show asymmetric behavior, which is defined as different yield strength and hardening behavior under tension and compression. Such asymmetry is arising from twinning deformation [17] and is different from hydrostatic stresses-associated strength-differential effect seen in high strength steels [18]. In addition, wrought magnesium alloys exhibit anisotropy, i.e., the material behavior varies in different orientations. It has been shown that in rolled AZ31B, asymmetric behavior is dominant, and anisotropy is not significant [19].

In this paper, a simple numerical method based on the VMP approach [20], with the capability of considering the asymmetric hardening behavior, is implemented to model the cold expansion process. A detailed 3D finite element model assuming symmetric hardening behavior is developed for the same problem. A comparison is made between the asymmetric solution from the VMP method and the symmetric solution from the FE analysis, to investigate the effect of material symmetry.

## II. MATERIAL AND MODELING

### A. Split sleeve cold expansion process

In split sleeve cold expansion process, a tapered mandrel surrounded with a split sleeve, is pulled through the hole. Since the summation of the maximum diameter of the mandrel and split sleeve thickness is greater than the initial hole diameter, the hole expands. Upon removal of the mandrel elastic region around the hole springs back, which creates compressive residual stress around the hole. Schematic illustration of the split sleeve cold expansion process is shown in Fig. 1. Details of the geometry of different parts that are used in this study is given in Table 1. Sheet material is AZ31B with properties given in [21].

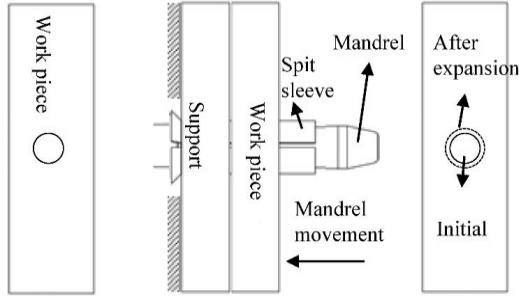

Figure 1. Schematic illustration of the split sleeve cold expansion process

Table 1. Geometry of different parts used in the cold expansion model

Part	dimension	size (mm)
Mandrel	Major diameter	5.84
Split sleeve	Thickness	0.20
Workpiece	Thickness	4.00
Workpiece	Initial hole diameter	6.00

### B. VMP approach

First, a brief review of the VMP method is presented here. Total strain in a body subjected to general force can be written as:

$$\varepsilon_{ij} = \varepsilon_{ij}^e + \varepsilon_{ij}^p \quad (1)$$

in which  $\varepsilon$ ,  $\varepsilon^e$ , and  $\varepsilon^p$  stand for total strain, elastic strain, and plastic strain, respectively. According to Hook's law:

$$\varepsilon_{ij}^e = \frac{1+v}{v} \sigma_{ij} - \frac{v}{E} \sigma_{kk} \delta_{ij} \quad (2)$$

where  $v$ ,  $E$ ,  $\delta$ ,  $\sigma$  are Poisson's ratio, Young's modulus, Kronecker delta, and stress components. According to the Hencky's total deformation theory:

$$\begin{aligned} \varepsilon_{ij}^p &= \phi S_{ij} \\ S_{ij} &= \sigma_{ij} - \frac{1}{3} \sigma_{kk} \delta_{ij} \\ \phi &= \frac{3 \varepsilon_{eq}^p}{2 \sigma_{eq}} \end{aligned} \quad (3)$$

where  $S$  stands for deviatoric stress and  $\phi$  is a scalar value, obtained from uniaxial stress-strain curve. Combining "(3)" and "(2)" with "(1)" results in:

$$\begin{aligned} \varepsilon_{ij} &= \left( \frac{1+v}{E} + \phi \right) \sigma_{ij} - \left( \frac{v}{E} + \frac{\phi}{3} \right) \sigma_{kk} \delta_{ij} \\ \varepsilon_{ij} &= \frac{1+v_{eff}}{E_{eff}} \sigma_{ij} - \frac{v_{eff}}{E_{eff}} \sigma_{kk} \delta_{ij} \\ E_{eff} &= \frac{3E}{3+2E\phi} \\ v_{eff} &= \frac{3v+E\phi}{3+2E\phi} \end{aligned} \quad (4)$$

In which, the "eff" subscript stands for the effective value.

To solve an axisymmetric boundary value problem, such as a cylinder subjected to an internal pressure, Fig. 2, the body is discretized into a finite number of annuli. The VMP method, being an iterative solution, starts with a fully elastic solution in the first iteration. Then, the equivalent stress is calculated for all the elements. For the elements where the equivalent stress is higher than the yield strength of the material, the values of  $v_{eff}$ ,  $E_{eff}$  are updated according to Equation (4), which are used in the next solution iteration. The effective Young's modulus at each element is found from the projection method, illustrated in Fig. 2(b). According to the projection method, the effective Young's modulus is the secant modulus at the strain value obtained in the previous iteration, point  $b'$  in Fig. 2(b). Eliminating  $\phi$  in Equation (4) gives the effective Poisson's ratio. Then, the elastic solution in each iteration is obtained from the well-known Lame's solution in the plane stress condition [20]. This procedure is repeated until the equivalent stress and strain values for all the elements match the uniaxial stress-strain curve. In case of the cold expansion problem, the process is modeled as a cylinder, with inside diameter equal to the hole diameter and outside diameter which is five times the hole diameter, subjected to radial displacement at inner radius.

As mentioned earlier, in magnesium alloys uniaxial tension and compression curves are not the same. To consider the asymmetric behavior, the Cazacu-Barlat yield criterion [22] was implemented to calculate the equivalent stress in the VMP method iterations. This criterion is given by:

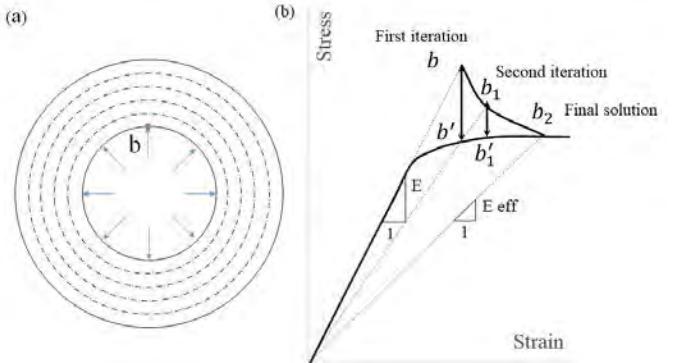

Figure 2. (a) Pressurized thick-walled cylinder discretized into finite number of annuli, (b) demonstration of the projection method

$$\begin{aligned} \sigma_{eq} &= A \left( J_2^{\frac{3}{2}} - c J_3 \right)^{\frac{1}{3}} \\ c &= \frac{3\sqrt{3}}{2} \left( \frac{\sigma_{yt}^3 - \sigma_{yc}^3}{\sigma_{yt}^3 + \sigma_{yc}^3} \right) \end{aligned} \quad (5)$$

$$A = 3 \left( 3^{\frac{3}{2}} - 2c \right)^{-\frac{1}{3}}$$

In which,  $\sigma_{yt}$ ,  $\sigma_{yc}$ ,  $J_2$  and  $J_3$  are tension and compression yield strengths, second and third invariants of deviatoric stress tensor, respectively. For the case of symmetric materials, i.e.  $\sigma_{yt} = \sigma_{yc}$ , this yield criterion reduces to the Von-Mises criterion. The asymmetry parameter,  $c$ , determines the shape of the yield locus. The parameter  $c$  at a given plastic strain is obtained from the ratio of stresses on the uniaxial tension and compression curves (Fig. 3) in that plastic strain. Therefore, the shape of the yield locus for the Cazacu-Barlat criterion evolves during the plastic deformation, while it is fixed for the Von-Mises criterion. It is noteworthy that for both the symmetric (Von-Mises criterion) and asymmetric (Cazacu-Barlat criterion) solutions, only the uniaxial tension curve is used in the projection method. For the asymmetric solution, the evolution of the parameter  $c$  accounts for the compression hardening curve being different than the tension curve.

To obtain the residual stress field created by cold expansion two steps of loading and unloading are required. The unloading solution is similar to the loading part, but now each element has a specific unloading behavior defined by the level of loading strain. For the unloading phase, a pressure with the same value as the pressure at the end of the loading step with an opposite sign is applied to the inner radius of the cylinder. The negative pressure in the unloading step simulates the removal of the mandrel. Since in the Cazacu-Barlat yield criteria, tension and compression curves need to be determined. For the unloading solution, second part of the tension-compression curve (Fig. 4b) is considered as tensile curve. Likewise, the second part of the compression-tension (Fig. 4a) is considered as compression curve as the input for the VMP method. Simple interpolation method was used to generate the curves that are in between unloading curves shown in Fig. 4. After solving the unloading part, the residual stress field was obtained by:

$$\begin{aligned}\sigma_{\text{Radial}}^{\text{Res}} &= \sigma_{\text{Radial}}^{\text{load}} + \sigma_{\text{Radial}}^{\text{Unload}} \\ \sigma_{\text{Hoop}}^{\text{Res}} &= \sigma_{\text{Hoop}}^{\text{load}} + \sigma_{\text{Hoop}}^{\text{Unload}}\end{aligned}\quad (6)$$

In which,  $\sigma^{\text{Res}}$ ,  $\sigma^{\text{Load}}$ ,  $\sigma^{\text{Unload}}$  are residual stress, stress in the loading step, and the stress in the unloading step, respectively.

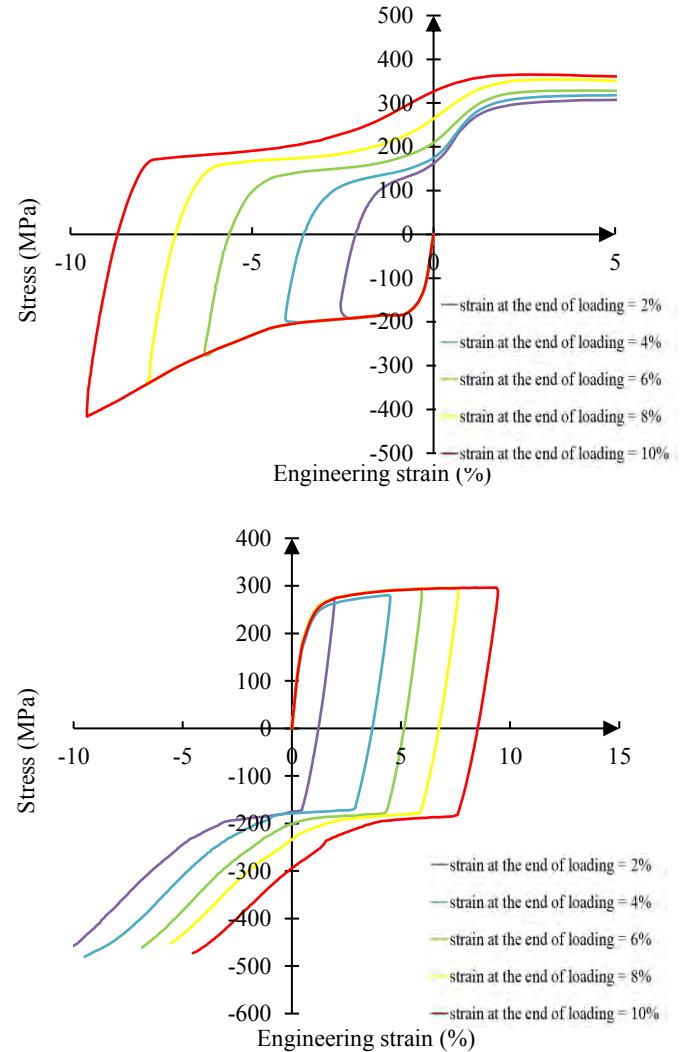

Figure 4. (a) Compression-tension and (b) tension-compression behavior for rolled AZ31B ([21],[23])

### C. Finite element

ABAQUS finite element software was used in this study to simulate the cold expansion process (Fig. 5). In order to apply a more realistic boundary condition, the support of the workpiece was also included in the model. Owing to the symmetry, only half of the structure was modeled. Boundary conditions of the model are shown in Fig. 6. On the X-Y plane, movement of the external edges of the workpiece and the support were constrained. Mandrel was considered rigid, while the split sleeve and steel support were linear elastic material with the Young's modulus of 200 GPa and Poisson's ratio of 0.3. The workpiece followed the tensile curve (Fig. 3) for the loading step, and the hardening behavior was assumed to be isotropic for the unloading step. Three surface-to-surface contacts were applied to the model: between mandrel and split sleeve, split sleeve and workpiece, and workpiece and support. They all were considered as frictionless contact. Hexahedral linear brick elements with 8 nodes and one integration point, C3D8R, were used to construct the workpiece. Because the most important region of the workpiece is the area close to the hole, the mesh size was biased towards the hole.

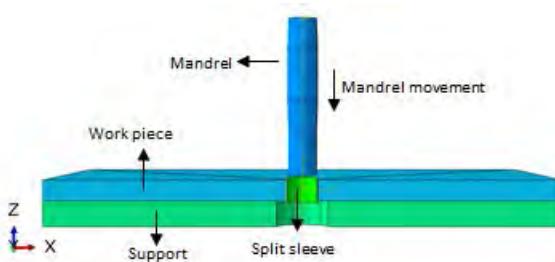

Figure 5. Assembly view of the 3D model

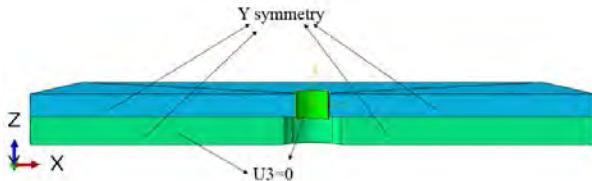

Figure 6. Boundary condition of the model

### III. RESULT AND DISCUSSION

To validate the results of the VMP solution, a comparison between the VMP and the ABAQUS results using only the tension curve and assuming isotropic hardening in both VMP and ABAQUS was made. Fig. 7 and Fig. 8 show the loading and residual stress distributions, respectively. The results from ABAQUS is for the mid-plane of the workpiece and far from the position of split. As expected, the results are in good agreement. The difference can be attributed to the fact that ABAQUS is a 3D model that considers more detail such as effect of support for workpiece, contact between mandrel and split sleeve and workpiece, while the VMP models the process as a 2D uniform expansion. Fig. 9 and Fig. 10 show the effect of considering asymmetric behavior in loading and unloading in stress distribution.

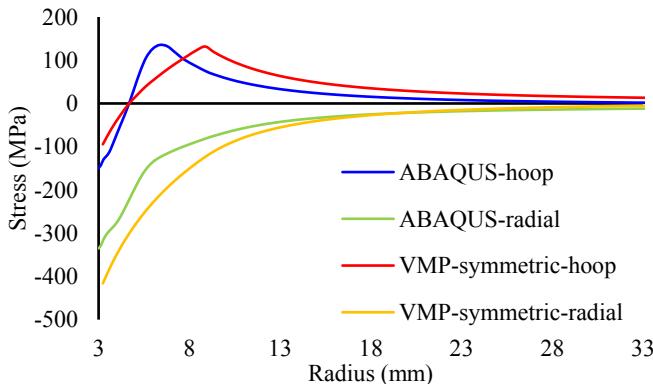

Figure 7. Hoop and radial stress distribution at the end of loading assuming symmetric hardening behavior

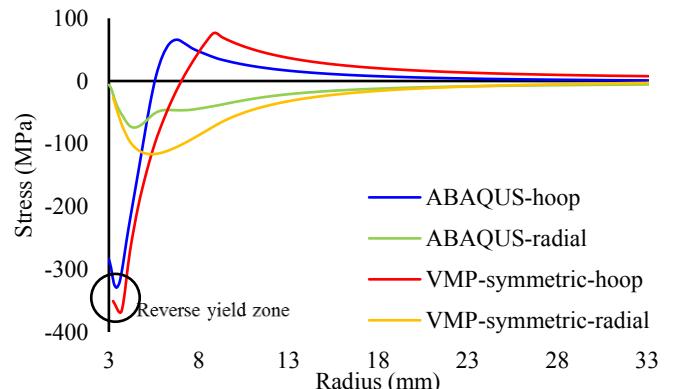

Figure 8. Residual hoop and radial stress distribution assuming symmetric hardening behavior

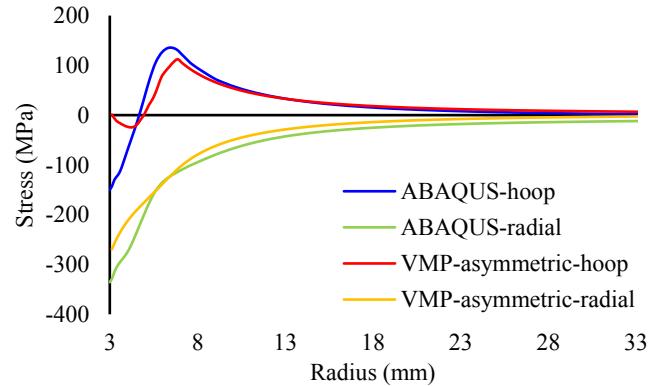

Figure 9. Hoop and radial stress distribution at the end of loading assuming symmetric hardening in the ABAQUS and asymmetric hardening in the VMP solution

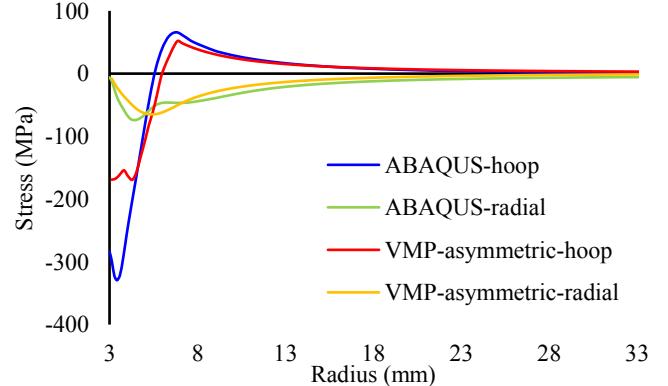

Figure 10. Residual hoop and radial stress distribution assuming symmetric hardening in the ABAQUS and asymmetric hardening in the VMP solution

In Fig. 9 and Fig. 10, the results of VMP is obtained with asymmetric material model, while in ABAQUS, symmetric behavior was assumed.

Hoop stress distributions close to the hole in loading and unloading steps were significantly different between the symmetric ABAQUS and asymmetric VMP solutions. Close to hole, which is the area of interest for the cold expansion problem, the VMP predicts the value of hoop stress to be close to zero, Fig. 9. Likewise, the residual hoop stress distribution is meaningfully different. ABAQUS predicts the reverse yield zone to be close to the hole, while Asymmetric VMP model predicts the reverse yield zone to be larger, i.e. farther from the hole (Fig. 10). This can be explained by different unloading

curves used in ABAQUS and VMP. VMP considers actual material unloading behavior (Fig. 4), in which reverse yield in the unloading part, happens at lower stress, while in ABAQUS model, the unloading curve is constructed using the isotropic hardening assumption. Moreover, considering the actual unloading behavior of the material by VMP and assuming isotropic hardening rule by ABAQUS, also contributed to the difference between the calculated residual stress field. The difference in residual stress distribution is also due to difference in the hoop stress distribution in the loading step. The plastic strain obtained from VMP around the hole during the loading step is shown in Fig. 11, for symmetric and asymmetric behavior. The larger plastic strain in the asymmetric solution is due to compression behavior accounted for in this solution. Because the yield stress in compression is smaller than that in tension (Fig. 3), it is expected that the plastic strain close to hole to be higher in the asymmetric model compared to the symmetric model.

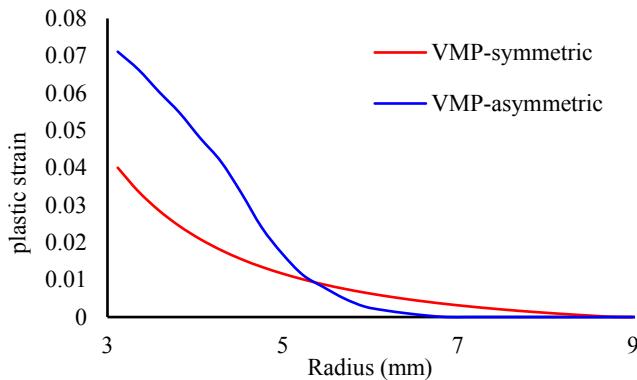

Figure 11. Plastic strain around the hole at the end of loading

#### IV. CONCLUSION

The cold expansion process in AZ31B wrought magnesium alloy has been modeled using the finite element and the VMP methods. The asymmetric hardening behavior of AZ31B was captured by the VMP, but the finite element method did not account for the asymmetric hardening behavior. Following conclusions can be drawn from this study:

- The VMP method is capable of modeling the cold expansion process. For symmetric materials, the results of this simple 2D model are in agreement with predictions of the 3D finite element model in the mid-plane.
- Asymmetric hardening behavior of materials can significantly affect the stress distribution in loading and unloading steps of the cold expansion process.
- Hoop stress distribution is significantly different in the asymmetric model, while the radial stress is almost not affected.

**Abstract**— Composites are abrasive materials that generate heat during machining operations. This heat generates thermal damage locally and may severely alter the mechanical properties of the components if it exceeds the glass transition temperature of the matrix. This research studies the influence of additives, mixed to the epoxy matrix of Glass Fiber Reinforced Polymer (GFRP), on the cutting temperature. The results show that wax together with clay and a wetting agent, contribute to reduce the maximum cutting temperature, on a 300mm length of cut, a value up to 28% as compared to a plain epoxy matrix.

## I. INTRODUCTION

The advanced industries such as the automotive, aerospace and wind industries are constantly innovating to improve the performance in terms of the weight and mechanical performance of their products. Traditionally used materials are metals that provide good mechanical performances. Metallic materials not only have good mechanical properties but are also relatively easy to machine. On the other hand, metals have a fairly high density, which implies high energy consumption by vehicles and mobile structures built with these materials. In order to reduce energy consumption, industries have introduced composite materials into the design and manufacture of mechanical parts. However, although these materials are mechanically efficient with a density that leads to reduced energy consumption, these materials have an abrasiveness that influences the temperature during machining operations.

The composite materials generally consist of a thermoset or thermoplastic matrix, and fibers as reinforcement elements. The most used and widespread fibers are carbon and glass mainly because of their mechanical and thermal properties. The use of composite materials in the manufacturing of parts or structures often requires cutting operations, like drilling, trimming or milling, before the assembly process [1]. However, these machining operations pose difficulties and quality issues because of their heterogeneity and anisotropic behavior as well as the abrasiveness of the fibers [2, 3].

The abrasiveness of the fibers alone is a cause of wear for the cutting tools. This wear is the source of a temperature increase which in turn provokes thermal damage on the cut surfaces and on the mechanical properties, specifically if the glass transition temperature ( $T_g$ ) of the matrix is exceeded [4-6]. Previous studies showed that cutting temperature may reach values up to 450°C [7, 8] during machining if tool wear is not properly controlled.

The tool wear do not only affect the temperature, but also the cutting forces. In fact, both phenomena are related, so that monitoring the forces may help to diagnose a worn tool [6, 8, 9].

This research proposes to introduce additives or chemical components within the matrix as a solution to improve the machining process. The research aims to find additives that would allow a better interaction in the matrix-fiber contact surface in order to maintain good or improved mechanical performances [10-12], while reducing the temperature of cut which lead to better quality and lesser tool wear. The introduction of additives as a solution to reduce the cutting temperature was initially explored by Lasseur [5] study showing the performance of three additives. This paper will consider the study of five additives over a length of cut equal to 300 mm.

## II. METHODOLOGY

### A. Materials

The material with which the experiments were made consists of long glass fibers with modified epoxy resin as matrix. The characteristics of the fibers and the resin are summarized in Table I.

TABLE I. CHARACTERISTICS OF THE FIBERS AND EPOXY RESIN

Materials	Name	Company	Density [g/cm <sup>3</sup> ]	Surface density [g/m <sup>2</sup> ]	Resin viscosity [Pa.s]
Fibers	E-Glass	TEXONIC	1,239	440	-
Resin	Marine 820	ADTECH	1,106	-	1,2

Different laminate of 300 mm by 300 mm size were manufactured using the infusion method. A total of 16 unidirectional plies were stacked with a 45 ° angle in order to have a trimming direction with respect to the fiber orientation of -45 °. This configuration is the worst one in terms of surface quality resulting from trimming operations. In fact, previous studies proved that such fiber orientation generates more delamination (uncut fibers and fiber pullout) and worst surface roughness than any other orientation with respect to the cutting direction [2, 13-16]. The thickness of all plaques manufactured with the various epoxy mixtures was controlled to be of 4.7mm, to ensure no variability in the results due to the fiber content. Five mixtures of epoxy were considered in this study considering three different additives with the following concentrations:

- Unmodified resin (RE)
- Resin + 1% wt wetting agent (WA)
- Resin + 1% wt WA + 1.5% wt clay (CL)
- Resin + 1% wt WA + 2% wt wax (WAX)
- Resin + 1% wt WA + 1% wt WAX + 1% wt CL.

All mixtures were made according to the protocol proposed by Quaresimin, et al. [10], and Withers, et al. [11]. The characteristics and tradenames of the additives are summarized in table II. Based on these studies, as well as on the supplier technical documentation, these additives should play the following roles:

- The wetting agent, which is an antistatic, should allow diffusion, homogenization and stabilization of the additives in the mixture with the resin.
- The clay particles, which are particles having storage stability and sag resistance should improve the mechanical properties of the composite.
- The wax particles which have a low transition temperature 288.15K (115°C) and low viscosity should therefore melt at the cutting surface during high temperature machining. It is expected to act as a lubricant to the cutting surface thus reducing the cutting temperature.

TABLE II. CHARACTERISTICS OF THE ADDITIVES

Additives	Characteristics and Supplier
Wetting agent (WA)	BYK-W 972, BYK
Clay particles (CL)	Ømax=59 µm GARAMITE-1958, BYK
Wax particles (WAX)	Ømax=11µm, CERAFLOUR 996, BYK

### B. Cutting temperature acquisition

The temperature acquisition was done through two thermocouples welded symmetrically on diametrically opposed teeth of the cutting tool. The thermocouples are of type K having a diameter of 0.076 mm (0.003"). The welded tip and the stripped thermocouples were covered with OmegaBond-400 cement which has high thermal conductivity. Finally, the tip is covered with a J-B weld epoxy resin to reinforce the shear strength and prevent the weld from easily tearing during machining. In addition, it was determined experimentally that the distance between the cutting zone and the welded tip on the tool is 1.7 mm in order to avoid a detachment of the thermocouples due to the chip flow and temperature variation [5, 7]. In addition, the closer are the thermocouples to the cutting zone, the more accurate will be the measurements [2, 9]. The cutting tool type is a CVD (Chemical Vapor Deposition) diamond coated having a 9.5 mm diameter with following characteristics:

TABLE III. CHARACTERISTICS OF THE CUTTING TOOL

Machining Tool	Material	Tungsten Carbide
	Coating material	Diamond
	Coating process	Chemical Vapor Deposition (CVD)
	Diameter	9.5 mm (3/8")
	Number of teeth	6
	Helix angle	10°

The tool instrumented with thermocouples is mounted in a holder equipped with a wireless transmission system on which the red-AL (aluminum) and yellow-CR (chromium) pairs of wires are connected to transmit the signal during the cutting process (fig. 1). The cutting operations were performed using a 3-axis Huron K2X10 CNC machine having a maximum speed of 28 000 RPM and power of 40 kW. Not only the temperature data was recorded, but also the cutting forces through a Kistler 9255B dynamometric table, as shown in figure 2. The forces data will help to understand the first contact between the tool and the laminate.

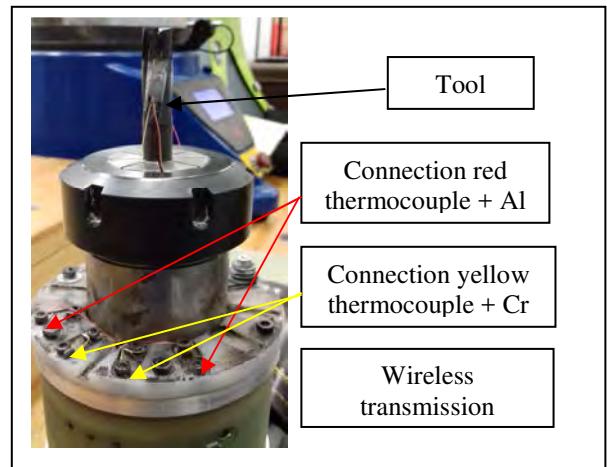

Figure 1. Tool mounting on the spindle

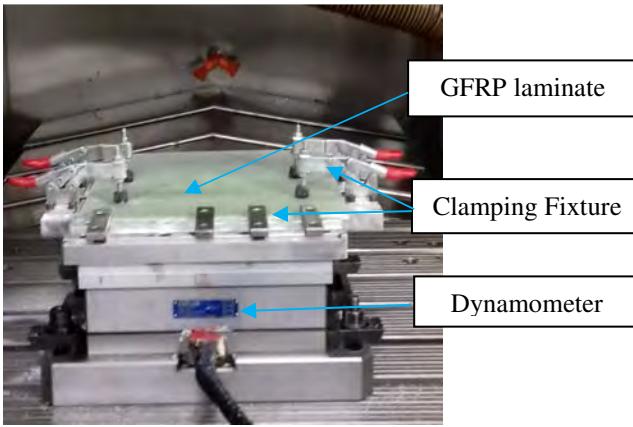

Figure 2. Experimental cutting configuration

With the objective of observing the influence of additives on the cutting temperature, the cutting parameters were fixed constant. The maximum allowed rotational speed of the wireless telemetry system used for temperature acquisition being 10 000 RPM, the cutting speed of the laminates was fixed to 300 m/min. Regarding the feed rate, based on previous experiments, it was fixed to 1140 mm/min (0.0190 mm/tooth). The cutting operation was carried out over a distance of 300 mm.

### III. RESULTS AND DISCUSSION

The cutting operations for the different laminates started at room temperature, which corresponds 20 °C. The figure 3 shows the temperature along a cutting distance of 300 mm for all types of laminate. It can be noted that the laminates containing the WA, the WA-WAX, and the WA-WAX-CL have a lower cutting temperature than the reference laminate containing only the epoxy resin (RE). In contrast, only the cutting temperature for the WA-CL laminate is higher than that of the reference laminate. Focusing on the laminates containing respectively WA-CL, WA, WA-WAX, one could validate how the wax plays a beneficial role of lubricating after a certain cutting temperature. The curves start almost from the same point and they are close to each other over a distance of 20 mm. Afterwards, we observe that the WA-CL and WA-WAX-CL curves are visibly off the other three curves. From this result, one may conclude of a combinatory phenomenon between the clay and the wax which favors a reduction of the cutting temperature. However, more study is further required to confirm this hypothesis, since the standard deviation of the temperature differences remains large for some mixtures as shown in Figure 4.

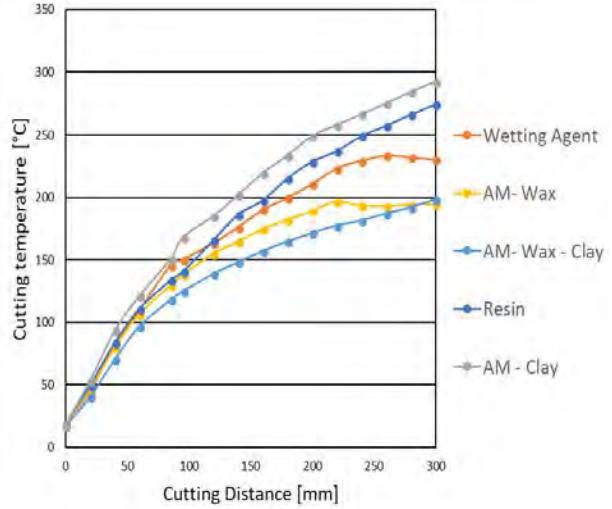

Figure 3. Cutting temperature over a distance of 300 mm.

Evaluating the average temperature differences (Figure 4) relative to the reference temperature which is that of the unmodified resin, it can be noted as expected that the average temperature difference is positive only for the laminate WA-CL. However, the values of the average temperature difference are significant over a cutting distance of 300 mm, unlike those obtained by Lasseur [5] over a reduced distance of 100 m. The negative values of the average temperature differences observed for the WA, WA-WAX, WA-WAX-CL laminates reflect a reduction in cutting temperature compared to the reference (Resin). Figure 4 also shows standard deviations of the temperature differences. It is observed, however, that the range of standard deviations obtained with the WA-WAX and WA-WAX-CL laminates does not intercept the reference axis as opposed to the gap obtained with the WA laminate. Hence, the wetting agent (WA), alone, would not be appropriate to reduce the cutting temperature. The addition of the clay to the wetting agent would involve an increase in cutting temperature. The figure 5 shows the maximum temperature values achieved for each laminate. The graph reflects the analysis mentioned above. In addition, from this figure, we observe that the laminates containing WA-WAX and WA-WAX-CL are those that actually lead to a reduction of the cutting temperature by taking into account the standard deviations of the temperature differences. Thus, there is a decrease of respectively 28.7% and 26.5% in the cutting temperature.

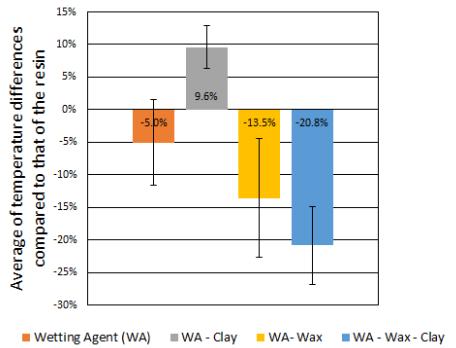

Figure 4. Average of temperature differences compared to that of the resin over a distance of 300 mm.

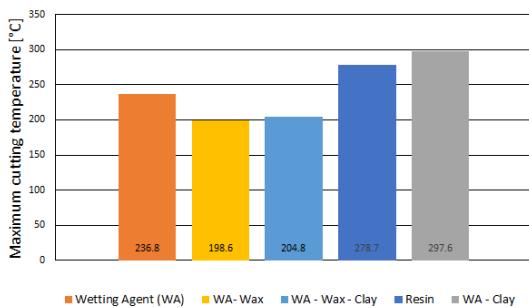

Figure 5. Maximum cutting temperature over a distance of 300 mm.

#### IV. CONCLUSION

The objective of this work was to study the influence of additives on the cutting temperature of GFRP laminates. It is apparent that the cutting temperature of the laminates made from WA-CL additives to the epoxy generates higher cutting temperature. Addition of wax to the epoxy clearly lowers the cutting temperature. The best mixture found was the WA-WAX-CL with a maximum temperature decrease up to 28%. Further development will focus on the effect of these mixtures on the mechanical properties of the GFRP composite.

**Abstract**—The Ranque-Hilsch Vortex Tube (RHVT) is a small tube without any moving parts receiving compressed air from a tangential inlet and exhausting cold air from a small hole at one end of the tube while exhausting hot air from an annular exit at the opposite end. Nearly a century has passed since the RHVT was first patented, and the mechanism responsible for this so-called "temperature separation" remains unclear. The present work tests the hypothesis that kinetic energy is transferred from the stream of air leaving the cold exit to the air stream leaving the hot exit.

To test the hypothesis, a parametric study using an axisymmetric model of the RHVT has been carried out using CFD software, wherein the pressure at the hot exit was varied. The study has been validated against previous experimental and computational models. The results show that the dominant mode of energy transfer between the two streams is work transfer, which supports the hypothesis.

**Index Terms**—Ranque-Hilsch Vortex Tube, Compressible flow, Computational Fluid Dynamics

## I. INTRODUCTION

Consider the schematic shown in figure 1. A compressible fluid is supplied at the entrance shown at some pressure  $p_{in}$ . Provided  $p_{in}$  exceeds  $p_{cold}$  and  $p_{hot}$ , some fraction of the inlet mass  $\mu_c = \dot{m}_{cold}/\dot{m}_{in}$  leaves via the cold exit, while the remaining fraction  $1 - \mu_c$  is exhausted at the hot exit. While this observation is rather unremarkable, many researchers [1], [2], [3], [4] have observed physical experiments in which the static temperature of cold exit stream was significantly lower than that of the inlet stream, while the static temperature of the hot exit stream was significantly higher than that of the inlet stream. This "temperature separation" was first noticed by George J. Ranque [5] in 1922, and is often referred to as the Ranque effect. In a later investigation Hilsch [1] discussed the effects of varying the geometric constraints of the flow boundaries. The vortex tube is now commonly referred to as the Ranque-Hilsch Vortex Tube (RHVT) after the aforementioned researchers. Sometimes the abbreviation is shortened to VT.

While vortex tubes are easy to construct and operate, the mechanism(s) responsible for the temperature separation phenomenon are still unknown, as noted in a recent review by Thakare et al. [6]. Many researchers have conducted studies and proposed theories of operation over the past century, and

while much data is available, the complex interaction between fluid mechanics and thermodynamics remains unclear.

Ranque [5] originally suggested that the temperature separation could be explained using the isentropic ideal gas relation, wherein the sudden expansion at the inlet causes a decrease in density and a sharp drop in temperature. Experiments by Gao et al. [7] and Xue et al. [8] indicate this theory significantly over-predicts the temperature drop at the cold exit. Furthermore this does not explain the corresponding temperature increase at the hot exit.

Some numerical studies have revealed the presence of re-circulation region(s) at various points within the VT. Both Ahlborn and Groves [2], and Xue and others [9] have suggested multiple re-circulation zones exist, each one behaving as a heat pump to move energy away from the core and towards the periphery. While earlier papers have provided mediocre evidence for this theory, more recent papers reporting the results of steady and unsteady, 3D, RANS and LES results have included streamline plots depicting multiple recirculation zones occurring within short vortex tubes [10], [11], [12], [13]. The re-circulation zones appear to be mobile and sensitive to geometry and boundary conditions.

A third theory states that cold stream transfers kinetic energy to the hot stream through viscous shear. This work transfer theory was first proposed by Hilsch [1], who suggested that 'internal friction' was the mode by which energy is transferred from the axis to the periphery. Aljuwayhel et al. [14] have since analyzed the results of an axisymmetric CFD model and provided quantitative evidence that work transfer from the cold stream to the hot stream is dominant mechanism of energy transfer in the RHVT. More recently, Polihronov et al. [15] and Tlili El May et al. [16] have observed wall shear stress spikes in 3D simulations of the VT, suggesting the cold stream is transferring kinetic energy to the hot stream.

In the present work we aim to quantify the energy transfer between the cold stream and the hot stream, testing our hypothesis that shear work is the primary mechanism of temperature separation. Section II provides the governing equations applicable to the current analyses, section III details the CFD model used, section IV reports the results of our simulations, and section V analyzes the energy transfer

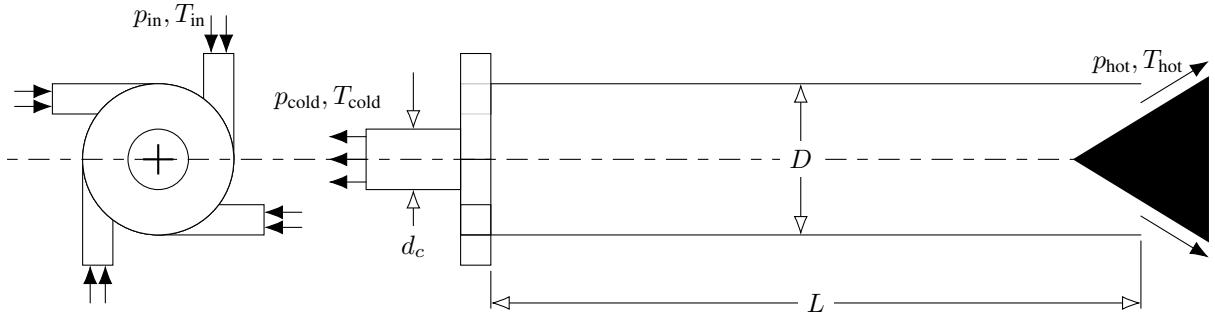

Fig. 1. A schematic of a typical Ranque-Hilsch Vortex Tube.

between the cold and hot streams.

## II. GOVERNING EQUATIONS

The conservation of mass is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0, \quad (1)$$

where  $\mathbf{u}$  is the velocity,  $\rho$  is the density,  $t$  is time, and  $\nabla$  is the gradient operator. The conservation of momentum for a Newtonian fluid where Stokes' hypothesis has been invoked is

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\frac{\nabla p}{\rho} + \frac{\mu}{\rho} \left( \nabla^2 \mathbf{u} + \frac{1}{3} \nabla (\nabla \cdot \mathbf{u}) \right), \quad (2)$$

where  $p$  is the thermodynamic pressure and  $\mu$  is the dynamic viscosity. The conservation of internal energy is

$$\rho \left( \frac{\partial \varepsilon}{\partial t} + \mathbf{u} \cdot \nabla \varepsilon \right) = -p(\nabla \cdot \mathbf{u}) - \nabla \cdot \mathbf{q}, \quad (3)$$

where  $\varepsilon$  is the specific internal energy and  $\mathbf{q}$  is the heat flux vector.

### A. Auxillary equations

All fluids analyzed in this work are assumed to obey the ideal gas equation of state:

$$p = \rho R_s T, \quad (4)$$

where  $R_s$  is the specific ideal gas constant, and  $T$  is the static, absolute temperature.

We will further assume a constant heat capacity for all fluids analyzed in this work, so that the internal energy and enthalpy may be respectively written as

$$\varepsilon = c_v T, \quad (5)$$

$$h = c_p T, \quad (6)$$

where  $c_v$  is the volumetric heat capacity and  $c_p$  is the isobaric heat capacity. Fluids which obey the ideal gas law and have constant heat capacities are called perfect gases [17].

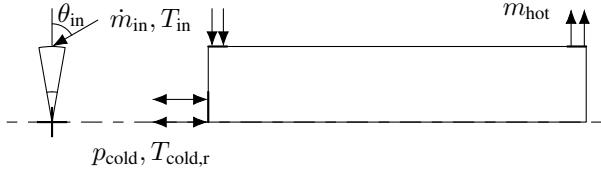

Fig. 2. Simplified VT geometry for CFD study

TABLE I  
PARAMETERS OF THE PRESENT CFD STUDY.

Measurement	Value
Working tube length [mm]	106
Working tube inner diameter [mm]	11.4
Nozzle total inlet area [mm <sup>2</sup> ]	8.2
Cold exit diameter [mm]	6.2
Cold exit area [mm <sup>2</sup> ]	30.3
Hot exit area [mm <sup>2</sup> ]	95
Nozzle angle [°]	75.48
Inlet conditions	
mass flow rate [g s <sup>-1</sup> ]	8.34
Total Temperature [°C]	21.21

## III. CFD STUDY

To analyze the energy transfer between the hot and cold streams we have performed a CFD analysis of the commercial vortex tube studied by Skye et al. [4]. The simplified vortex tube geometry is visible in Fig. 2, and the relevant geometric parameters are given in Table I.

For each simulation, the mass flow rate at the inlet is  $\dot{m}_{in} = 8.34 \text{ g s}^{-1}$ , the inlet velocity angle is  $\theta_{in} = 75.48^\circ$ , and the inlet total temperature is  $T_{in} = 21.21^\circ \text{C}$ . Skye et al. notes the presence of reverse flow at the cold exit for small cold mass fractions, so an opening boundary condition is applied at the cold exit, where the total temperature of the recirculating air,  $T_{cold,r}$ , is set to the bulk mean total temperature of the leaving air,  $T_{cold}$ . To replicate the experiment conditions of Skye et al. the cold exit pressure  $p_{cold}$  has been set to the experimentally measured value for each cold mass fraction.

Two non-orthogonal structured grids have been generated

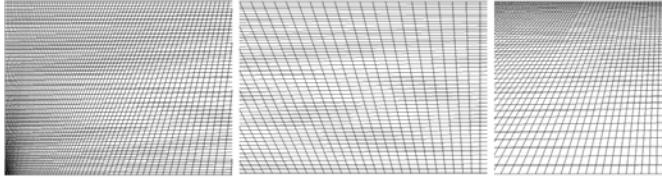

Fig. 3. Sample views of the fine mesh at inlet, middle, and hot outlet end.

using ANSYS Workbench<sup>©</sup> Meshing Software [18]: a relatively coarse grid containing 1890 nodes and a fine grid containing 41778 nodes. Sample images of the fine grid are provided in Fig. 3. The  $\mu_c = 0.208$  case was run using each mesh and the results were compared. The cold exit temperature differed by 0.22% and the hot exit temperature differed by 0.017%, indicating our results are grid-independent. The fine grid has been used for the remainder of the simulations reported on in this work.

In each simulation convergence was achieved when the rms residuals for the mass, momentum, and turbulent equations were fell below  $10^{-6}$ , while the energy equation rms residuals fell below  $10^{-5}$ .

ANSYS-CFX<sup>©</sup> 16 [19] has been used to setup and solve each of the simulations. The standard  $k - \varepsilon$  turbulence model has been used.

#### IV. RESULTS AND DISCUSSION

The measured temperature separation values at the cold and hot exits are defined by

$$T_{s,c} = T_{in} - T_{cold} \quad (7)$$

$$T_{s,h} = T_{hot} - T_{in} \quad (8)$$

where the total temperatures have been used. The cold and hot temperature separation values have been plotted in Figs. 4 and 5 alongside data obtained from experimental and computational results. The cold exit temperature separation appears to peak at a cold mass fraction of  $\mu_c \approx 0.35$ , while the hot exit temperature separation steadily increases with cold mass fraction. The 3D, unsteady Large Eddy Simulations conducted by Farouk and Farouk [20] predict the cold stream temperature separation more accurately than the present model.

Despite our less accurate predictions, the present model still closely captures the trend of the experimental data at both the hot and cold exits. A possible explanation for the discrepancy between the present model and Farouk and Farouk's is that the mechanism present in the axisymmetric models is augmented or supplemented by unsteady circumferential variations. In either case, the results of the axisymmetric model can be further analyzed to gain more insight into at least one temperature separation mechanism.

Fig. 6 shows a typical streamline plot of the axisymmetric VT, where several interesting features are present. First, the hot stream occupies only a narrow band around the tube

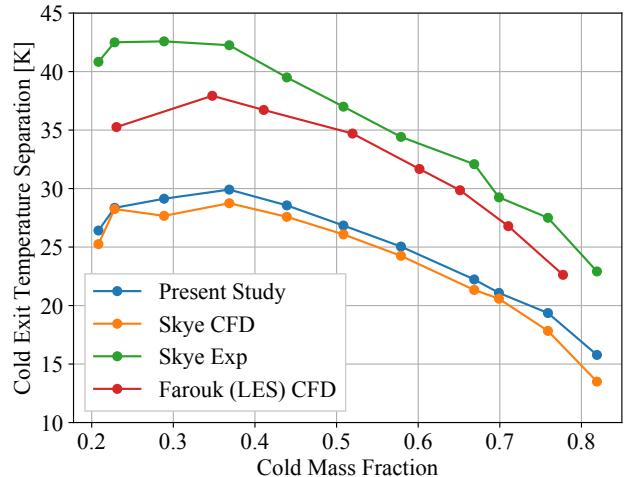

Fig. 4. Cold exit temperature separation.

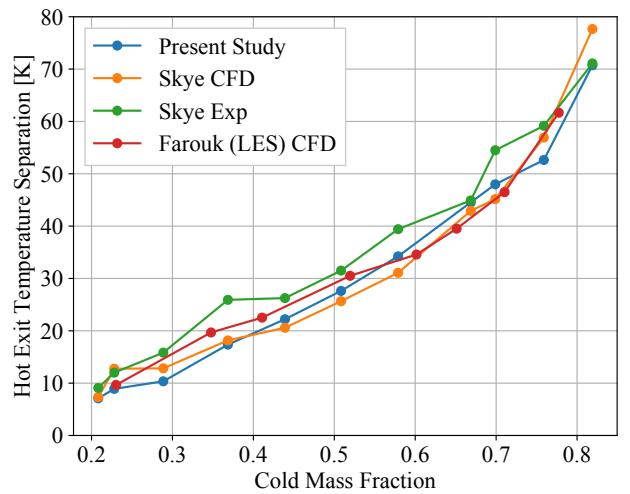

Fig. 5. Hot exit temperature separation.

wall, while the rest of the domain is occupied by the slender reverse flow region of the cold stream. Furthermore there is a recirculation region present in at the cold outlet, caused by the strong radial pressure variation. This recirculation region disappears for cold mass fractions greater than 0.4. Finally, a stagnation streamline connects the inlet to a zero velocity region near the hot outlet. When the stagnation streamline is revolved about the tube axis, it represents a stream surface separating the hot stream from the cold stream.

#### V. ENERGY TRANSFER MODES

With the converged solution fields at hand, the energy transfer modes across the stagnation streamline may be computed. We follow the same procedure as Aljuwayhel et al. [14], by computing the various energy transfers across the stagnation streamline. The differential energy transfers associated with conduction heat transfer, circumferential shear work, and axial shear work are given by

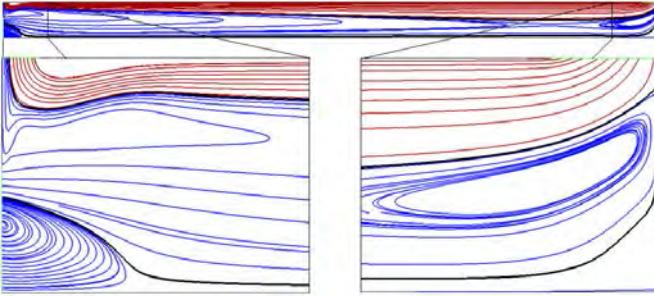

Fig. 6. Streamline plot of axisymmetric CFD results, with a cold mass fraction of 0.208. Red streamlines proceed from the inlet to the hot exit, blue streamlines terminate at the cold exit, and two stagnation streamlines are represented by thick black lines. The stagnation streamline of interest divides the hot and cold streams.

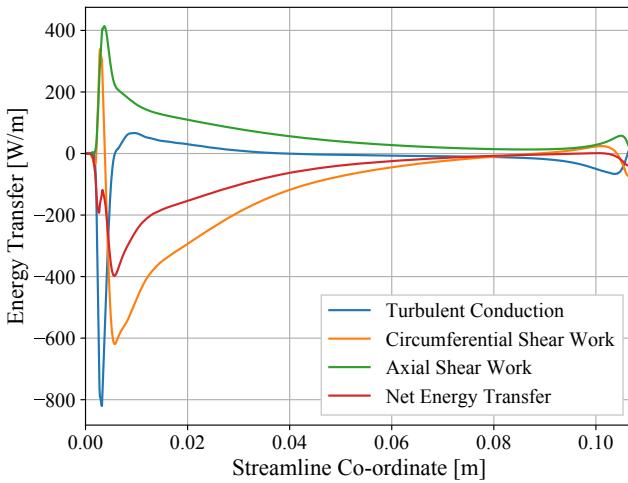

Fig. 7. Energy transfer across the stagnation streamline for the case  $\mu_c = 0.208$

$$\frac{\partial \dot{Q}}{\partial s} = -2\pi k_{\text{eff}} r \frac{\partial T}{\partial n} \quad (9)$$

$$\frac{\partial \dot{W}_\theta}{\partial s} = -2\pi \mu_{\text{eff}} v_\theta r \frac{\partial}{\partial n} \left( \frac{v_\theta}{r} \right) \quad (10)$$

$$\frac{\partial \dot{W}_z}{\partial s} = -2\pi \mu_{\text{eff}} v_z r \frac{\partial v_z}{\partial n} \quad (11)$$

where  $s$  is a streamline co-ordinate, and  $n$  is the normal vector pointing towards the hot stream. The contributions from each of these have plotted as a function of the streamline co-ordinate for two cold mass fractions Figs. 7 and 8. In the case of a low cold mass fraction, the majority of the energy transfer between the streams takes place near the inlet, diminishes as the streamsurface contracts towards the axis, and recovers near the hot exit. The circumferential shear work transfer is the dominant energy transfer mechanism. For a cold mass fraction of 0.819, the majority of the energy transfer takes place near the hot exit.

The total energy transferred via each mechanism can be found by integrating over the stream line, and the results

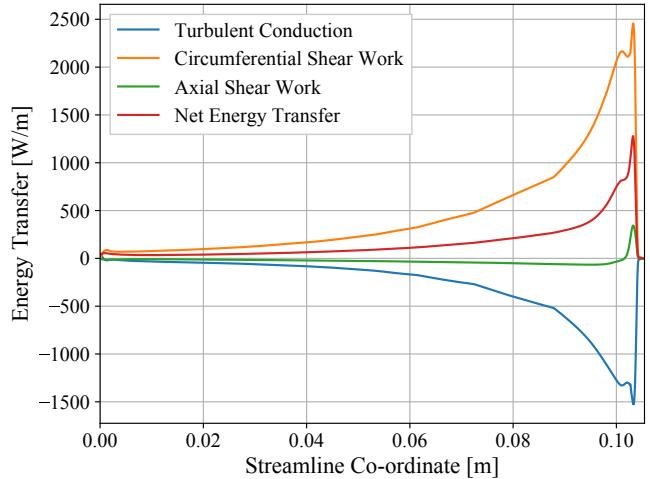

Fig. 8. Energy transfer across the stagnation streamline for the case  $\mu_c = 0.819$

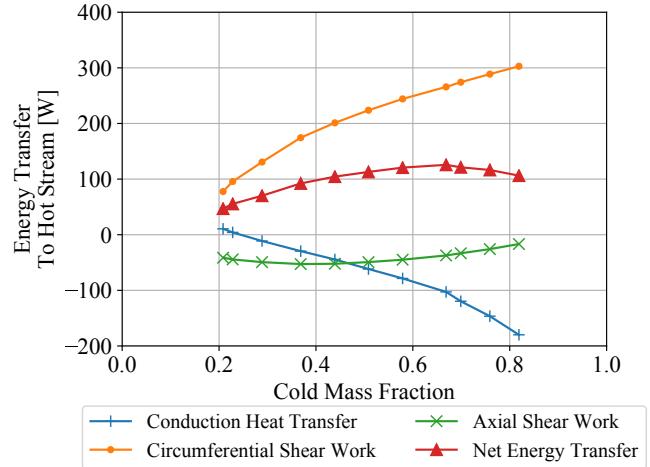

Fig. 9. Total Energy transfer across the stagnation streamlines.

have been plotted as a function of cold mass fraction in Fig. 9. As the cold mass fraction increases, the energy transferred through circumferential shear work and conduction heat transfer increase. Since the energy is transferred in opposite directions, the net effect is only a modest increase in energy transfer.

To validate our findings, we have compared the energy increase of the flow leaving the hot exit with the net energy transfer to the hot stream across the stagnation streamline. The hot stream energy increase has been computed using

$$\Delta E_{\text{hot}} = (1 - \mu_c) \dot{m} c_p T_{s,h} \quad (12)$$

The percent differences between the energy transfer across the stagnation streamline and equation 12 have been plotted in Fig. 10. Overall the discrepancies are modest. It is likely there is a small amount of energy transferred via radial shear at smaller mass fractions since the stagnation streamlines have

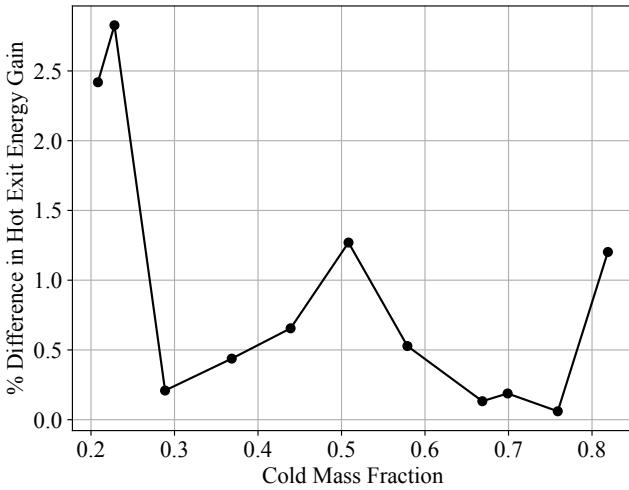

Fig. 10. Percent difference between energy increase computed based on the difference between the inlet and hot exit and the total energy transferred across the stagnation streamline.

the most significant radial variation, which could account for the greater discrepancies at low mass fractions.

## VI. CONCLUSION

In this work we have re-analyzed the vortex tube studied by Skye et al. [4] using an axisymmetric CFD model. It was observed that the trends in temperature separation matched those seen in experiments, though they are less accurate than 3D unsteady CFD models. We have also computed the transfers of kinetic and thermal energies across the stagnation streamline, demonstrating that circumferential shear work transfer is the dominant energy transfer mechanism.

Although the hypothesis has been supported, result is unsatisfying as the study fails to answer the deeper questions about the mechanism behind temperature separation; a complete picture of the energy movement in the system is still elusive, and there aren't any clear indications of which parameters are most important in vortex tube design. Furthermore, recirculation regions near the boundaries are present and cast doubt on the correctness of the velocity field. Future work will focus on better matching the boundary conditions between experiments and computational results.

**Abstract** — Architected cellular materials, as a novel class of low density materials, gain their unprecedented multifunctional performance mainly from their underlying architecture. In this paper, we focus on thermal conductivity of cellular materials. Standard mechanics homogenization with periodic boundary conditions is used to determine the thermal conductivity of cells with supershape pores. The computational results confirm that a wide range of possible anisotropic behaviour for thermal conductivity is achievable for cellular materials. Effective thermal conductivity of shellular materials based on three triply periodic minimal surfaces are also compared with those of cells with supershape pores. It is found that unlike the shellular materials, which only cover a narrow portion of thermal conductivity vs. relative density chart, cellular materials with anisotropic effective thermal conductivity could be engineered by employing supershape pores in cells.

## I. INTRODUCTION

Limited material and energy resources, economical restrictions, and concerns over the prospect of global climate changes, promote the design and manufacturing of lightweight materials with tunable multifunctional properties. Architected cellular materials are one of the cutting-edge alternative lightweight and optimized materials which can simultaneously satisfy multiple functionalities, from structural stiffness to thermal insulation and heat exchanging [1].

Cellular materials are divided into two categories: foams, where a gaseous phase is randomly dispersed in a continuous solid medium, and periodic lattices, which consist of a periodic architected cell [2]. The concept of using cellular metals emerged in early 1970s, by inspiration from the excellent

properties of natural materials like bone, wood and cork. Hexagonal honeycomb structures in sandwich cores, used in aviation industry, can be named as one of the first applications of periodic cellular materials [3]. Driven by the high performance of these cellular materials and recent development of additive manufacturing, advanced polymeric and metallic cellular materials are being widely fabricated. A non-exhaustive list of applications of cellular materials found in the literature includes: lightweight structural elements in aircrafts and high-speed trains, energy-absorbing elements in automotive industry, thermal insulation, thermal energy storage devices, hydrogen storage tanks, and scaffold for tissue engineering [2-11].

To exploit multifunctional potentials of cellular materials, a mathematical predictive model, capable of accurately predicting their effective properties, is of crucial importance. Early efforts on this subject range from the simple volumetric averaging of properties of constituent cellular materials, so-called as '*rule of mixtures method*', to several empirical equations for predicting the multiphysical properties of cellular materials [2, 12]. Investigations have clearly shown that cell architecture, in addition to the properties of the constituents' materials, plays a significant role in the emergence of their outstanding properties [13, 14]. In this regards, as thermal conductivity, electrical conductivity and magnetic permeability are all mathematically described by the Laplace equation, existing approaches used in the electric and magnetic fields have been also applied for thermal properties of cellular materials [15, 16]. The introduction of thermal-circuit method, based on the analogy between the electrical and thermal conductivities, could be considered as a turning point in theoretical modelling of thermal conductivity of cellular materials [16]. It is worth mentioning that most of the analytical models have been mainly developed for random pore distribution [17], or simple pore topologies, e.g. cubic, circular, cylindrical, and spherical [18, 19], leaving more complex periodic architectures with potential superior multifunctional properties unexplored. Although analytical upper and lower bounds, e.g. those bounds presented by Hashin

and Strikman [20] or thermal-circuit method, are valuable for estimating the effective thermal conductivity with a minimum knowledge about the actual heat flow and temperature profile in cellular materials, advanced computational models, e.g. Lattice-based Monte Carlo approach [21], micropolar modelling [22], and standard mechanics [23] and asymptotic homogenizations [24], have been developed to precisely take into account the effect of microarchitecture of cellular materials to accurately predict their effective thermal properties. The physical properties and application of cellular materials have been summarized in several textbooks, among which the book by Gibson and Ashby [2] provide the most comprehensive overview.

In this paper, we present two methodologies for predicting the effective thermal conductivity of architected cellular materials: (1) Theoretical modelling using the thermal-circuit method [25] and (2) Computational modeling based on standard mechanics homogenization. While the theoretical model is used to provide a narrow bound for thermal conductivity of cellular materials with simple 2D microarchitecture, standard mechanics homogenization is used to determine the exact thermal conductivity of cellular materials with complex 2D microarchitecture. To highlight the effect of cell topology on the thermal conductivity of periodic cellular materials, modified supershape formula [26] has been employed to create 2D pore shapes on square cells. Moreover, to address the ever growing interests on the lightweight 3D cellular materials, shellular materials based on three triply-periodic minimum surfaces have been analyzed and compared with the rest of selected cellular-based metamaterials.

## II. CAD DESIGN OF ARCHITECTED CELLULAR MATERIALS

To apply computational standard mechanics homogenization to explore the effect of topology and relative density on the effective thermal conductivity of cellular materials, 2D square unit cell with one supershape pore and 3D cubic shellular representative volume element (RVE) are selected.

### A. 2D RVEs

As a powerful formula for creating a variety of pore shapes, superformula (1) is selected and modified to generate void geometries while scaling and rotation ( $\beta$ ) parameters are considered to increase the possibilities of pore topologies.

$$\begin{bmatrix} x \\ y \end{bmatrix} = [| \cos(m\phi/4) | + | \sin(m\phi/4) |]^n \begin{bmatrix} \cos(\phi) \\ \sin(\phi) \end{bmatrix} \quad (1)$$

$(-\pi \leq \phi \leq \pi, m = 1 \sim 8, n = -5 \sim 5)$

Fig 1 shows sample 2D RVEs for different topological parameters. The pore shape corresponding to each set of geometrical parameters, introduced in (1), is directly modeled inside ANSYS APDL (Fig. 2) by creating several keypoints and using them to make spline curves. The area surrounded by the spline curves is formed, scaled, rotated and moved to the center of the RVE to be subtracted from the RVE and to finalize the 2D RVE.

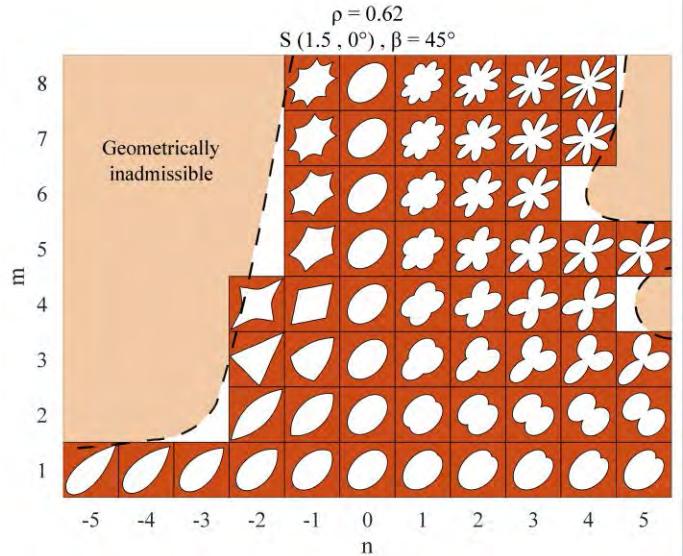

Figure 1. Sample 2D RVEs for different parameters:  $p=0.62$ , scaled by 1.5 in horizontal direction, and rotated by  $45^\circ$

### B. 3D shellular RVEs

A Triply Periodic Minimal Surface (TPMS) is a non-self-intersecting surface in  $R^3$ , which has a crystalline structure repeated in three independent directions and has zero mean curvature at each point [27]. The presence of TPMS in natural structures, like biological membranes [28] and crystals [27], has inspired researchers to consider TPMS architectures in tissue engineering, and biomimetic material design [29-32]. It is worth mentioning that “Shellular” term has recently been used in the literature to represent thin TPMS cellular shells. Among many known TPMSs, Schwarz’s Primitive (P) and Diamond (D) and Schoen’s Gyroid (G) are selected. These surfaces can be trigonometrically approximated using the following level surface equations [33]:

$$\begin{aligned} G: \cos x \cdot \sin y + \cos y \cdot \sin z + \cos z \cdot \sin x &= f \quad (f=0) \\ P: \cos x + \cos y + \cos z &= f \quad (f=0, 0.4, 0.8) \quad (2) \\ D: \sin x \cdot \sin y \cdot \sin z + \sin x \cdot \cos y \cdot \cos z + \\ &\cos x \cdot \sin y \cdot \cos z + \cos x \cdot \cos y \cdot \sin z = f \quad (f=0) \end{aligned}$$

We develop a MATLAB code to solve the level surface equations to determine the coordinates of several points on the surface. These points together with multiple cross section curves satisfying the surface equations are firstly created inside Solidworks using a Visual Basic code and then are used to create a smooth surface. This part of the surface is then patterned to create the mid-surface of the shellular RVE and subsequently thickened in order to add the desired thickness (as illustrated in Fig. 3). To focus more on the lightweight structures, five thicknesses ( $t_{rel}$ ) between 2 to 10 percent of RVE’s length are considered. Fig. 4 demonstrates some of the selected shellular architectures.

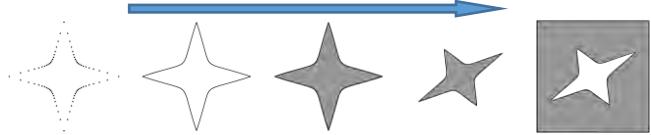

Figure 2. Different steps in modeling of 2D RVEs

### III. PREDICTIVE METHODS

Fourier's law assumes the following linear relation between heat flux ( $\vec{q}$ ) and temperature gradient ( $\vec{\nabla}T$ ) through a symmetric thermal conductivity tensor ( $K_{eff}$ ):

$$\vec{q} = -K_{eff} \vec{\nabla}T \quad (3)$$

For a thermally isotropic homogenous solid material,  $K_{eff}$  tensor reduces to  $KI$ , where  $I$  is the identity tensor and  $K$  is called isotropic thermal conductivity. However, in the case of a cellular material, overall thermal conductivity is generally anisotropic and depends on microarchitectural parameters of the cells [1].

Since the simplistic volumetric averaging approach is indifferent to cell architecture, it is unable to capture the anisotropic thermal properties of cellular materials and its prediction can significantly overestimate the effective thermal conductivity. To address these shortcomings, several analytical and computational methods have been developed, among which thermal-circuit method (or Resistor approach) has been widely used for the theoretical upper and lower bounds of thermal conductivity for a given cell geometry [4]. More advanced methods, e.g. computational homogenization, are required to exactly model the microarchitecture of cellular materials.

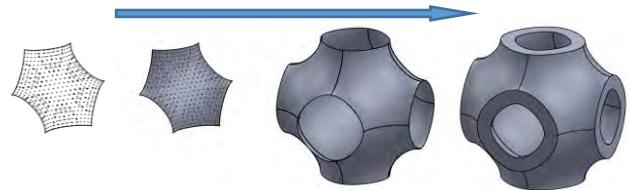

Figure 3. Steps for 3D modeling of a 3D shellular RVE

It is worth mentioning that the contribution of heat transfer mechanisms other than conduction, i.e. radiation and convection, is assumed to be small and consequently disregarded. For a cellular material made by a highly conductive matrix and an empty void or a gaseous inclusion, this assumption is valid for small pore sizes working at temperature ranges close to the ambient [34-37].

#### A. Analytical model

Using the analogy between thermal and electric fields, the thermal circuit method with parallel and series configurations is used to derive closed-form expressions for the upper and lower bounds of thermal conductivity of cellular materials with rectangular or elliptic inclusion/pore. In this approach, thermal gradient is analogous to electric voltage, the heat flow represents electric current and thermal resistance, being equal to the reciprocal of thermal conductivity for a unit cell, corresponds to electric resistance [25]. To establish this model, as presented in Fig. 5, the unit cell is divided into rectangular elements acting as thermal resistors, while the heat flux is considered to be along "y" direction and perfect thermal contact is assumed between the matrix (solid cell walls) and the filler material (such as air for cellular materials).

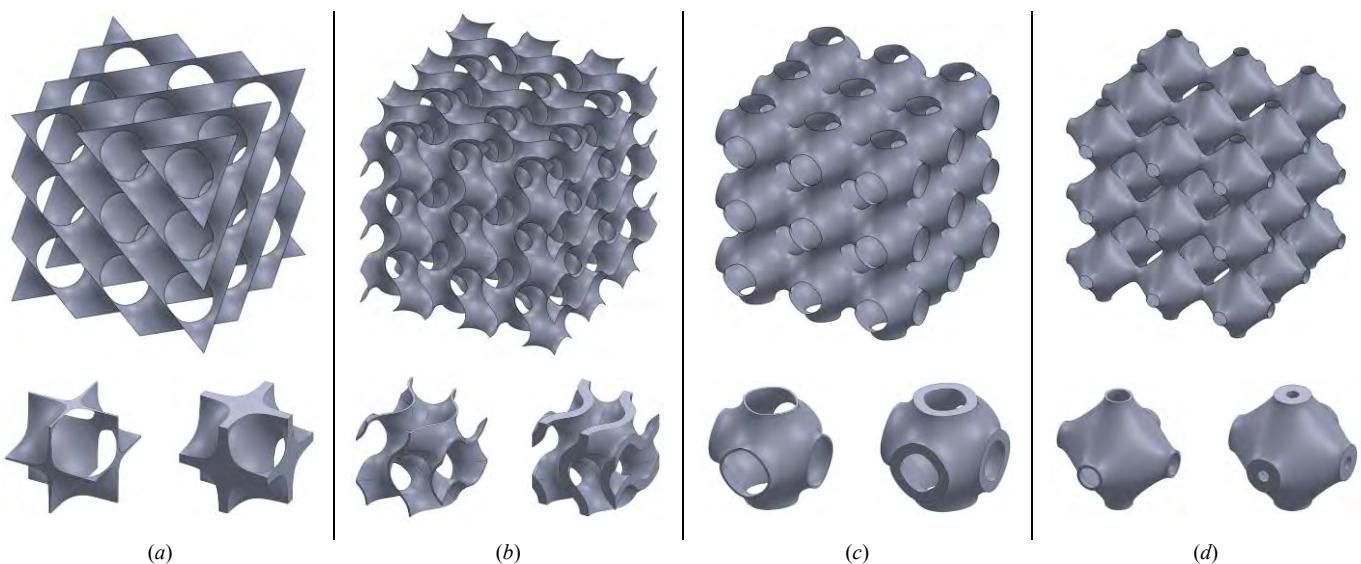

Figure 4. 3x3x3 TPMS cells together with two shellular RVEs at 0.02 and 0.10 relative thicknesses: (a) Schwarz D, (b) Gyroid, (c) Schwarz P with  $f = 0$ , and (d) Schwarz P with  $f = 0.8$

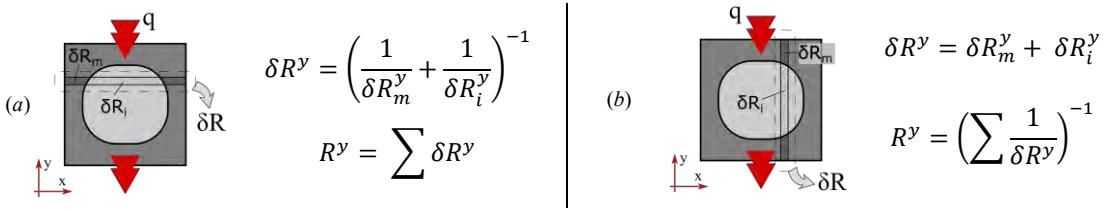

Figure 5. Schematic view of the thermal resistive elements for: (a) Horizontal iso-thermal lines and (b) Vertical adiabatic lines

Closed-form thermal conductivity formulations are presented in Table I, where  $k_m$  and  $k_i$  are the thermal conductivity of the matrix and inclusion respectively,  $\lambda_a = a/l$ ,  $\lambda_b = b/l$ ,  $\lambda_k = k_i/k_m (< 1)$ ,  $\theta = \text{atan}(\sqrt{((1 - \lambda_k)\lambda_a)^{-2} - 1})$  and  $A = \lambda_b(1/\lambda_k - 1)$ . It can be found that ‘Vertical adiabatic lines’ expressions for both rectangular and elliptic geometries reduce to  $k_{eff}^{yy}/k_m = 1 - \lambda_a$  when  $k_i = 0$ , which corresponds to cellular materials with empty pores. The relative density of the matrix can be calculated as  $(\rho_m)_{rel} = (l^2 - ab)/l^2 = 1 - \lambda_a\lambda_b$  and  $(\rho_m)_{rel} = (l^2 - \pi ab/4)/l^2 = 1 - \pi\lambda_a\lambda_b/4$ , for cells with rectangular and elliptic inclusion/pore, respectively. As the symmetry in the selected architectures of matrix and inclusion/pore dictates, the off-diagonal terms of the thermal conductivity tensor are zero ( $K_{eff}^{xy} = 0$ ) and thermal conductivity in “x” and “y” are equal.

### B. Computational standard mechanics homogenization

Under the assumption that an RVE of a periodic cellular material is repeated in all three directions and the RVE is far from the boundaries, the following periodic boundary conditions (4) together with independent unit thermal gradients (5) on the cell boundaries are adopted [23]:

Periodicity in x-direction:

$$T(x_0, y, z) - T(x_0 + l_x, y, z) = l_x \left( \frac{\partial T}{\partial x} \right)_i \quad (4.a)$$

Periodicity in y-direction:

$$T(x, y_0, z) - T(x, y_0 + l_y, z) = l_y \left( \frac{\partial T}{\partial y} \right)_i \quad (4.b)$$

Periodicity in z-direction:

$$T(x, y, z_0) - T(x, y, z_0 + l_z) = l_z \left( \frac{\partial T}{\partial z} \right)_i \quad (4.c)$$

Independent unit thermal gradients:

$$(\bar{\nabla T})_i = \left( \frac{\partial \bar{T}}{\partial x}, \frac{\partial \bar{T}}{\partial y}, \frac{\partial \bar{T}}{\partial z} \right)_i = \begin{cases} (1,0,0), & i = 1 \\ (0,1,0), & i = 2 \\ (0,0,1), & i = 3 \end{cases} \quad (5)$$

where  $i$  is the thermal loading case number and  $x_0, y_0$  and  $z_0$  are the locations of the three faces of the cubic RVE, while  $l_x, l_y$  and  $l_z$  represent RVE’s dimensions along “x”, “y” and “z” axis, and  $\bar{\nabla T}$  is the average macroscopic thermal gradient applied to the RVE’s boundaries in order to calculate microscopic thermal gradients inside the cell. Since the RVE is

TABLE I. CLOSED-FORM EXPRESSIONS FOR  $k_{eff}^{yy}/k_m$  OF CELLS MADE BY THERMALLY ISOTROPIC AND HOMOGENEOUS MATRIX AND FILLER MATERIALS, HAVING RECTANGULAR AND ELLIPTIC INCLUSION/PORE SHAPES, UNDER THE ASSUMPTIONS OF ‘HORIZONTAL ISO-THERMAL LINES’ OR ‘VERTICAL ADIABATIC LINES’

	$k_{eff}^{yy}/k_m$	
	Horizontal iso-thermal lines	Vertical adiabatic lines
	$\frac{1 + \lambda_a(\lambda_k - 1)}{1 + \lambda_a(\lambda_k - 1)(1 - \lambda_b)}$	$1 - \frac{\lambda_a\lambda_b(1 - \lambda_k)}{\lambda_k + \lambda_b(1 - \lambda_k)}$
	$\frac{1}{1 - \lambda_b + \frac{\lambda_b}{\lambda_a(1 - \lambda_k)} \left( \frac{\pi - \theta}{\sqrt{1 - ((1 - \lambda_k)\lambda_a)^2}} - \frac{\pi}{2} \right)}$	$\begin{cases} 1 - \lambda_a + \frac{\lambda_a}{A} \left( \frac{\pi}{2} - \frac{\ln(A + \sqrt{A^2 - 1})}{\sqrt{A^2 - 1}} \right), & A > 1 \\ 1 + \lambda_a \left( \frac{\pi}{2} - 2 \right), & A = 1 \\ 1 - \lambda_a + \frac{\lambda_a}{A} \left( \frac{\pi}{2} - \frac{\arctan \left( \frac{\sqrt{1 - A^2}}{A} \right)}{\sqrt{1 - A^2}} \right), & A < 1 \end{cases}$

a unit square in two-dimensional (2D) analysis and a unit cube in three-dimensional (3D) analysis of this research, Eqs. (4) and (5) can be further simplified to:

$$\begin{pmatrix} T(x_0, y, z) - T(x_0 + 1, y, z) \\ T(x, y_0, z) - T(x, y_0 + 1, z) \\ T(x, y, z_0) - T(x, y, z_0 + 1) \end{pmatrix}_i = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}_{i=1}, \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}_{i=2}, \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}_{i=3} \quad (6)$$

In 2D analysis, “z” dimension diminishes leading to two independent thermal loading cases. Energy balance equation, i.e. energy equation combined with Fourier heat conduction over the RVE, is solved using finite element method (FEM). The effective thermal conductivity of the cell can then be calculated by the volumetric averaging of the resultant heat flux based on standard mechanics homogenization:

$$\bar{K}_{ij} = \frac{1}{V_{RVE}} \int K_{ik} M_{kj}^T dV_{RVE} \quad (i, j, k = 1, 2, 3) \quad (7)$$

where  $\bar{K}_{ij}$  is the effective thermal conductivity tensor,  $V_{RVE}$  represents the volume of the RVE,  $K_{ik}$  is the local thermal conductivity tensor, and the matrix of  $M^T$  relates the average and the local temperature gradients by  $\nabla T = M^T \nabla \bar{T}$ .

#### IV. RESULTS AND DISCUSSION

To show the effect of filler material on the overall thermal conductivity and to examine the validity of neglecting the thermal conductivity of the gas inside the cellular materials, the homogenized thermal conductivity of a square cell with an empty square pore is benchmarked against the effective thermal conductivity of the same cell infilled with air at room temperature. As shown in Fig. 6, even for relative densities as low as 10%, air’s thermal conductivity can be neglected without affecting the effective thermal conductivity when the thermal conductivity of the matrix material is several orders of magnitude higher than the air, such as in metallic cellular materials.

Under the validated assumption of neglecting the air, derived closed form expression for the cells with rectangular and elliptical pore topologies are compared with the results obtained by standard mechanics homogenization. As illustrated in Fig. 7, for all aspect ratios of pores (1, 2 and 3 in the horizontal direction), distances between higher and lower bounds of the effective thermal conductivity of the cells with elliptical pores are larger than those for the cells with rectangular pores. Moreover, by increasing the relative density, the gap between the theoretical bounds increases. In this case, although the pore geometry is accounted for deriving the theoretical upper and lower bounds, the simplifying assumptions made in deriving the closed form formula based on the thermal-circuit method make it impossible to accurately predict the effective thermal conductivity.

Close to the smallest possible relative density for each aspect ratio of pore, the effective thermal conductivity of cells with elliptical pores reveals sharper drops in comparison with cells with rectangular pores. This is partly because of the higher rate of decreasing of the minimum wall thickness with respect to decreasing in the relative density for the former topologies.

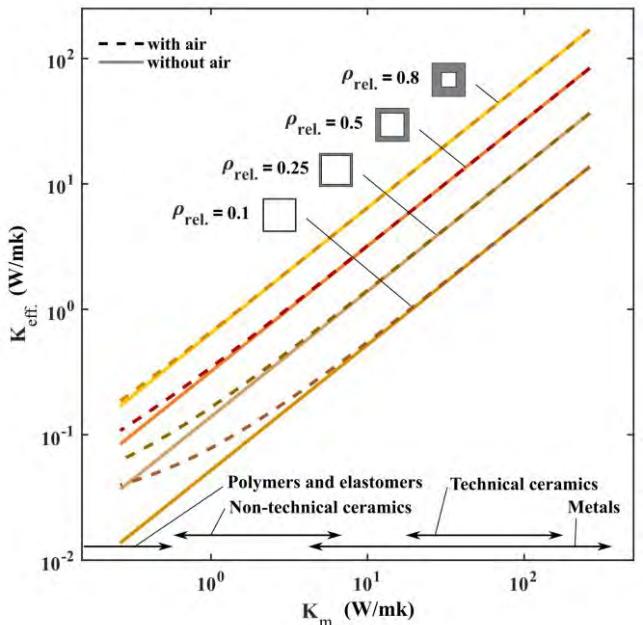

Figure 6. Effective thermal conductivity of air-filled ( $k_{air} = 0.0263$  W/m.K) and empty ( $k_i = 0$ ) cellular materials for a square pore shape versus thermal conductivity of the solid matrix (plotted in a log-log scale)

The standard mechanics homogenization is applied to cells with supershape pore topologies, while different aspect ratios (1 to 3, with 0.5 increments) and rotations (generally from 0 to 90°) of the pore has been taken into account. The predicted in-plane effective thermal conductivities are generally anisotropic, therefore instead of  $K_{xx}$ ,  $K_{yy}$  and  $K_{xy}$ , the effective principal thermal conductivities are presented in Fig. 8. Sample relative densities are highlighted with different colors to show the achievable range of  $K_1$  and  $K_2$  by the chosen pore topologies. The large area of  $K_1$  versus  $K_2$  for each relative density allows the engineering of architected cellular materials, while keeping the weight constant.

Unlike most of the considered 2D pore geometries, the computational analysis shows that P, D and G types of shellular materials are thermally isotropic and thus only one value is reported in Fig. 9 as the thermal conductivity for each microarchitecture. The G, D and P shellular materials (when  $f = 0$ ) are found to have almost equal thermal conductivity at each relative density, which is in agreement with the findings in [38]; however, by increasing the value of  $f$  for the P shellular materials, the effective thermal conductivity decreases.

#### V. CONCLUDING REMARKS

Theoretical and computational methodologies have been introduced in this paper for obtaining the effective thermal conductivity of architected cellular materials. We first examine the validity of neglecting the thermal conductivity of the air inside the pores of cellular materials when we determine the effective thermal conductivity of cellular materials. We then derive closed-form expressions for the upper and lower bounds of the in-plane effective thermal conductivity of cellular materials with rectangular and elliptic pores. The computational predictions of standard mechanics homogenization are also used

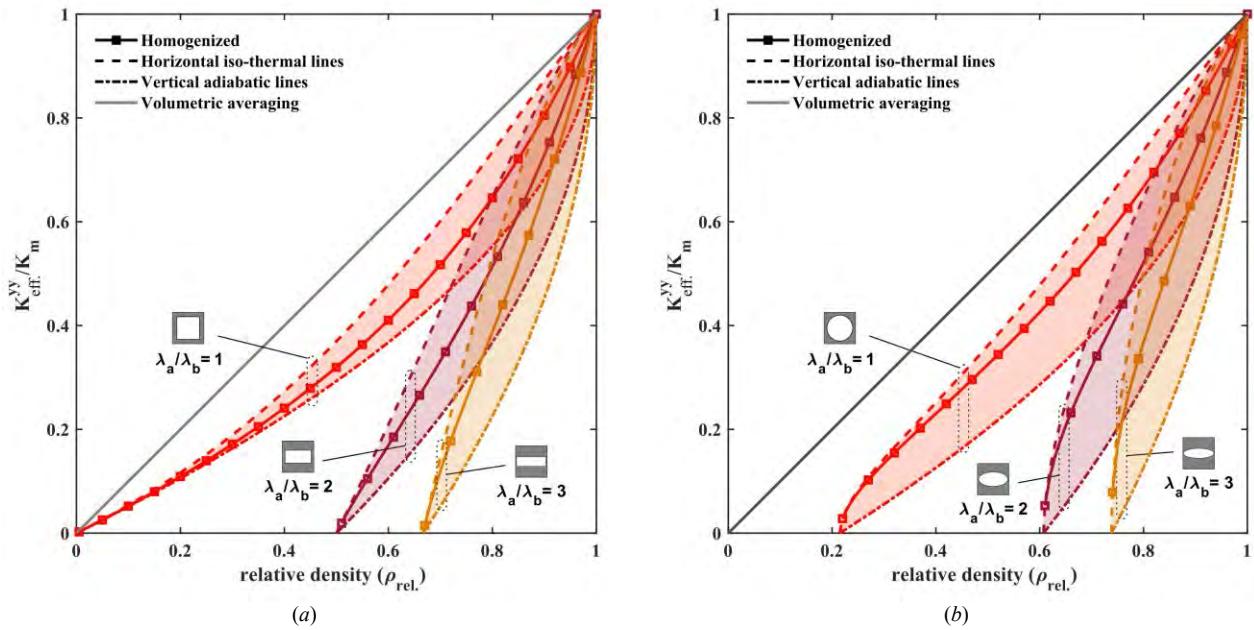

Figure 7. Theoretical upper and lower bounds along with computational homogenized values of effective thermal conductivity in "y" direction, normalized by the thermal conductivity of the solid matrix: (a) Rectangular pore and (b) elliptic pore

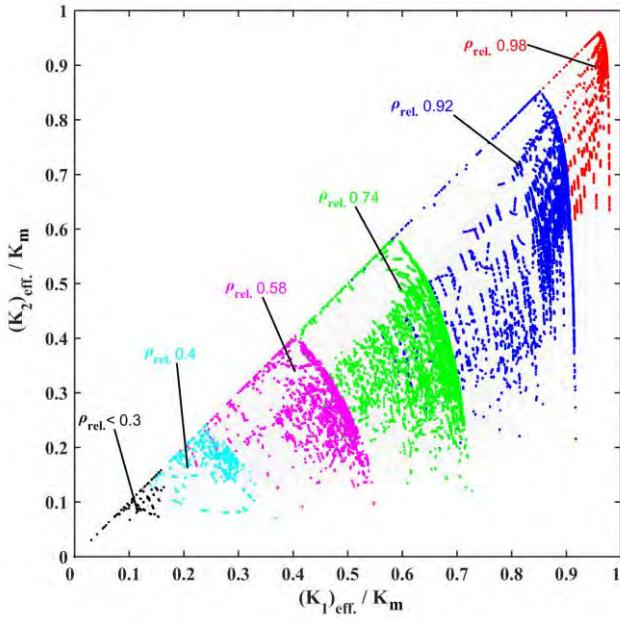

Figure 8. Normalized effective principal thermal conductivities, obtained using standard mechanics homogenization (for 2D supershape voids)

as benchmark for analyzing the effect of cell microarchitecture on effective thermal conductivity. The predictions show that increasing aspect ratio of the pores, widens the gap between the theoretical upper and lower bounds of thermal conductivity. Computational homogenized predictions are found to be close to the theoretical upper bound for small relative densities. The results present a wide range of achievable anisotropic effective thermal conductivity for different relative densities. Different TPMSs are also selected to create 3D shellular materials. For the considered range of relative density ( $\rho_{rel} < 25\%$ ), G, D and P

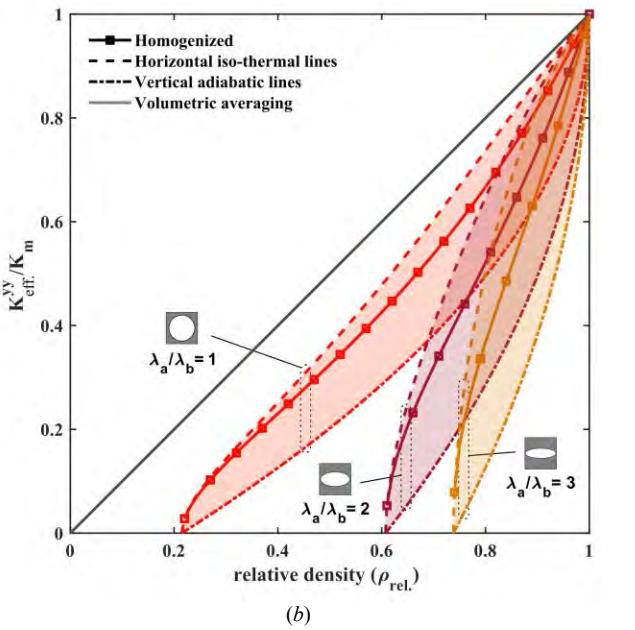

Figure 9. Effective thermal conductivity of shellular materials, normalized by thermal conductivity of the solid matrix

shellular materials with  $f = 0$ , are found to have equal homogenized thermal conductivity. The methodology presented in this paper sheds light on the thermal application of lightweight and mechanically robust advanced cellular materials manufacturable by additive manufacturing technology.

# Displacement Flows of Viscoplastic Fluids in Near-Horizontal Channels: Numerical and Analytical Simulations

Ali Eslami, Roozbeh Mollaabbasi, Seyed Mohammad Taghavi

Department of Chemical Engineering, Laval University, Quebec, QC, Canada

Seyed-Mohammad.Taghavi@gch.ulaval.ca

**Abstract-**The miscible displacement flow of a viscoplastic fluid by a Newtonian fluid is studied numerically and analytically in a near-horizontal 2D channel. We focus on a density-unstable flow configuration where the displacing fluid is heavier than the displaced one with a laminar imposed flow. Using numerical and analytical approaches, we demonstrate that the channel inclination has the significant impacts on the viscoplastic flow morphology and front height. In addition, we study the yield stress impacts on the viscoplastic flow features.

**Keywords**-Displacement flow; viscoplastic fluid; inclination impacts, numerical and analytical approaches

## I. Introduction

Many industrial processes require the cleaning and removal of a gelled-like material (i.e., typically viscoplastic) from a duct. For example, it can be mentioned oil & gas well cementing, waxy crude oil pipeline restarts, gas-assisted injection molding, biomedical applications (mucus, biofilms), cleaning of equipment and environmental surfaces, and food processing [2]. An import issue in these processes is the existence of the residual deposits. The aforementioned processes may have different fluid properties (e.g., different densities/viscosities and miscible/immiscible liquids) and flow geometries (e.g., pipe, annulus, channel). In this study, we numerically and analytically consider buoyant miscible, iso-viscous displacement flows of a viscoplastic fluid (displaced fluid) by a Newtonian one (displacing fluid) in a plane channel where the imposed flow is laminar.

Previously, we have investigated the impacts of three

dimensionless numbers (i.e., the Bingham number, the densimetric Froude number and the Reynolds number) on the displacement of a viscoplastic fluid by a Newtonian fluid of higher density numerically [1] and analytically [4]; which covered various buoyancy effects from very small to very large Froude numbers. For brevity, we refer to these papers for a more detailed introduction and review of previous works. The main finding in the previous works was that the yield stress can lead to appear various flow regimes and have a significant effect on the displacing fluid front profile and residual layer thickness. The novelty of the current work is in studying impacts of channel inclination on the viscoplastic displacement flows at very small Froude number, through numerical and analytical approaches, which have not been studied so far.

## II. Governing Equations

In this study the miscible displacement flow of a Bingham fluid (light fluid) by a Newtonian one (heavy fluid) along a channel is studied. These fluids have the same viscosity whereas their density are different. We choose Cartesian coordinates  $(\hat{x}, \hat{y})$  with  $\hat{x}$  representing the streamwise direction.<sup>1</sup> The flow geometry and notation used in the current study is represented in Fig. 1. The governing dimensionless equations of motion are:

$$[1 + \phi At] Re \left[ \frac{\partial}{\partial t} \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} \right] =$$
 (1)

<sup>1</sup>In this paper, we adopt the convention of denoting dimensional quantities with the  $\hat{\cdot}$  symbol and dimensionless quantities without.

$$-\nabla p + \nabla \cdot \tau + \frac{\phi Re}{Fr^2} \mathbf{e}_g,$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2)$$

$$C_t + \mathbf{u} \cdot \nabla C = \frac{1}{Pe} \nabla^2 C, \quad (3)$$

where  $p$ ,  $\mathbf{u}$  and  $\tau$  are the pressure, the velocity and the deviatoric stress. Here  $\mathbf{e}_g = (\cos \beta, -\sin \beta)$  and the function  $\phi(C) = 2C - 1$  interpolates linearly between  $-1$  and  $1$  for  $C \in [0, 1]$ . No slip conditions are satisfied at the walls, the heavy fluid enters fully developed (plane Poiseuille profile) at  $x = -L/4$  (inlet) and outflow conditions are applied at  $x = 3L/4$  (outlet).

Five dimensionless numbers appear in (1-3) including:

the Reynolds number  $Re = \frac{\hat{V}_0 \hat{D}}{\hat{\nu}}$  (here  $\hat{D}$  is the channel width), Péclet number  $Pe = \frac{\hat{V}_0 \hat{D}}{\hat{D}_m}$  (here  $\hat{D}_m$  is the molecular diffusivity), densimetric Froude number  $Fr = \frac{\hat{V}_0}{\sqrt{At \hat{g} \hat{D}}}$ , channel inclination  $\beta$ , Atwood number  $At = \frac{(\hat{\rho}_H - \hat{\rho}_L)}{(\hat{\rho}_H + \hat{\rho}_L)}$  which represents a dimensionless density difference, where  $\hat{\rho}_H$  and  $\hat{\rho}_L$  are the density of Newtonian fluid and Bingham fluid, respectively. Since  $\hat{\rho}_H > \hat{\rho}_L$  (i.e., the heavy fluid displaces the light fluid),  $At > 0$  in this paper. It should be mentioned that displacement flows with small density differences were considered, for which the Boussinesq approximation is implemented. The density differences can remarkably affect buoyancy effects, captured by the densimetric Froude number. Finally,  $Pe \gg 1$  which means that on the timescale of interest,  $\hat{D}_m$  does not play a major role in the flows studied.

The constitutive laws for Newtonian fluid (displacing fluid) is  $\tau(\mathbf{u}) = \dot{\gamma}(\mathbf{u})$  with  $\dot{\gamma} = \nabla \mathbf{u} + (\nabla \mathbf{u})^T$  and for the Bingham fluid (displaced fluid) which includes a yield stress is:

$$\tau_2(\mathbf{u}) = \left[ 1 + \frac{Bn}{\dot{\gamma}(\mathbf{u})} \right] \dot{\gamma}(\mathbf{u}) \Leftrightarrow \tau_2(\mathbf{u}) > Bn, \quad (4)$$

$$\dot{\gamma}(\mathbf{u}) = 0 \Leftrightarrow \tau_2(\mathbf{u}) \leq Bn, \quad (5)$$

where the second invariants ( $\dot{\gamma}(\mathbf{u})$ ) and  $\tau_2(\mathbf{u})$ , are defined by:

$$\begin{aligned} \dot{\gamma}(\mathbf{u}) &= \left[ \frac{1}{2} \sum_{i,j=1}^2 [\dot{\gamma}_{ij}(\mathbf{u})]^2 \right]^{1/2}, \\ \tau_2(\mathbf{u}) &= \left[ \frac{1}{2} \sum_{i,j=1}^2 [\tau_{2,ij}(\mathbf{u})]^2 \right]^{1/2}, \end{aligned} \quad (6)$$

where  $Bn$  is the Bingham number:  $Bn \equiv \frac{\hat{\tau}_Y}{\hat{\mu}_1 [\hat{V}_0 / \hat{D}_0]}$ .

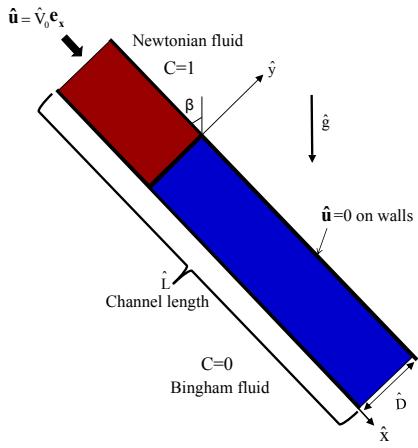

Figure 1: Schematic view of the numerical domain and initial flow configuration.

### III. Computational Method

The equations of motion was discretized using a mixed finite element-finite volume method, using the classical augmented Lagrangian method of [3] to resolve unyielded zones. More details of the numerical approach are described in [5]. The present numerical algorithm was implemented in C++ and solved using an open source platform, PELICANS. More details about employing this platform for numerical simulation of displacement flow are given in [6].

In the current simulation study, 63,000 mesh cells ( $1500 \times 42$ ) were used for all simulations while the meshes (regular rectangular) in the  $y$ -direction were refined slightly towards the channel walls. The initial interface between the two fluids was placed at distance  $L/4$  from the channel inlet in the computational domain which means that at  $t = 0$ , the two fluids are separated by an imaginary gate valve located at  $x = 0$ . It is worth noting that the dependency of results on the mesh size have been examined and also the results are validated which shows a great agreement with the previous model [1]. Note that the computational cost is high.

### IV. Analytical Method

In this part, a lubrication approximation model is developed to simplify the governing displacement flow equations and propose a semi-analytical solution for the heavy and light fluid flux functions to reduce the computational cost. Therefore, we scale our equations using a dimensionless length-scale,  $\delta^{-1} \gg 1$ , over which the interface elongates. We assume that  $\delta$  has a size of  $\hat{D}/\hat{L}$ , in which  $\hat{L}$  denotes the characteristic spreading length of the interface. Defining  $\delta x = X$ ,  $\delta t = T$ ,  $\delta p = P$ ,  $v = \delta V$  and following standard methods, we can now re-scale our equations to (assume that

$\delta \rightarrow 0$  with fixed  $Re$ ):

$$0 = -\frac{\partial P}{\partial X} + \frac{\partial}{\partial y}\tau_{k,xy} + \frac{\partial}{\partial z}\tau_{k,xz} \pm \frac{\chi}{2}, \quad (7)$$

$$0 = -\frac{\partial P}{\partial y} \mp \delta \frac{\chi}{2} \tan \beta, \quad (8)$$

$$0 = -\frac{\partial P}{\partial z}, \quad (9)$$

where  $\chi = \frac{2Re \cos \beta}{Fr^2}$ . The interface is advected via a kinematic condition furnishing the dependence of the velocity on space and time:

$$\frac{\partial h}{\partial T} + u \frac{\partial h}{\partial X} = V. \quad (10)$$

Combining the incompressibility condition with the kinematic condition results in

$$\frac{\partial h}{\partial T} + \frac{\partial q}{\partial X} = 0, \quad (11)$$

where  $q$  is defined as:

$$q = \int_0^h u dy. \quad (12)$$

## V. Results

In this section the computational results are presented. In a typical simulation, as time progresses, due to the imposed velocity, the heavy fluid layer penetrates into the light fluid layer and displaces it. Through the displacement flow process, different interesting flow patterns are formed at the interface between fluids.

Figure 2 shows the concentration maps of the numerical simulation as time evolves, run for  $Re = 400$  and  $Fr = 0.9$ . The yield stress in the horizontal channel ( $\beta = 90^\circ$ ) for the Fig. 2a and Fig. 2b is different such that the yield stress for Fig. 2a is zero ( $Bn = 0$ , Newtonian fluid) while for the Fig. 2b is considerable ( $Bn = 10$ , Bingham fluid). A nearly symmetric displacement flow is observed in Fig. 2a and the displacing finger is similar to a Poiseuille-like profile. At  $Bn = 10$ , the displacement flow remains symmetric and the front shape is similar to a plug-like profile (see Fig. 2b). The only difference between the Fig. 2b (horizontal channel) and Fig. 2c ( $\beta = 88^\circ$ ) is that the channel is more inclined with respect to vertical in the latter. Figure 2b shows a qualitatively stable flow while in the Fig. 2c the yield stress of the displaced fluid has not been able to damp interfacial instabilities due to channel inclination.

Figure 3 presents examples of our simulations, for  $\beta = 80^\circ$ ,  $Bn = 50$ ,  $Re = 400$  and  $Fr = 0.9$  at given time. Initially at  $x = 0$ , the Newtonian fluid and Bingham one are completely separated. However, as time progresses, impacts of the imposed flow and the density ratio, leads to penetration of the heavy fluid through the light fluid and

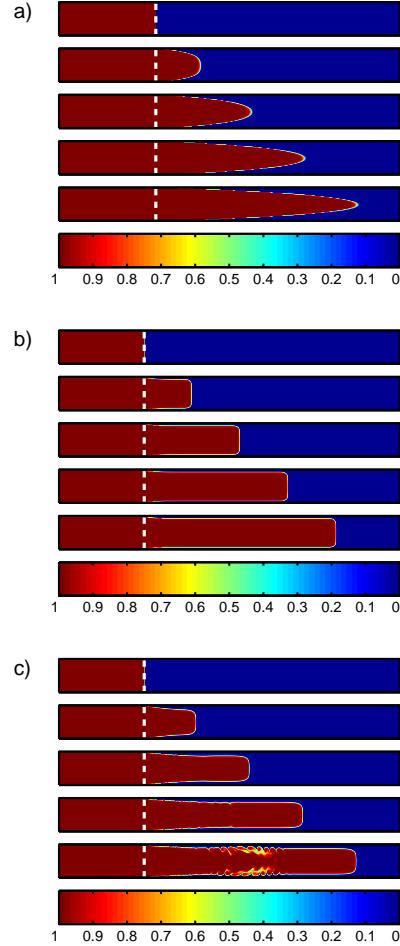

Figure 2: Concentration colormaps of the displacement flow at times  $t = [0, 8.75, \dots, 35]$  for  $Re = 400$  and  $Fr = 0.9$ ; a)  $Bn = 0$  and  $\beta = 90^\circ$ . b)  $Bn = 10$  and  $\beta = 90^\circ$ . c)  $Bn = 10$  and  $\beta = 88^\circ$ . The last image at the bottom of each subfigure is the colorbar of the concentration values. The white broken lines display the position of the initial interface  $x = 0$  (gate valve). The domain size shown is  $1 \times 100$ .

attempts to sweeps it. Figure. 3a depicts the concentration colormap of the displacement flow such that at longer spatial position with respect to the initial gate valve, the displaced layers adjacent to the walls become apparently static. Furthermore, it can be observed that the displacement flow is stable over a long time. The shear stress colormaps at the same time as the colormap of concentration is plotted in Fig. 3b, confirming that the stress field asymmetry results in asymmetric static layers on the top/bottom walls. Figure 3c displays the speed contours,  $V = \sqrt{V_x^2 + V_y^2}$ , at the same simulation parameters as in Fig. 3a, where  $V_x$  and  $V_y$  are the stream-wise and depthwise velocity components, respectively. A Poiseuille profile is observed before

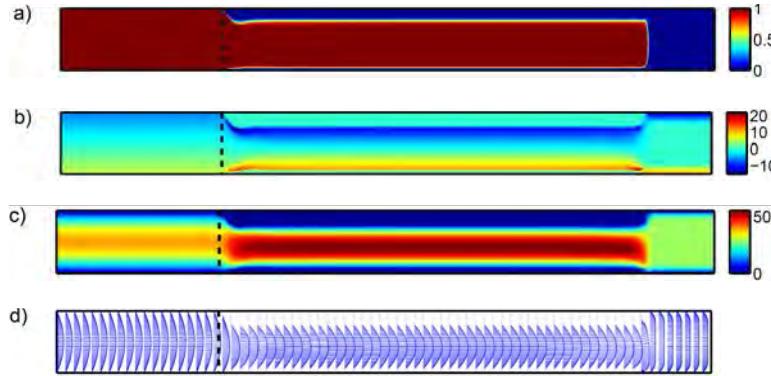

Figure 3: Computational results for  $Bn = 50$ ,  $Re = 400$  and  $Fr = 0.9$  and  $\beta = 80^\circ$  at time  $t = 34$ : a) Concentration colormap; b) Shear stress colormap; c) Speed contours:  $V = \sqrt{V_x^2 + V_y^2}$ . d) Velocity vectors. The black broken lines display the position of the initial interface  $x = 0$ .

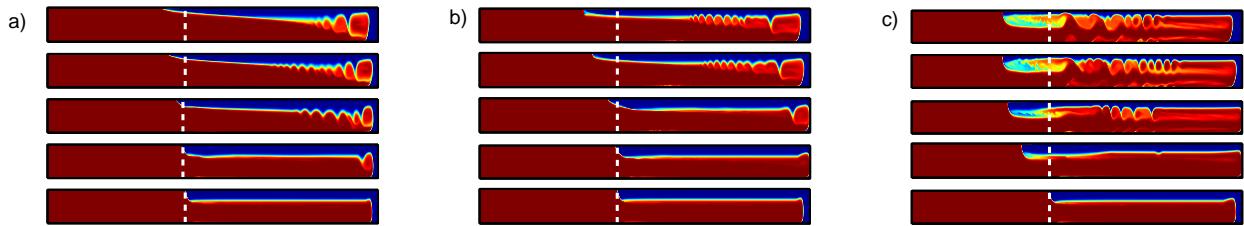

Figure 4: Panorama of concentration colormaps at  $t = 16$ ,  $Fr = 0.5$  and  $Re = 400$  for a)  $\beta = 90^\circ$ , b)  $\beta = 88^\circ$  and c)  $\beta = 82^\circ$ . The rows from top to bottom show  $Bn = 0$ ,  $Bn = 5$ ,  $Bn = 20$ ,  $Bn = 50$ ,  $Bn = 100$ . The domain size shown is  $1 \times 60$ .

the gate valve location such that the high-speed regions remain towards the channel center. However, the speed contours are zero within the displaced fluid layers adjacent the upper and lower walls after the gate valve, which means that the remaining displaced layers are completely static. Figure 3d shows the velocity vector fields along the channel length. This graph confirms that the flow is nearly stable and that the displaced fluid layer close to top wall is entirely static. It can be observed that the fluid within the displaced layer has a zero velocity.

The effects of yield stress value and channel inclination for  $Re = 400$  and  $Fr = 0.5$  are presented in Fig. 4. Figure 4a, b and c show panoramas of the concentration colormaps at  $t = 16$  for  $\beta = 90^\circ$ ,  $\beta = 88^\circ$  and  $\beta = 82^\circ$ , respectively. As seen, for a given channel inclination, by increasing the dimensionless yield stress, the flow morphology changes remarkably. For example, at  $\beta = 88^\circ$ , the interfacial instabilities decrease by increasing the Bingham number such that the yield stress can damp the interfacial waves. Moreover, the trailing front has an indirect relation with  $Bn$ . In other words, at small yield stress the trailing front moves upwards, while at larger Bingham number, the moving of the trailing front completely stops. It also can be seen, at fixed  $Bn$ , by increasing the channel inclination the

flow becomes more unstable and trailing front shows different behavior. Finally, it can be conclude that from Fig. 4 and Fig. 2, at large Froude number, the displacement flow is nearly symmetric which means that the displacing fluid moves more or less along the center of the channel. However, at small  $Fr$ , the displacement flow is asymmetric; displacing finger advances approximately near the lower wall of the channel.

The analytical results are presented in Fig. 5 and Fig. 6. Figure 5 shows the dependency of the displacing front height to yield stress. By increasing the yield stress of displacing fluid the front height decreases and the static layer increases.

Figure 6 shows the effect of increasing the buoyancy force ( $\chi$ ) in the heavy-light fluids displacement. Increasing the inclination of the channel reinforces the buoyancy force therefore, the buoyancy overcomes the yield stress and the back flow is observed in Fig. 6c. Our results show that the analytical approach is also generally able to predict the variation of flow morphology with yield stress and channel inclination in the viscoplastic fluid displacement with low computational cost.

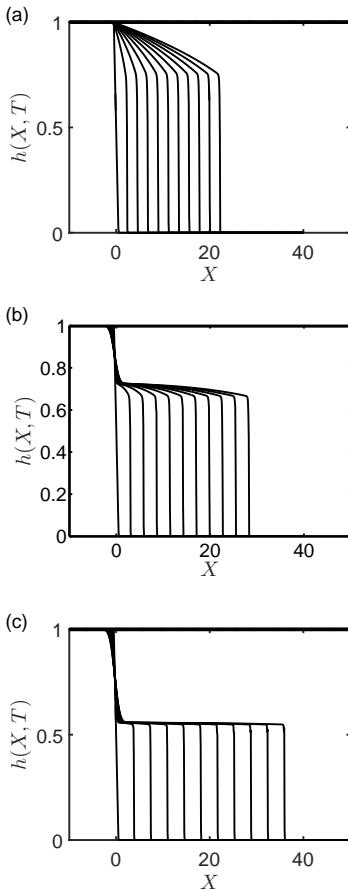

Figure 5: Interface evolution in time,  $T = 0, 2, \dots, 18, 20$ .  $\beta$ ,  $Fr$  and  $Re$  are  $90^\circ$ , 0.5 and 400 respectively in all figures.  $Bn$  number is 0, 5 and 50 from up to down. The displacing fluid is Newtonian.

## VI. Conclusion

In this study, we have numerically and analytically considered a fascinating displacement flow where the heavier displacing fluid (Newtonian fluid) pushes the lighter displaced fluid (viscoplastic fluid) along a 2D plane channel. During the miscible displacement flow, the results demonstrate that the variation of channel inclination and yield stress has the remarkable impacts on the flow morphology. Also the results show that the yield stress (at larger Bingham number) damps the interfacial instabilities. The viscoplastic displacement flows, at given  $Bn$ , for more channel inclination can be more unstable.

**Abstract**— Modal testing is being investigated as a means of non-destructive evaluation of wooden utility pole strength. In order to understand the effects of conductors on the dynamics of the poles, a numerically efficient model based on lumped segments for the conductor has been developed and experimentally validated. The cable is modeled as number of lumped segments jointed with axial and torsional springs and dampers representing the cable's compliance and damping. In order to validate the models, an experimental set up for vibration testing of the cable has been built. Time response measurement and modal testing are performed and the comparison of the experimental results with the numerical results show that the lumped segment model has the fidelity to capture the dynamics of the cables efficiently and accurately.

**Keywords;** *Cable dynamics; Lumped segment model; Modal testing; Bond graph model*

## I. INTRODUCTION

Wooden utility poles are extensively used in North America for electrical power transmission and distribution. These wooden poles are subject to deterioration due to aging, rot, woodpecker damage, and fungal attack. Developing a non-destructive pole evaluation method based on modal testing requires numerical modeling of the poles and attached cables (conductors). Because cables are attached to the utility poles, vibrations of the cables affect the measurement of the modal properties of the poles. Therefore, a numerically efficient model should be developed to capture the dynamics of the cables.

Barry *et. al.* [1] investigated the vibrations of a single transmission line conductor with attached Stockbridge damper. They modeled the system as a double-beam system and derived the equations of motion of the system using Hamilton's principle. They validated the analytical results with experimental results and investigated the effect of damper location and characteristics on the conductor natural frequencies. Ricciardi *et al.* [2] developed a continuous model for vibration analysis of cables with sag considering the bending stiffness. They derived the vibration equation of motion of a sagged cable as an Euler-Bernoulli beam and solved

the equation by an exact method. They performed a parametric study to investigate the effect of sag and bending stiffness on the cable natural frequencies and validated the results using finite element (FE) and finite difference methods. The exact method that they used could not be used when the cable is attached to a pole or moving support structure. Barbieri *et. al.* [3] used linear and nonlinear finite element models for analyzing the dynamic behavior of three different transmission line cables. They validated the numerical results by experimental tests and investigated the effect of inclusion of Stockbridge damper and linearity of the FE model on the natural frequencies. They concluded that linear finite element models provide good results for short cables only. Li *et. al* [4] and Wang *et. al* [5] presented a simplified computational model of a high-voltage transmission tower-line system under out-of-plane and in-plane vibrations due to seismic excitations. The transmission cables and their supporting towers were modeled as a lumped mass system. They did not consider the bending stiffness of conductors and their model was a simplified model for obtaining the response to seismic excitations. They obtained the mass and stiffness matrices of the coupled system and derived the linear equations of motion and validated the theoretical results with experiments. Papailiou [6] for the first time proposed a model for conductors that took into account the interlayer friction and the interlayer slip in the conductor during bending, obtaining a bending stiffness that changes with the bending displacement and the tension applied to the conductor. Spak *et. al.* [7] reviewed helical cable models with a focus on cable damping modeling. They described the work done in the literature on the inclusion of damping through frictional effects, variable bending stiffness, and internal friction. Spak *et. al.* [8, 9] developed the distributed transfer function method to model cables and simple cabled structures. They included shear effects, tension, and hysteretic damping for modeling of helical stranded cables and investigated the effect of cables on the dynamics of cabled structures using the developed model and by experimental tests. Pinto *et. al* [10] developed a bond graph model for a wooden pole with a cable attached to the free end. In their paper, the cable was modeled as a series of point masses connected by translational springs and the pole was represented

by a modal expansion based on separation of variables. They obtained the modal parameters of the cable and pole-cable systems numerically and experimentally. They concluded that their model should be expanded and improved from point masses to rigid bodies with rotational inertia, connected with bending stiffness and damping elements as well as axial ones.

The bond graph formalism, details of which can be found in [11] is chosen because of the ease with which it allows expansion of the model by adding segments in a modular way. Bond graphs, which use a small set of generalized elements to model multi-domain systems, facilitate connection of the cable model with other subsystem models such as poles, regardless of whether the poles are modeled using lumped segments or modal expansion.

This paper consists of two main sections. In Section II, a bond graph lumped segment model of the cable is presented. In this model, the cable is modeled as number of segments that are attached to each other by springs and dampers representing the axial and bending compliances and damping of the cable, respectively. Section III describes the experimental set up and procedure that is used for performing time series measurement and modal testing of the stranded cable. The modeling assumptions and the results are explained in Section IV.

## II. LUMPED SEGMENT MODEL

### A. Theoretical Development

In this paper, the cable is modeled as a pinned-pinned beam divided into number of segments. A numerical solution is obtained by a lumped segment approximation that captures axial and bending motions. To the purpose of modeling, two types of coordinate systems are used in the model. The first coordinate system is the inertial coordinate system. A body-fixed coordinate system is attached to each segment, the origin of which is located at the center of gravity and the local  $x$  axis of which is in the axial direction. The advantages of using body coordinate system are that axial springs between the segments can be modeled simply along the local coordinates, and that orientation angles and inertia properties are more easily handled if the model is expanded to three dimensions. Figure 1 shows representative segments of the cable, and local and global coordinate systems.

The cable is represented by a series of rigid cylinders of equal length and cross section; each rigid body has the same properties as the corresponding portion of the cable. As the number of segments approaches infinity, the behavior of the lumped segment model will converge to that of the continuous cable. The length of each segment is defined by the number of rigid bodies,  $n$ . For each segment, three points are defined:  $B$  in the left end of the segment,  $A$  in the right end and  $G$  in the center of mass. Point  $A$  of element  $i$  and point  $B$  of element  $i+1$  are linked by one torsional and two linear springs. The torsional spring represents the bending compliance or flexural rigidity of the beam in the  $x-y$  plane, and the linear springs in  $x$  and  $y$  local directions represent the axial and shear compliance respectively. Each spring is complemented with a damper acting in parallel to it that acts as the cable material damping. Figure 1 shows the connection of each segment to the next and previous segments

using torsional and linear springs, also illustrates the body-fixed coordinate system. For simplicity purposes, the dampers are not shown in the figure.

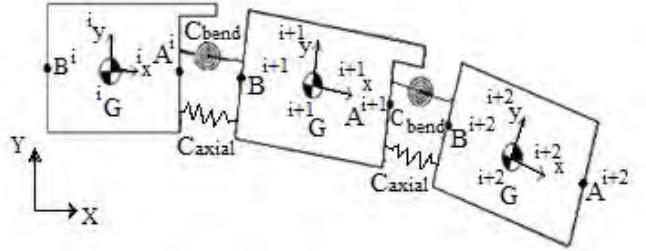

Figure 1. Multibody dynamic model

### Cable Compliance:

Equations (1)-(2) present the axial and bending compliance of the cable, respectively [12].

$$C_{\text{axial}} = \frac{EA}{l} \quad (1)$$

$$C_{\text{bend}} = \frac{EI}{l} \quad (2)$$

where:

$E$  = Young's modulus of beam

$A$  = Cross sectional area of the cable

$l$  = Length of the cable segment

$I$  = Area moment of inertia of the cross section

### Cable Inertia:

The translational inertia of the lumped segments is equal to their mass. The rotational inertia of a cylinder about the axis perpendicular to the body-fixed coordinate plane, through the center of mass  $G$ , is as follows.

$$J_G = \frac{1}{12} m \left( \frac{3}{4} d^2 + l^2 \right) \quad (3)$$

Where  $m$  is mass of a segment,  $d$  is diameter of cable cross section, and  $l$  is segment length.

### Cable Damping:

Damping in the cable is due to the material damping associated with the hysteresis energy losses in the material and interlayer wire slip. Because the stranded cable consists of number of layers, the layers can slip on each other during vibration and this interlayer friction increases the damping in the stranded cables. In this paper, axial and bending dampers are placed in parallel with the springs in the model. The damper values are tuned to give decay of the response and natural frequencies close to experimental results. Further work should be done in the future to model the damping in the numerical model more accurately.

## B. Kinematics of Rigid Bodies

In the bond graph model, we need to develop the velocity relations between points  $G$  and  $A$  and  $B$  in Figure 1. Eq's (4)-(5) represent the velocity of end points  $A$  and  $B$  in the local coordinate of the segment, respectively.

$${}^i\vec{V}_A = {}^i\begin{bmatrix} V_{Ax} \\ V_{Ay} \end{bmatrix} = {}^i\vec{V}_G + {}^i\vec{V}_{A/G} = {}^i\begin{bmatrix} V_{Gx} \\ V_{Gy} \end{bmatrix} + {}^i\begin{bmatrix} 0 \\ AG\omega \end{bmatrix} \quad (4)$$

$${}^i\vec{V}_B = {}^i\begin{bmatrix} V_{Bx} \\ V_{By} \end{bmatrix} = {}^i\vec{V}_G + {}^i\vec{V}_{B/G} = {}^i\begin{bmatrix} V_{Gx} \\ V_{Gy} \end{bmatrix} + {}^i\begin{bmatrix} 0 \\ -BG\omega \end{bmatrix} \quad (5)$$

where

${}^i\vec{V}_{A/G}$ ,  ${}^i\vec{V}_{B/G}$  = relative velocity of points A and B with respect to  $G$

$\omega$  = angular velocity of segment

Positive rotational speed of the segment is considered counterclockwise. Having defined the endpoint velocities, their relative motions are constrained by axial and bending springs and dampers. The velocity of center of mass ( $G$ ) of each segment, while defined in the local coordinate system, must be transformed to the inertial coordinate system in order to apply gravity, and to allow system initialization through a static vertical displacement of a point on the cable, which is then released to create free vibration. The coordinate transformation for velocity of point  $G$  is as follows.

$${}^I\vec{V}_G = {}^I\begin{bmatrix} V_{Gx} \\ V_{Gy} \end{bmatrix} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} {}^i\vec{V}_G \quad (6)$$

where  $\theta$  = angle of rotation of segment  $i$ .

Also, because the end point velocities of each segment need to be related, both end point velocities should be expressed in the same frame, in this case the local coordinate of the segment to the right. Eq. (7) represents the coordinate transformation relation between two connected sections.

$${}^{i+1}\begin{bmatrix} V_{Ax} \\ V_{Ay} \end{bmatrix} = \begin{bmatrix} \cos(\theta_{i+1} - \theta_i) & \sin(\theta_{i+1} - \theta_i) \\ -\sin(\theta_{i+1} - \theta_i) & \cos(\theta_{i+1} - \theta_i) \end{bmatrix} {}^i\begin{bmatrix} V_{Ax} \\ V_{Ay} \end{bmatrix} \quad (7)$$

Eq. (8) represents Newton's Law for the segment in local coordinates.

$$\sum {}^i\vec{F} = \frac{d}{dt} {}^i\vec{P} = {}^i\begin{bmatrix} m\dot{v}_x \\ m\dot{v}_y \end{bmatrix} + \vec{\omega} \times {}^i\begin{bmatrix} mv_x \\ mv_y \end{bmatrix} = {}^i\begin{bmatrix} m\ddot{v}_x \\ m\ddot{v}_y \end{bmatrix} + {}^i\begin{bmatrix} -m\omega v_y \\ m\omega v_x \end{bmatrix} \quad (8)$$

The first term on the right-hand side is modeled with generalized inertias in the bond graph, and the second term using modulated gyrators.

## C. Bond Graph Model

The bond graph model of the cable consists of 30 segments, which is enough to produce the first few frequencies with reasonable accuracy. Each segment is connected to the next

segment with a connection sub-model and each connection sub-model contains the compliance and damping bond graph elements. Figure 2 shows the bond graph model of a segment of the cable. A bond graph 1-junction represents a generalized Kirchoff loop law, with all bonded elements having the same flow, and efforts algebraically summing to zero. A bond graph 0-junction represents a generalized node law, with all bonded elements having the same effort. The 0-junction also sums velocities of bonded elements to zero, making it the element used to enforce velocity constraints. As can be seen from Figure 2, there are two modulated transformers (MTF), one for each row of Eq. (6), two MTF's for defining Eq's (4) and (5) and one modulated gyrator (MGY) for defining the Euler's Equations inner product terms of Eq. (8). The power bonds (with half-arrows) contain both force and velocity information. In Figure 2 sample junction equations are given. The 1-junction representing Newton's Law in the  $x$  direction sums forces, including constraint forces from adjoining elements that are on the same bonds that communicate velocity of points A and B to adjoining elements. Left superscripts indicate the local ( $i$ ) or inertial ( $0$ ) frame. Figure 3 shows the bond graph of one connection sub-model between two adjoining segments. As can be seen in Figure 3, there are four MTF's for defining coordinate transformation Eq. (7). The top row of the bond graph represents the velocities and elements in the  $x$  and  $y$  directions and the most bottom row represents the bending compliance.

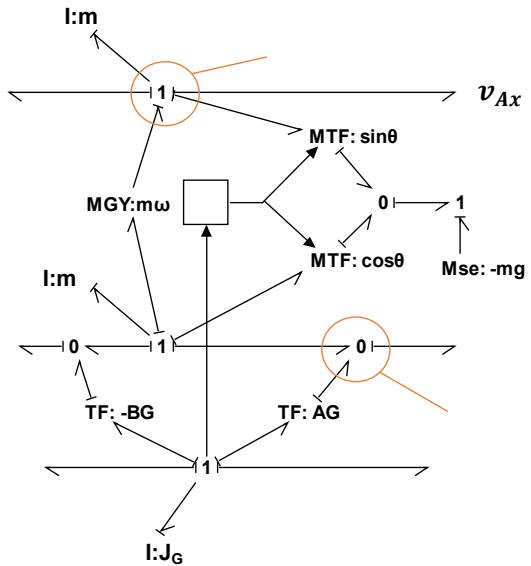

Figure 2. Bond Graph Model of a Segment of the Cable

TABLE 1. MATERIAL PROPERTIES OF CABLE

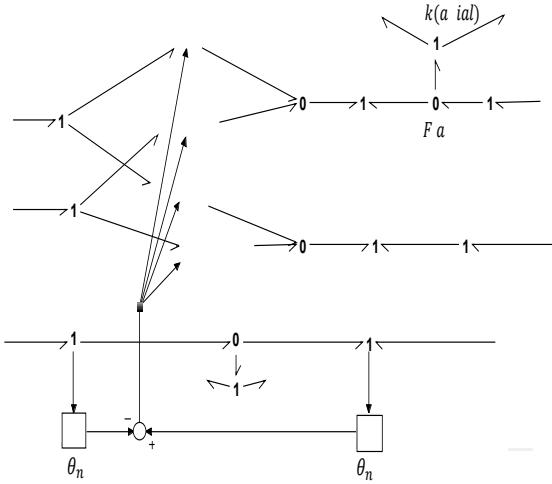

Figure 3. Bond graph model of compliant connection between consequent segments

In Figure 3, the 0-junction  $F_{axial}$  defines the velocity  $v_{k(axial)}$  as the difference between  $v_{Bx}$  on segment  $i+1$  and  $v_{Ax}$  on segment  $i$  defined in the  $i+1$  coordinate system. The 1-junction equates the velocities of the parallel axial spring and damper. The bending spring/damper velocity is defined similarly. The block diagram elements define the relative angle between segments for the velocity transformation.

Point B of the left-most segment and Point A of the right-most segment are attached to the wall and therefore have zero velocity. Thus, two zero flow sources are used at each point in the  $x$  and  $y$  directions. In order to create the desired initial tension in the cable, the model is given zero initial conditions and then stretched until the desired tension is achieved. In this paper, four values of tension are considered for the analysis. For applying the stretching displacement to the right end of the cable in bond graph model, a flow source was temporarily applied to the 1-junction associated with the velocity of the right end of the cable in local  $x$  direction. After creating the desired tension, the zero flow source was reinstated at the right end. The cable was then excited, with results of the bond graph model compared to experimental results.

### III. EXPERIMENTAL VIBRATION TESTING OF THE CABLE

#### A. Cable Bending Stiffness Measurement

The material properties of the conductor used for testing are tabulated in Table 1. The bending stiffness ( $EI$ ) of the cable should be measured as it is stranded cable and its bending stiffness is not equal to the bending stiffness of solid cable with the same diameter [6]. Figure 4 shows the setup used for measuring the bending stiffness ( $EI$ ) and consequently area moment of inertia ( $I$ ) of the cable.

Material	Length [m]	Density [kg/m <sup>3</sup> ]	$E$ [GPa]	Area [m <sup>2</sup> ]
Stainless Steel 7×7 wires	3.6	9537	195	2.78x10 <sup>-5</sup>

Figure 4. Set up for Bending Stiffness Measurement

A section of the cable is clamped between two ends and a fixed-fixed configuration is made. Various weights are hung in the middle of the cable section and a LDVT is used to measure the deflection of the cable at midspan. By using standard force-deflection formulae for a fixed-fixed beam with force applied at midspan, the bending stiffness of the cable is obtained [13]. It should be noted that the value of measured  $EI$  from bending test is between theoretical minimum and maximum bending stiffness bounds for the stranded cables.  $EI_{min}$  corresponds to when all the layers of the cable slip on each other and  $EI_{max}$  is for all the wires are bonded and make a solid cable. The details of the theoretical bounds for bending stiffness can be found in [6]. Bending of the cable in a cantilever configuration was also performed with different lengths of the cable and the results were the same, which shows that the bending stiffness of the cable is not sensitive to length, over the range of segment lengths considered in this work. A measured constant value for  $EI$  is directly used in the bond graph model in numerical analyses. Table 2 presents the value of  $EI$  for three different lengths of cable sections.

TABLE 2. VALUE OF MEASURED  $EI$  WITH DIFFERENT LENGTHS

Length (mm)	$EI$ (Nm <sup>2</sup> )
205	0.555
364	0.444
400	0.547

### B. Experimental Modal Testing

Figure 5 shows the set up used for modal impact testing of the cable.

Figure 5. Cable Vibration Test Set up

Figure 6 presents a schematic illustrating two set-ups used for testing the cable. Two pin support structures hold the cable. The right end of the cable is attached to a threaded rod to adjust the static tension of the cable. A load cell is at the left end of the cable to measure the longitudinal tension of the cable. The load cell is directly inline with the cable to measure the longitudinal tension of the cable. The rectangular solid shapes and the black arrows represent respectively the position of the accelerometers and the hammer hits along the cable.

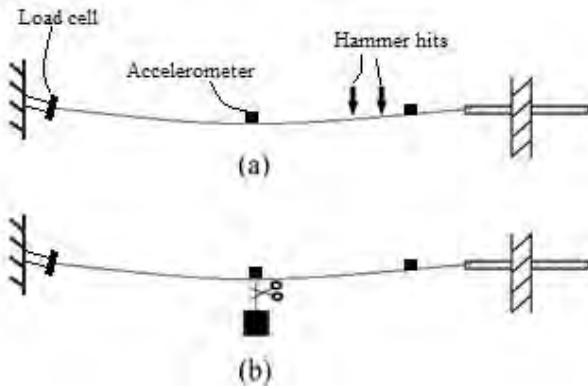

Figure 6. Schematic view of cable vibration testing

Modal tests are performed with a Brüel & Kjaer 8205-002 impact hammer, 4507 B 004 70-g accelerometers, and a National Instruments NI USB-4432 power supply and signal conditioner. Cable tension is measured with a load cell. Also, the software ModalView [14] is used to analyze the data. All modal tests averaged 5 hits.

Figure 6 (a) illustrates the set up used to perform hammer modal testing over the cable, experiment “A”. With accelerometers positioned at 0.3 and 1.8 m from the right side, the measurements taken hitting the hammer in two different positions, at 1/4 and 1/5 of the cable span. The modal test was performed with different tensions which are tabulated in Results section.

Another experiment, “B”, is performed as illustrated by Figure 6 (b). The cable is supported the same way as before, however now there is a mass attached to the middle of the cable through a string. Cutting the string creates a force excitation that can be replicated in simulation.

### IV. RESULTS AND DISCUSSIONS

The Frequency Domain Toolbox in the 20sim® bond graph simulation environment numerically generates a system transfer function from which eigenvalues are calculated. Table 3 presents the experimental and numerical results of the natural frequencies and damping ratios of the tensioned cable. In the simulation, an impulse force is applied at the quarter of the cable span which is in the 7th cable segment and the time response is obtained at the midspan of the cable. The result of experiment (b) in Figure 6 and corresponding simulation results are illustrated in Figure 7 and Figure 8. The measured and simulated acceleration time response of the midspan can be compared from these figures. Figures 7-8 show accelerations of similar magnitude. Discrepancies are primarily attributed to inaccurate high-frequency modes inherent in a lumped-segment representation. Figure 9 presents the stabilization diagram obtained from ModalView to extract the natural frequencies of the cable with 350 N tension. The peaks in the stabilization diagram correspond to the natural frequencies of the cable.

TABLE 3. CABLE MODAL DATA: SIMULATION AND EXPERIMENTAL RESULTS

## V. CONCLUSIONS AND FUTURE WORK

A bond graph lumped segment model was developed to obtain the modal data of a conductor. The natural frequencies and damping ratios from modal testing of the physical setup were compared to those from simulation, along with time responses. The overall system frequencies were predicted with the simulation model for the range investigated. Discrepancies

in damping ratios, and in time response, are attributed to the use of simple linear viscous damper elements. Developing and tuning a more accurate damping model remains an open research problem. In addition, as the overall goal of the research is to capture the effects of cable on dynamics of poles, cable numerical models should be combined with the pole models to investigate the effects of cables in a line of pole-cables in the future work.

**Abstract**— In this study, a program based on finite element method is developed for rotor dynamic analysis of gas turbine rotors. In the FE model of the rotors, various minor and major parts of the rotor are modeled using the cylindrical and tapered Timoshenko beam elements and the lateral vibration behavior of the rotor is evaluated. In the paper, the lateral vibration behavior of a certain gas turbine rotor is analyzed using the developed finite element program and coupled lateral-torsional vibration behavior of the rotor is analyzed using 3D finite element model. A good agreement exists between the results obtained from two FE models. Two design models are used for the rotor one of which has 2 bearings and the other one has 4 bearings with specific locations. The effects of the number of the bearings on the critical speeds, operational deflection shapes and unbalance response of the rotor is investigated. It is found that the number of the bearings has significant effect on the first critical speed but slight effect on the second and third critical speeds. It is demonstrated that the number of the bearings can be used as one of the system design parameters.

Keywords; Timoshenko beam elements, Dynamic analysis, Campbell diagram, Unbalance response, Operational deflection shape

## I. INTRODUCTION

Rotor dynamics is a branch of systems dynamics dealing with mechanical systems in which at least one part, usually defined as rotor, rotates with significant angular momentum [1-4]. It is vital to consider the dynamics of the rotating machines in the design stage to avoid catastrophic failures that may occur because of resonance condition in their operation. Dynamic analysis of rotating machines and turbo machinery rotors has been performed by many researchers and finite element method has been of interest of many researchers recently as a numerically efficient method to analyze the dynamics of rotating machines and mechanical structures [5-10].

Chiang et al. [11] developed finite element models to investigate the dynamic characteristics of single- and dual-rotor-bearing turbomachinery systems. The models were

analyzed to predict the natural frequencies, produce critical speed maps, and estimate the bearing stiffness. They demonstrated that the speed ratio of the high speed to low-speed shaft in dual-rotors could be used as one of the dual-rotor system design parameters. Jeon et al. [12] performed a full rotor dynamic analysis for a high thrust liquid rocket engine fuel turbo pump using finite element method. They found out that the rear bearing stiffness was the most important parameter for the critical speed and instability, because the first vibration mode of the rotor was turbine side shaft bending mode. Jeon et al. [13] used 1D and three-dimensional finite element methods to perform critical speed analysis of a 30-ton thrust turbo pump while considering the casing structural flexibility. They also analyzed the effect of loads on the bearings on the dynamic behavior of the rotor. Jalali et al. [14, 15] predicted the dynamic behavior of a rotor-bearing system with a 1D finite element model, a 3D finite element model and experimental modal test. They obtained natural frequencies and mode shapes of the rotor at rest under free-free boundary condition using beam model, 3D model and modal test. Also, they performed a full rotor dynamic analysis for the rotor using both FE models. Brusa and Zolfini [16] investigated the dynamic behavior of the Galileo Galilei Ground (GGG) test facility through numerical and experimental analyses. They used one dimensional beam finite element model to model the system and They compared the results with experimental results. Creci et al. [17] performed a full rotor dynamic analysis for a 5-KN thrust gas turbine using a 1D finite element model considering bearing stiffness and damping dynamics. They obtained mode shapes and operational deflection shapes of the rotor and they performed a transient analysis to simulate the transition of the system through resonance.

In this paper, a finite element model based on cylindrical and tapered Timoshenko beam elements, by considering the rotary inertia, gyroscopic effect and shear deformations, is used to study the dynamic behavior of a gas turbine rotor. The difference of this beam FE model with the models in the literature is that the various minor and major parts of the rotor are modeled with beam elements in this model, therefore dynamics of the rotor can be evaluated exactly. A 3D finite element model based on solid elements is also constructed in

Ansys software to validate the beam FE results. A parameter study is carried out to examine the effects of the number of the bearings on the lateral vibration behavior of the rotor. The mode shapes, Campbell diagram, critical speeds, operational deflection shapes (ODS) and unbalance response of the rotor are obtained in both cases with 2 bearings and 4 bearings with specific locations to compare the dynamics of the designed rotors and to evaluate which design would be better. It is found that the number of the bearings can be a design parameter, because it influences the vibration behavior of the rotor significantly.

## II. THEORETICAL FORMULATION

The rotor system can be divided into rigid disks, rotor segments, and linear bearing supports. The vector of the nodal displacements, i.e., of the generalized coordinates of a Timoshenko beam element used in this study is:

$$\mathbf{q} = \begin{bmatrix} x_1 & y_1 & \theta_{x1} & \theta_{y1} & x_2 & y_2 & \theta_{x2} & \theta_{y2} \end{bmatrix} \quad (1)$$

Where  $x_1, y_1, \theta_{x1}$  and  $\theta_{y1}$  represent node 1's displacements and rotations about the nodal axes and  $x_2, y_2, \theta_{x2}$  and  $\theta_{y2}$  represent node 2's displacements and rotations about the nodal axes. The value of displacements through the elements can be obtained by shape functions and the nodal displacements from the following equation.

$$\begin{cases} \mathbf{x} \\ \boldsymbol{\theta}_y \end{cases} = \begin{bmatrix} N_{11} & N_{12} & N_{13} & N_{14} \\ N_{21} & N_{22} & N_{23} & N_{24} \end{bmatrix} \begin{cases} x_1 \\ \theta_{y1} \\ x_2 \\ \theta_{y2} \end{cases} \quad (2)$$

$$\begin{cases} \mathbf{y} \\ \boldsymbol{\theta}_x \end{cases} = \begin{bmatrix} N_{11} & N_{12} & N_{13} & N_{14} \\ N_{21} & N_{22} & N_{23} & N_{24} \end{bmatrix} \begin{cases} y_1 \\ \theta_{x1} \\ y_2 \\ \theta_{x2} \end{cases}$$

Where  $N_{ij}$  ( $i, j = 1, 2$ ) are the shape functions of Timoshenko beam element which can be found in [18]. The motion equation of a complete rotor-bearing system that is axially symmetrical around its spin axis and rotates at a constant spin speed  $\Omega$ , is in the following general form:

$$\mathbf{M}\ddot{\mathbf{q}}(t) + (\mathbf{G})\dot{\mathbf{q}}(t) + (\mathbf{K})\mathbf{q}(t) = \mathbf{f}(t) \quad (3)$$

Where  $\mathbf{q}(t)$  is a vector containing the generalized coordinates, referred to an inertial frame and the other matrices are the assembled matrices for the system.  $\mathbf{M}$  is the symmetric mass matrix,  $\mathbf{G}$  is the skew-symmetric gyroscopic matrix,  $\mathbf{K}$  is the symmetric stiffness matrix, and  $\mathbf{f}(t)$  is a time-dependent vector in which all forcing functions are listed. The gyroscopic matrix contains inertial and hence conservative terms that, in the case of rotor dynamics, are strictly linked with the gyroscopic moments acting on the rotating parts of the machine. When dealing with rotating systems, one of the forcing functions is

usually that caused by the residual unbalance that, although small, cannot nevertheless be neglected. Unbalance forces are harmonic functions of time, with an amplitude proportional to  $\Omega^2$  and a frequency equal to  $\Omega$ .

Most flexible rotors can be considered as beam-like structures. Under fairly wide assumptions, the lateral behavior of a beam can be considered as uncoupled from its axial and torsional behavior [1, 18]. The same uncoupling is usually assumed in rotor dynamics, with the difference that no further uncoupling between bending in the principal planes is possible. When the flexural behavior can be uncoupled from the axial and torsional ones, Equation (3) holds for the first one.

In order to solve the eigenvalue problem of the Equation (3) (with  $\mathbf{f}(t) = 0$ ), the second-order homogeneous Equation (3) should be reduced into  $2n$  first-order differential equations. A

$2n$ -column vector  $\mathbf{X} = \begin{Bmatrix} \dot{\mathbf{q}} \\ \mathbf{q} \end{Bmatrix}$  is used so that Equation (3) with zero force can be expressed as:

$$\begin{bmatrix} \mathbf{0} & \mathbf{M} \\ \mathbf{M} & \mathbf{G} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{q}} \\ \dot{\mathbf{q}} \end{Bmatrix} + \begin{bmatrix} -\mathbf{M} & \mathbf{0} \\ \mathbf{0} & \mathbf{K} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{q}} \\ \mathbf{q} \end{Bmatrix} = \begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (4)$$

Equation (4) can be simplified into:

$$\mathbf{A}\dot{\mathbf{X}} + \mathbf{B}\mathbf{X} = \mathbf{0} \quad (5)$$

By assuming  $\mathbf{X} = \{\psi\} e^{\lambda t}$ , Equation (5) can be expressed as:

$$\lambda\mathbf{A} + \mathbf{B}\{\psi\} = \mathbf{0} \quad (6)$$

The eigenvalues of the Equation (6) is  $\lambda_k = \sigma_k + i\omega_k$  where  $\sigma_k$  is the decay rate of the  $k$ th natural frequency and  $\omega_k$  is the  $k$ th natural frequency. When the natural frequencies of the rotor at various rotor speeds are calculated, the Campbell diagram can be plotted. The natural frequencies of the rotor at various rotor speeds can be calculated by solving the eigenvalue problem Equation (6). In addition, the unbalance response of the rotor can be calculated by obtaining the solution of the Equation (7) which is derived when in Equation (3),  $\mathbf{f}(t)$  is a harmonic function of time, with amplitude proportional to  $\Omega^2$  and a frequency equal to  $\Omega$  and by assuming the response to be  $\mathbf{q}(t) = \mathbf{q}_0 e^{i\omega t}$ .

$$(-\Omega^2\mathbf{M} + i\Omega\mathbf{G} + \mathbf{K})\mathbf{q}_0 = \Omega^2\mathbf{f}_r \quad (7)$$

## III. FINITE ELEMENT MODELS

### A. Beam Finite element Model

The studied rotor is a single spool gas turbine rotor and consists of two fan stages, six compressor stages and two turbine stages. The compressors and fans are made of aluminum alloy by the density of  $4437 \text{ kg/m}^3$ , Young modulus of  $113.8 \text{ GPa}$  and the Poisson ratio of  $0.342$ . The material of the other parts of the rotor is assumed to be steel by the density

of  $7700 \text{ kg/m}^3$ , Young modulus of 215 GPa and the Poisson ratio of 0.3. The total length of the shaft is 70 cm. Figure 1 and Figure 2 show the finite element design model of the rotor with 2 and 4 bearings, respectively. In these Figures, disks D1 and D2 are the fan stages, D3-D8 are the compressor stages, D9 and D10 are the turbine stages and D11 is the turbine starter. The model of the rotor in both Figures is the same and only the number of the bearings is different. The model consists of 60 nodes and 78 Timoshenko beam elements. A mesh convergence analysis is performed to explain why this number of nodes and elements is used in the beam model, but the results are not presented in the paper for brevity. The parts with the same colors in Figs. 1-2 have the same materials. The effects of rotary inertia, gyroscopic moments and shear deformations are included in the formulations and the damping is neglected. The dimensions of the various parts of the rotor are exactly equal to those in the 3D FE model. Every node used in the system has 4 degrees of freedom. These include translations in the nodal directions and rotations about nodal axes. In order to consider the inertial properties of fans, compressors and turbines and turbine starter, concentrated masses are used at the place of each one. Table 1 shows the geometric properties of the discs. Inertial properties of the disks can be calculated from the dimensions given in Table 1. Cylindrical Timoshenko beam elements are used to model the various parts of the shaft and the generator. It should be noted that, in order to model the rotor more accurately, some of the elements have equal nodes. It means that they are on top of each other with the same nodes. Tapered Timoshenko beam elements are used to model the minor parts such as the gaps between different stages of the fans, compressors and turbines. Springs are used to model the bearings at the place of bearings. Table 2 shows the stiffness coefficients of the bearings. The stiffness and damping cross-coupled terms for the bearings are considered null.

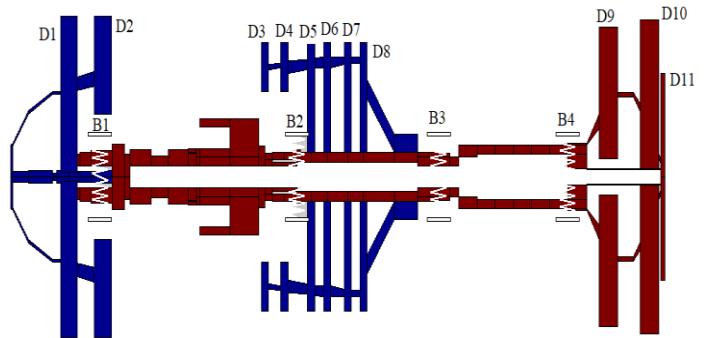

Figure 2. FE model of rotor with 4 bearings

TABLE 1. GEOMETRIC PROPERTIES OF DISCS

Discs	D1	D2	D3-D4	D5-D8	D9	D10	D11
Outer diameter (mm)	262	262	219	219	244	257	169
Inner diameter (mm)	7.06	102	140	40	30.1	13.31	0
Width (mm)	17.5	17.98	7.62	7.62	20	20	5

TABLE 2. STIFFNESS COEFFICIENTS OF THE BEARINGS

Bearing Number	Stiffness (N/m)
B1	1.57e+07
B2	1.77e+07
B3	3.91e+06
B4	7.04e+06

### B. 3D Finite Element Model

The coupled lateral-torsional vibration analysis of the rotor is carried out using 3D FEM. The Ansys software is used to construct the 3D finite element model with 10 node tetrahedral solid elements. Figure 3 shows the 3D finite element model of the rotor. The model consists of 50809 nodes and 27982 solid elements. All the parts are considered elastic and the material and geometric properties of this rotor model are exactly equal to that of the beam finite element model. Spring elements in the two lateral directions are used at the place of the bearings to model the bearings for 2 and 4 bearing cases.

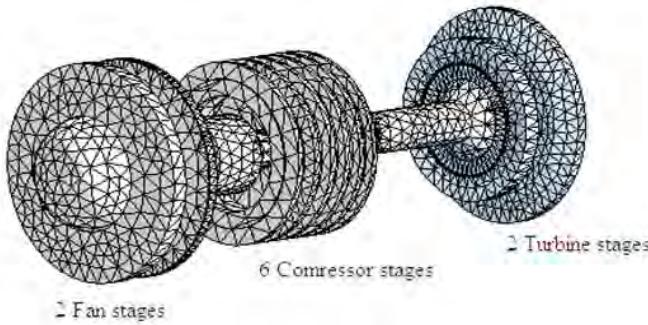

Figure 3. 3D Finite Element Model

#### IV. RESULTS

##### A. Dynamic Analysis of the Rotor with 2 Bearings

In order to investigate the dynamic behavior of the rotor at operational speeds, critical speeds and the Campbell diagram are obtained using the beam FE model. The speed range considered is 0 to 36000 rpm. The Campbell diagram of the rotor obtained from beam FEM excluding the rigid body modes is illustrated in Figure 4. The three first bending critical speeds of the rotor corresponding to the forward whirling obtained from beam FE model are 2099.97 rpm, 10479 rpm and 15556 rpm, respectively. Also, the Campbell diagram obtained from 3D finite element model excluding the rigid body modes is shown in Figure 5. As can be seen, the gyroscopic softening/stiffening of some of the modes have minor error between two Figs. which is expected because of the difference in modeling methods of the inertial properties of the disks in two FE models.

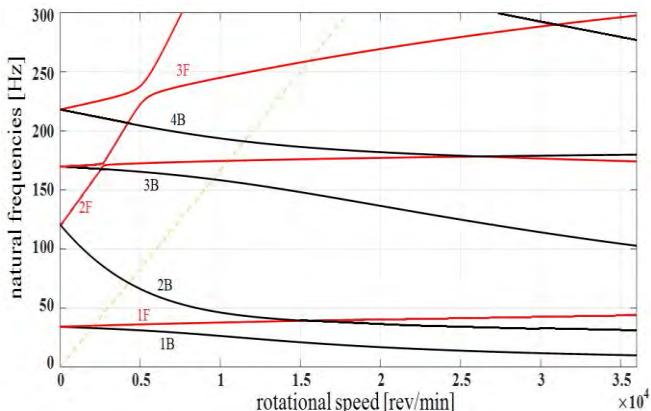

Figure 4. Campbell diagram of the rotor with 2 bearings (Beam FE model)

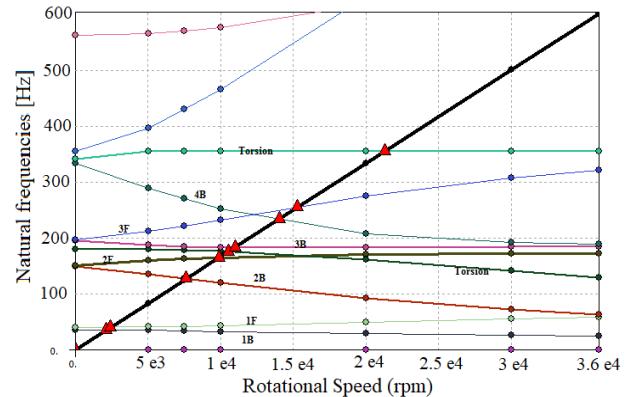

Figure 5. Campbell diagram of the rotor with 2 bearings (3D FE model)

The critical speeds obtained from two models are presented in Table 3. It should be noted that from the beam finite element model, only the bending critical speeds of the rotor are calculated but from 3D finite element model, the torsional and bending critical speeds are calculated.

TABLE 3. CRITICAL SPEEDS OF THE ROTOR WITH 2 BEARINGS

Critical Speed	First bending	Second bending	First torsional	Third bending	Second torsional
Beam FE (rpm)	2099.97	10479	N/A	15556	N/A
3D FE (rpm)	2416.2	9869.1	10503	15252	21250
Error (%)	13.0	6.1	N/A	1.9	N/A

In order to investigate the dynamic behavior of the rotor more practically and to verify the critical speed obtained from the Campbell diagrams, an imbalance of 1  $\mu\text{m}$  is considered at the gravity center of all of the discs which have inner diameter equal to the outer diameter of the shaft where they are located, to simulate the worst unbalancing condition. The imbalance is considered at the gravity center of disks D5, D6, D7, D8 and D10 (Table 1). The operational deflection shapes (ODS) at two bending critical speeds obtained from the Campbell diagrams are shown in Figure 6.

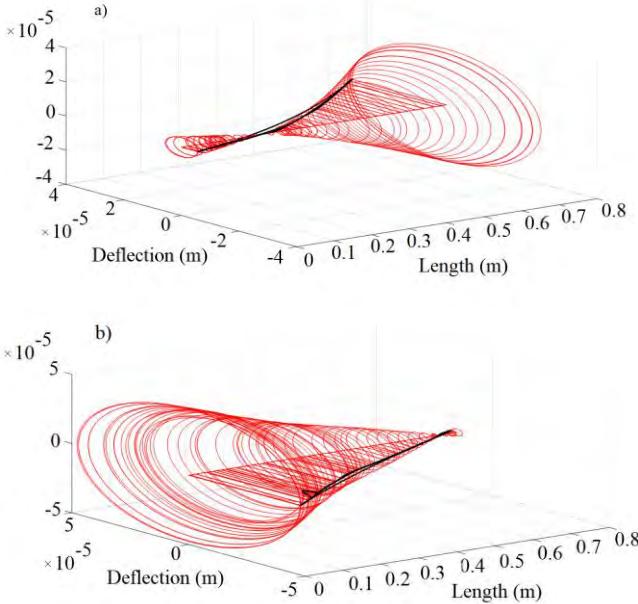

Figure 6. Operational deflection shape of the rotor with 2 bearings at  
a) first b) second critical speed (Beam model)

Figure 7. shows the unbalance response of the rotor evaluated the location of concentrated masses of disks D5, D6, D7, D8 and D10 at which the imbalance is considered. Nodes 27, 28, 29, 30, 45 are the location of concentrated masses of disks D5, D6, D7, D8 and D10, respectively. It can be seen that displacement peaks at the critical speeds points which were previously calculated.

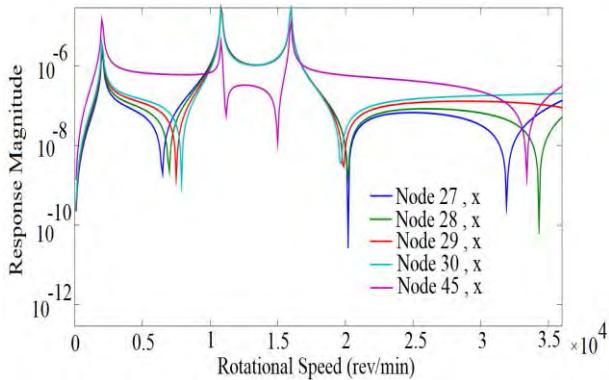

Figure 7. Unbalance response of the rotor with 2 bearings (Beam model)

### B. Dynamic Analysis of the Rotor with 4 Bearings

The Campbell diagram, operational deflection shapes and unbalance response to the worst unbalancing condition is obtained also in this case. The considered speed range is again 0 to 36000 rpm. The Campbell diagrams, excluding rigid body modes, obtained from beam FE model and Ansys are shown in the Figure 8 and Figure 9, respectively. The critical speeds obtained from two models are compared with each other in Table 4.

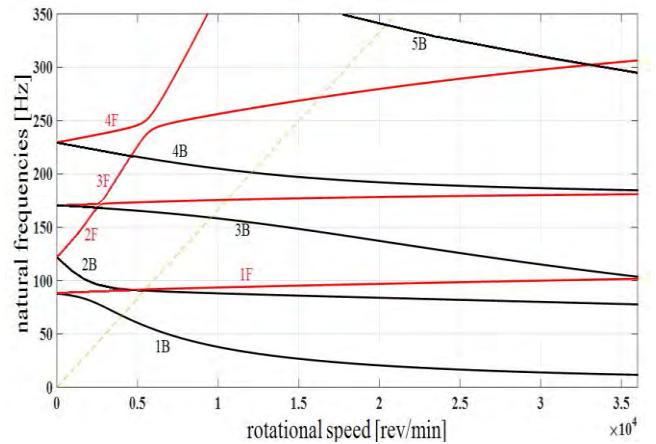

Figure 8. Campbell diagram of the rotor with 4 bearings (Beam FE model)

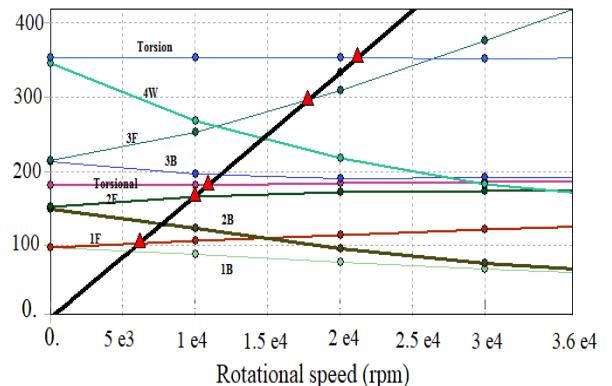

Figure 9. Campbell diagram of the rotor with 4 bearings (3D FE model)

TABLE 4. CRITICAL SPEEDS OF THE ROTOR WITH 4 BEARINGS

Critical Speed	First bending	Second bending	First torsional	Third bending	Second torsional
Beam FE (rpm)	5507.26	10549	N/A	16308	N/A
3D FE (rpm)	5446.9	9894.2	10868	17697	21180
Error (%)	1.1	6.6	N/A	7.8	N/A

An imbalance same as which was considered in the previous section is considered also in this case and the operational deflection shapes (ODS) at two bending critical speeds obtained from the Campbell diagrams and the unbalance response are calculated. The operational deflection shapes at two bending critical speeds are shown in Figure 10

and the unbalance response evaluated at the location of disks D5, D6, D7, D8 and D10 is shown in Figure 11.

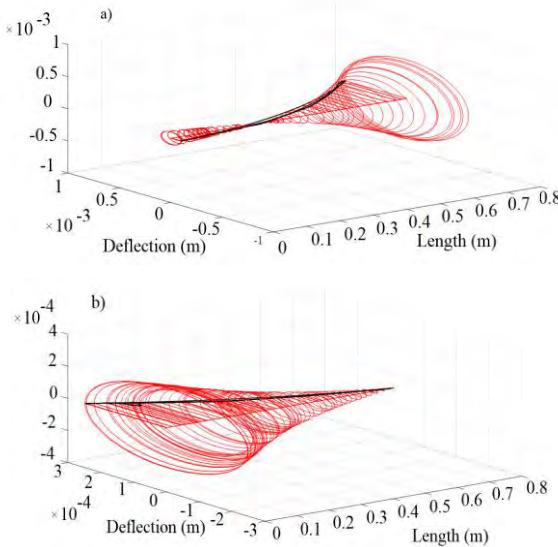

Figure 10. Operational deflection shape of the rotor with 4 bearings at  
a) first b) second critical speed (Beam model)

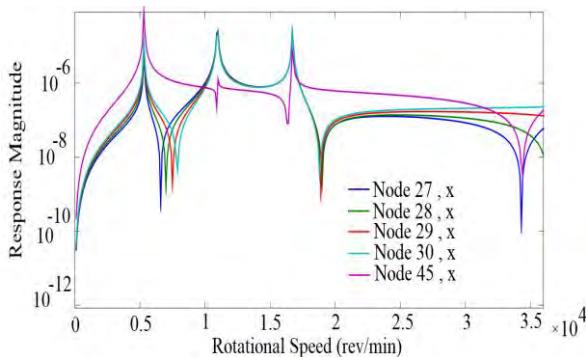

Figure 11. Unbalance response of the rotor with 4 bearings (Beam model)

By comparing the critical speeds of the rotor with 2 and 4 bearings from Tables 3 and 4, it is obvious that the number of the bearings has significant effect on the value of the first critical speed but slight effect on the value of the second and third critical speeds.

Also, by comparing the operational deflection shapes of the rotor with 2 and 4 bearings from Figure 6 and Figure 10, respectively, it is found that the effect of the number of the bearings on the overall deflection of the rotor at the first critical speed is much more than this effect on the overall deflection of the rotor at the second critical speed. In addition, the overall deflection of the rotor with 2 bearings at the critical speeds is much lower than the overall deflection of the rotor with 4 bearings at the critical speeds. It should be noted that in this paper, the effects of the number of the bearings on the dynamics of this rotor is evaluated but the locations of the bearings also can affect the dynamics of the rotor.

## I. CONCLUSIONS

A finite element model based on Timoshenko beam elements is presented. In this model, various minor and major parts of a gas turbine rotor are modeled using cylindrical and tapered beam elements. A full rotor dynamic analysis is carried out to evaluate the dynamic behavior of the rotor at operational speeds and to avoid vibration problems. Also, a 3D finite element model is constructed, and the lateral-torsional vibration behavior of the rotor is predicted. The comparison of the results shows good agreement between the results obtained from two FE models. The effect of the number of the bearings on the dynamic behavior of the rotor is also studied from the beam finite element model. It is found that the overall deflection of the rotor with 2 bearings (at specific locations) at its first two bending critical speeds is much lower than the overall deflection of the rotor with 4 bearings (at specific locations) at its first two bending critical speed. In addition, it is found that the effect of the number of the bearings on the overall deflection of the rotor at the first critical speed is much more than this effect on the overall deflection of the rotor at the second critical speed.

# Assessment of Aliphatic Based Soot Inception in Laminar Diffusion Flames

Nemanja Ceranic, Seth B. Dworkin  
Department of Mechanical and Industrial Engineering  
Ryerson University  
Toronto, Canada

**Abstract** – Soot models are key components of computation fluid dynamic combustion codes that attempt to prescribe how soot is formed. However, due to the complex nature of soot formation, not all pathways may have been fully characterized. This work investigates numerically the influence that an aliphatic-collision (open-chain hydrocarbon) based soot inception model has on soot formation for coflow ethylene/air and methane/air laminar diffusion flames. In the literature, prediction of the soot volume fraction along the centerline of coflow ethylene flames is lacking in accuracy. Similarly for methane flames, soot formation on the wings are under predicted by many models. A new collision based inception model has been developed for specific aliphatics, and applied using an existing framework for molecular collision, in conjunction with pyrene based inception. The purpose of this model is not to be completely fundamental in nature, but more so a proof of concept in that by using physically realistic values for surface reactivity and collision efficiency, this collision mechanism can account for soot formation deficiencies that exist with just polycyclic aromatic hydrocarbon (PAH) based inception. Using this new model, the peak soot volume fraction along the centerline of an ethylene flame can be increased while the peak soot volume fraction along the wings remains unchanged, showing potential to significantly improve the model's predictive capability. Applying this model to a methane flame has resulted in an increase in the soot volume fraction in both the centerline and the wings, again improving predictive capability.

## I. INTRODUCTION

Any form of hydrocarbon combustion leads to the generation of soot. These particles are hazardous to human health [1, 2] as well as dangerous for the environment [3-5]. Thus it is necessary that the characterization of soot formation be well understood in order to design more environmentally friendly combustion devices. Numerical combustion models require extensive knowledge of soot formation in order to obtain meaningful results. One of the advantages that numerical modelling can provide is that it allows researchers to test new theories at virtually no cost compared to experimental techniques.

Soot formation is a complex process consisting of polycyclic aromatic hydrocarbon (PAH) gas-phase growth, particle

nucleation, surface growth via surface reaction and PAH condensation, surface oxidation, particle coalescence, particle coagulation and fragmentation, gas-phase scrubbing, and radiation [6]. These pathways are widely considered by the scientific community to be the accepted routes of soot formation, however, due to its complex nature, other pathways may exist that have yet to be fully characterized.

Soot models have been the subject of discussion for several decades and continue to improve to this day. The three classifications of models are empirical, semi-empirical, and predominantly fundamental models. Semi-empirical soot models [7, 8] may have a foundation in the physics behind soot formation, but lack the fundamental physics behind the problem as they rely on tunable parameters. Although these models may not accurately portray what is occurring inside of the flame, they do give insight as to which parameters may be correlated. They are an essential milestone towards the creation of a fundamental model.

One such model is the Hydrogen-Abstraction-Carbon-Addition (HACA) growth mechanism introduced by Frenklach and Wang [9]. This model traditionally uses surface reactivity ( $\alpha$ ) as a tunable constant or function for matching numerical peak soot predictions to experimental peaks [9]. Therein lies the issue that current soot models face, which is, although peak soot may be correctly predicted, other regions of the flame may not be correctly predicted through the same tuning of  $\alpha$ . It has been postulated that the centerline of coflow laminar diffusion flames are dominated by inception whereas the wings are dominated by surface growth through the HACA mechanism [10]. By tuning  $\alpha$  to experimental peaks, which occur along the wings, the prediction in the wings region may be corrected. However, many models do not have sufficient reaction chemistry or appropriate sub mechanisms to accurately capture the trends along the centerline, and tend to under predict soot formation in that region [11-14].

Based on recent literature, soot is able to undergo mass growth in the absence of gas phase hydrogen atoms and nascent soot can be rich in aliphatic molecules in premixed flames [15]. This observation indicates that the HACA mechanism is not likely to be responsible for this growth. The HACA mechanism removes hydrogen from the surface of molecules meaning that gas phase hydrogen atoms would be present

whenever this mechanism is active. If the atoms are not present, another mechanism is responsible for this growth. It is proposed that aliphatic-collision based inception may have some influence on this soot mass growth. A semi-empirical model has been generated to investigate the impact that additional aliphatic collision based inception in the soot formation model would have on a variety of coflow laminar diffusion flames. More details on the physics and assumptions of the model will be explained in the following sections. The model is applied to both pure ethylene/air and methane/air laminar diffusion flames that use the same burner dimensions. Two parameters are key to this model which are the surface reactivity,  $\alpha$ , and the collision efficiency,  $\beta$ .

## II. BURNER AND NUMERICAL MODEL

CoFlame is the in-house FORTRAN code that this research implements, which was recently formalized and published in Eaves *et al.* [16]. The code has been parallelized to reduce computational cost and has been validated against ethylene/air and methane/air combustion [16]. The first flame that is simulated is a coflow ethylene/air laminar diffusion flame that was originally studied by Santoro *et al.* [17, 18]. In those works, Santoro and coworkers had conducted experiments for several flames, four of which were pure ethylene/air diffusion flames. Of those flames, the one of particular interest is the second non-smoking flame (NSII) due to its prevalence in the literature and abundance of experimental data [19-22]. The NSII has a fuel velocity of 3.98 cm/s and an air velocity of 8.9 cm/s [18]. The burner consists of an 11.1 mm diameter inner fuel passage with a wall thickness of 1 mm surrounded by an outer air passage with a diameter of 101.6 mm [18]. The second flame that is modelled follows the work of Lee *et al.* [23], which uses the same burner as the Santoro flame, but methane instead of ethylene as the fuel. For the methane flame, the fuel velocity is 10.24 cm/s while the air velocity is 11.94 cm/s [24]. The computational domain consists of a non-uniform axisymmetric mesh of 384 CVs in the axial direction and 150 CVs in the radial direction for both of the modelled flames as the burner dimensions are the same.

## III. ALIPHATIC COLLISION MECHANISM

For the mechanism, it is assumed that aliphatic molecules collide together and under the right conditions may stick together. These conditions are accounted for in the collision efficiency that is prescribed in the CoFlame code. This mechanism was developed to function in a similar manner to particle coalescence, which has been implemented in the CoFlame code and validated. The primary difference between this mechanism and particle coalescence being the specific molecules that are colliding and contributing to soot inception. Particle coalescence uses large PAHs for inception, such as Benzo-a-pyrene, whereas this mechanism uses specific aliphatic species for the same means. A value is given to the collision efficiency to indicate that only X in every Y collisions will result in effective sticking. For example, if the collision efficiency is set 0.01, this indicates that 1 in every 100 collisions will result in sticking, and the other 99 will

result in rebound. Once the molecules stick together, they are treated as an incipient soot particle. This in effect means that this mechanism is contributing to the inception of soot, in addition to traditional PAH routes. Furthermore, this collision efficiency is highly dependent on molecular dynamics. Each of the aliphatic molecules considered has a radius and a concentration. The size and concentration inherently have an influence on the soot mass growth as the number of collisions increases with an increase in either one of those two parameters. It is important to note that the purpose of this mechanism is to simply link the aliphatics in the gas phase to the incipient solid soot phase, so as to assess their potential impact on soot mass growth and spatial distribution. The rate of inception is calculated according to kinetic theory:

$$\frac{\partial N}{\partial t} = \beta \sqrt{[(8\pi k_B T)/\mu_{AB}](r_A + r_B)^2 A v^2 [A][B]} \quad (1)$$

where  $\beta$  is the collision efficiency,  $k_B$  is the Boltzmann constant,  $A_v$  is Avogadro's number,  $\mu_{AB}$  is the collisional reduced mass for the two colliding aliphatics,  $r_A$  and  $r_B$  are the radii of the two colliding aliphatics, and  $[A]$  and  $[B]$  are the concentrations of the two colliding aliphatics [25].

The present study implements a 94 species mechanism, which models ethylene or methane combustion and PAH growth [16]. Some of the aliphatic species have been filtered out of use in the inception model based on their concentrations and carbon mass. Extremely low concentrations with low carbon mass such as  $\text{CH}_2$  have been removed from the proposed mechanism. The results of this analysis have determined that only 6 species of aliphatics are of particular interest in the present study. Those species are:  $\text{CH}_4$  (methane),  $\text{C}_2\text{H}_2$  (acetylene),  $\text{C}_2\text{H}_6$  (ethane),  $\text{C}_3\text{H}_6$  (propene),  $\text{C}_4\text{H}_6$  (butyne), and lastly  $\text{C}_3\text{H}_8$  (propane).

While the present model does not represent the complete physics behind the problem, it can be used to determine the potential for mass transfer from the aliphatic gas phase to the soot solid phase. This strategy allows for analysis to be carried out, such that relationships can be made between the aliphatic species and soot mass growth. Adjusting the collision efficiency of aliphatics, and further adjustment to the soot surface reactivity parameter, as was done in [11] is a key component to this exercise. The present analysis has shown that the soot volume fraction, with respect to the proposed mechanism, can be tuned through the collision efficiency. Increasing the efficiency, leads to more soot growth whereas decreasing it has the opposite effect. Through this adjustment, it is hypothesized that the centerline soot volume fraction can be modified to better predict experimental values along the centerline of laminar diffusion flames.

The surface reactivity is a value that ranges from 0 to 1 and is representative of the portion of a soot particle's surface area that is available for chemical reaction. CoFlame allows for this surface reactivity to be modelled as either a constant or a function of temperature history. In the present study, it is taken as a constant value. This parameter is a factor in determining

HACA growth and oxidation. Decreasing the surface reactivity normally leads to a decrease in the soot volume fraction as the HACA mechanism's contribution to surface growth decreases. Further adjustment of the surface reactivity, beyond what is already provided in literature [11, 26] comes in when a new growth mechanism is introduced into the numerical model as is the case in the present study.

#### IV. RESULTS AND DISCUSSION

The generation of the model was predicated on being able to observe a positive influence that aliphatic-collision based inception would have on soot formation along the centerline of a laminar diffusion flame. It was not clear *a priori* if drawing aliphatics out of the gas phase for soot inception would reduce the amount of carbon available for PAHs or HACA growth thereby reducing soot concentrations in some locations of the flame. In order for the model to have some significance it had to be able to increase the soot volume fraction along the centerline while the wings remained close to the experimental peaks for the NSII flame. If that condition could not have been met then the model would not have a positive correlation between aliphatic collision based inception and soot distribution.

Figure 1 shows the predicted soot volume fraction along the pathline of maximum soot of the NSII flame as a function of height above the burner for varying collision efficiencies. The data are compared to a model without aliphatic inception and to experimental results. The solid horizontal line and gray band in Figure 1 at 9.7 ppm indicates the experimentally measured peak value and associated uncertainty. It can be seen from Figure 1 that the predictive capability along the wings of the flame is generally unaffected by the addition of aliphatic inception. Furthermore, only collision efficiencies less than 1e-10 can lead to reasonable results. Adding aliphatic inception, however, shifts the location of peak soot formation to higher heights above the burner.

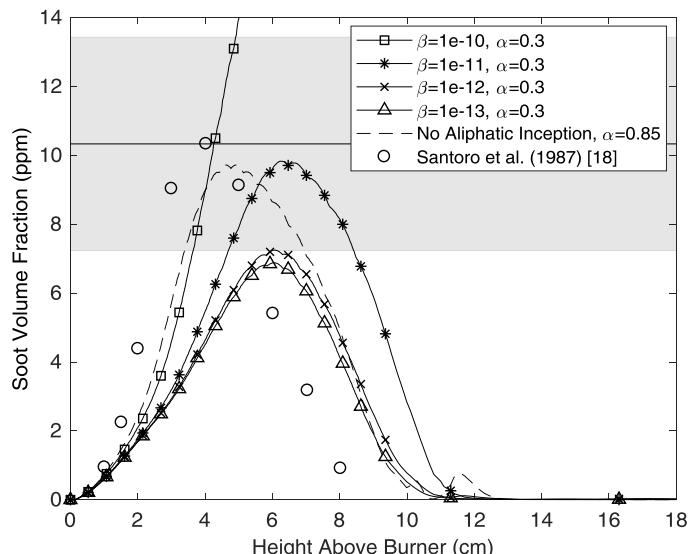

Figure 1. Predicted soot volume fraction as a function of height above the burner for varying collision efficiencies from 1e-10 to 1e-13 with constant

surface reactivity of 0.3 along the wings of the NSII flame. The results of a model without aliphatic inception with  $\alpha=0.85$  is shown alongside experimental results from [18]. The horizontal black line and gray band denote the experimentally measured peak.

Figure 2 shows the predicted soot volume fraction along the centerline of the NSII flame as a function of height above the burner for the same varying collision efficiencies. Here too the data are compared to a model without aliphatic inception and to experimental results. Again, only collision efficiencies less than 1e-10 lead to physically realistic results. Otherwise, implementing aliphatic based inception results in only a modest increase of soot volume fraction along the flame centerline. These figures illustrate that when  $\alpha$  is set to 0.3 and  $\beta$  is set to 1e-11 there is an increase in the soot volume fraction along the centerline while the wings remain close to the experimental peaks. The same upward peak shifting phenomenon can be observed along the centerline in Figure 2. Also, the results of varying the collision efficiency and surface reactivity show that for the NSII flame,  $\alpha$  can be lowered to a more physically realistic [27] value in order to correctly predict the wings peak soot volume fraction. In order to obtain results close to the experimental peaks for the NSII flame using CoFlame without an aliphatic collision based inception model,  $\alpha$  had to be set to 0.85.

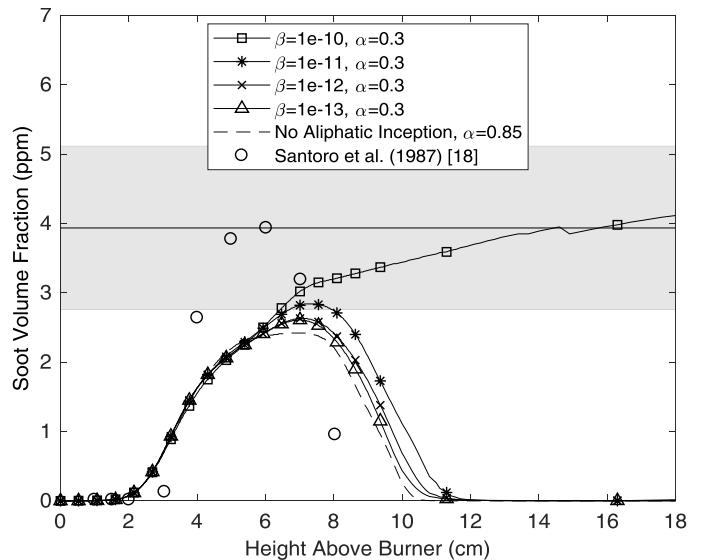

Figure 2. Predicted soot volume fraction as a function of height above the burner for varying collision efficiencies from 1e-10 to 1e-13 with a constant surface reactivity of 0.3 along the centerline of the NSII flame. The results of a model without aliphatic inception with  $\alpha=0.85$  is shown alongside experimental results from [18]. The horizontal black line and gray band denote the experimentally measured peak.

Similarly, the predicted soot volume fraction of the methane flame as a function of height above the burner for varying collision efficiencies and surface reactivity compared to a model without aliphatic inception and experimental results is shown in Figures 3 and 4. The results along the wings are shown in Figure 3 of the methane flame while Figure 4 shows the data along the centerline. The methane flame serves as a good benchmark to test the aliphatic collision based inception model for several reasons. The first and foremost reason is that

methane flames are known to be dominated by inception over surface growth through the HACA mechanism as the concentration of acetylene throughout the flame is lower compared to ethylene combustion [12]. Since methane is a single carbon fuel, much less acetylene is formed when it is burned, leaving less opportunity to achieve accurate model predictions by refining HACA rates. Secondly, current soot models typically under predict the soot volume fraction along both the centerline and the wings in methane flames [12]. Using the same value for  $\alpha$  and  $\beta$  as for the NSII flame that achieved the aforementioned condition, 0.3 and 1e-11 respectively, resulted in the under prediction of the soot volume fraction in both the centerline and wings. In ethylene flames, the surface reactivity can compensate for deficiencies in the chemical kinetic mechanism [12]. However, since methane flames are less influenced by HACA growth, the deficiencies in the reaction scheme remain prevalent. The latest version of CoFlame has added reactions specifically for methane flames as detailed by Chernov *et al.* [12]. Although there is an improvement in the model's predictive capability, increasing soot concentrations, even when the surface reactivity is set to its theoretical limit of unity, both regions of the flame remain under predicted. When the aliphatic collision based inception is applied with the same  $\beta$  of 1e-11 as before and  $\alpha$  is increased to 1, the theoretical maximum, there is an increase in the soot volume fraction along both the centerline and wings. Once again, the same peak shifting phenomenon can be observed. The aliphatic collision based inception model is able to improve the comparisons to experimental data, but not rectify all remaining inaccuracies in the methane flame.

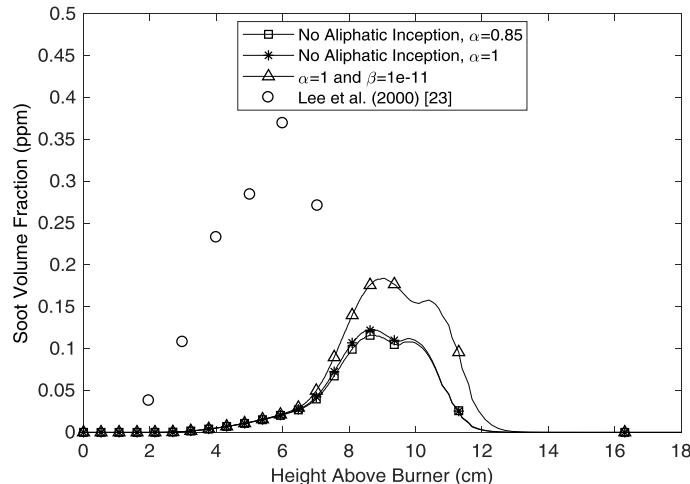

Figure 3. Predicted soot volume fraction as a function of height above the burner for a model without aliphatic inception using  $\alpha$  of 0.85 and 1.0 along the wings of the methane flame. The aliphatic inception model is shown using the same  $\beta$  as for the NSII, 1e-11. The experimental work of [20] is plotted.

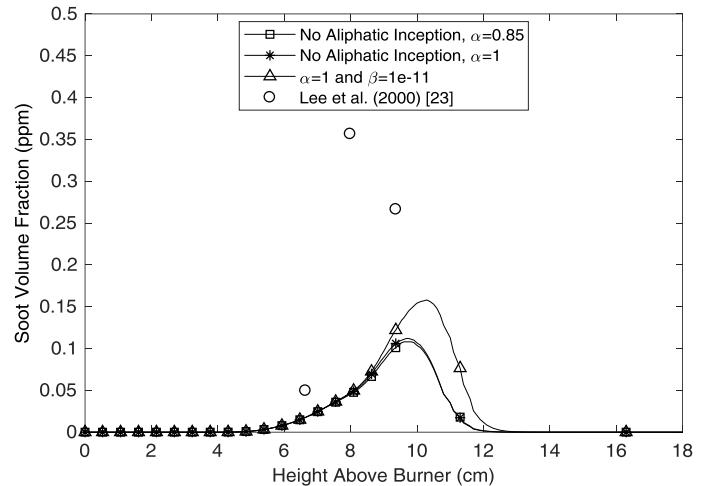

Figure 4. Predicted soot volume fraction as a function of height above the burner for a model without aliphatic inception using  $\alpha$  of 0.85 and 1.0 along the centerline of the methane flame. The aliphatic inception model is shown using the same  $\beta$  as for the NSII, 1e-11. The experimental work of [20] is plotted.

## V. SUMMARY AND CONCLUSIONS

A new collision based inception mechanism was developed using an existing framework for larger PAHs but applied to aliphatics. The aliphatic inception mechanism was combined with PAH inception and implemented in the CoFlame code. The influence that an aliphatic-collision based inception model would have on the soot volume fraction distribution for coflow ethylene/air and methane/air laminar diffusion flames was investigated. It was found that for the ethylene flame, a surface reactivity,  $\alpha$  of 0.3 and a collision efficiency,  $\beta$  of 1e-11 resulted in an increase in the peak soot volume fraction along the centerline, better predicting experimental values, while the predicted peak soot volume fraction along the wings was not degraded. For the methane flame, using the same  $\beta$  of 1e-11 resulted in an increase in both the centerline and wings of the flame as compared to using the same  $\alpha$  in a soot model without aliphatic-collision based inception. Future work remains to test the applicability of the model to other combustion systems, in particular those for which model predictions do not completely explain or characterize experimental data.

To test the validity of the model further, the results will be expanded to other flame systems in order to ensure applicability to a wide variety of flames. The results of the mechanism need to be applied to the other pure ethylene/air diffusion flames studied by Santoro *et al.* [17, 18] to observe the effects this mechanism would have in those systems. The other ethylene flames suffer from the same predictive discrepancies as the NSII flame. A potential pathway of interest may also be to consider aliphatic molecule condensation and determine if it plays a significant role in soot formation. The current model acts as a proof of concept in that transfer of carbon mass from the aliphatic gas phase to soot particles seems to significantly improve the model's predictive capability in the centerline region of the flames studied, without degrading the HACA growth dominated wings.

## ACKNOWLEDGEMENTS

The authors thank Dr. Nadezhda Slavinskaya and Prof. Uwe Riedel of the German Aerospace Center (DLR) for providing the chemical reaction mechanism, thermodynamic data, and transport data for ethylene combustion and PAH formation. The authors acknowledge the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support. This research was enabled in part by support provided by Sharcnet of Compute Canada.

**Abstract**— Glass remains a difficult to machine material. Its brittleness, chemical resistance and relatively high thermal conductivity challenges available technologies. An interesting approach is to the use of hybrid technologies such as Spark Assisted Chemical Engraving (SACE) which is a thermochemical process. Micro-drilling and micro-milling were intensively characterised and developed. SACE can however as well be used to micro-cut glass. This aspect was so far never discussed in the literature and no systematic data about its performance are available. As a first step, basic parameters such as depth of cut and tool feed rate must be determined. This communication aims to report systematic experiments on micro-cutting glass by SACE technology and demonstrates how using available data from SACE micro-drilling the maximal depth-of-cut and tool feed can be determined. Relations for depth-of-cut and tool feedrate are proposed to use as guidance for glass micro-cutting.

## I. INTRODUCTION

The application of glass science to the improvement of industrial tools occurred only in the past century, with a few exceptions. Glass has been employed in many forms to fabricate glazing and containers for centuries while it is now entering new applications that are appearing in micro and even nanotechnology like fibers, displays and Micro-Electro-Mechanical-System (MEMS) devices [1]. Many qualities make glass attractive since it is transparent, chemically inert, environmentally friendly and its mechanical strength and thermal properties. In fact, no other materials being mass-produced have shown such qualities over so many centuries. Nowadays glass offers recycling opportunities and allows for tailoring new and dedicated applications. Moreover, glass is radio frequency (RF) transparent, making it an excellent material for sensor and energy transmission devices. Another advantage of using glass in microfluidic MEMS devices [2] is its relatively high heat resistance, which makes these devices suitable for high temperature microfluidic systems [3] and sterilization by autoclaving.

However, glass remains a difficult to machine material. Its brittleness, chemical resistance and relatively high thermal conductivity challenges available technologies. An interesting approach is to the use of hybrid technologies such as Spark Assisted Chemical Engraving (SACE) [4] which is a thermochemical process (Fig. 1).

In SACE process, a voltage is applied between tool- and counter-electrode dipped in an alkaline solution - typical NaOH or KOH (Fig. 1). At high voltages (around 30 V), the bubbles evolving around the tool electrode coalesce into a gas film and discharges occur from the tool to the electrolyte through it. Glass machining becomes possible due to thermally promoted etching (breaking of the Si-O-Si bond) [4].

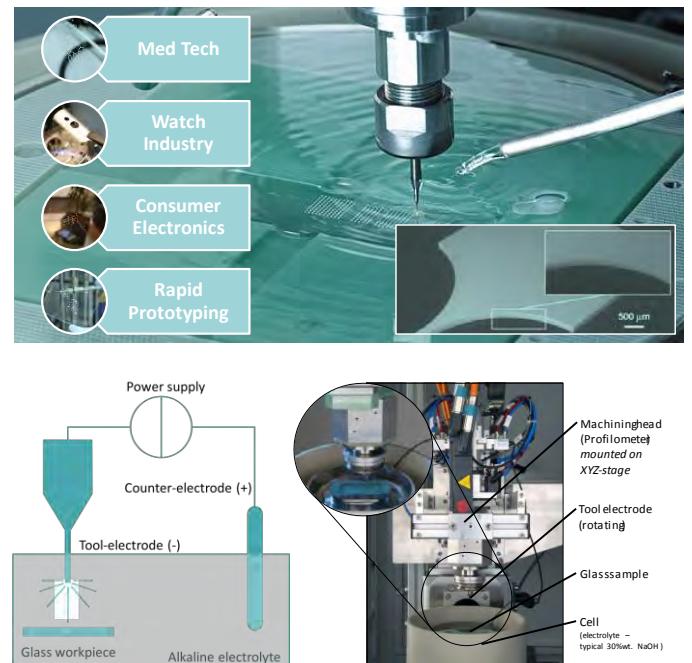

Figure 1. *Above left:* Overview of targeted applications/markets for SACE glass machining. *Above right:* SACE machined micro-hinge (scale bar = 500 μm - width of 'hinge' = 30 μm - thickness glass = 100 μm). *Below left:* Principles of SACE machining. *Below right:* SACE machining head.

Developed since the sixties in last century in academia [5], SACE found recently its entrance in the industrial world. Micro-drilling and micro-milling were intensively characterised and developed. The introduction of pulsed voltage machining did made a further significant step forward in term of quality of machining. SACE can however as well be used to micro-cut glass. This aspect was so far never discussed in the literature and no systematic data about its performance are available. As a first step, basic parameters such as depth of cut and tool feed rate must be determined. This is the aim of the present communication which reports systematic experiments on micro-cutting glass by SACE and demonstrates how using available data from SACE micro-drilling maximal depth-of-cut and tool feed can be determined.

## II. MATERIALS AND METHODS

Micro-cutting of pyrex glass (microscope slides) was performed on a Posalux FP1-SACE machine (Fig. 2). The machine incorporates a force sensor in the machining head that allows online measurement of the axial force (down to 1 mN) exerted on the tool-electrode. As electrolyte 30wt% Potassium Hydroxide (KOH), prepared from de-ionised water, was used. Low viscous electrolyte is chosen to reduce the chance that flushing with fresh electrolyte at the machining zone becomes the limiting factor for machining/cutting.

Cylindrical tool electrodes, made of tungsten carbide, 100  $\mu\text{m}$  diameter with a bevel of 45° where used. The spindle rotated at 1000 rpm. Cuts were performed over an equivalent length of at least two minutes of micro-cutting, adapted at the operating cutting speed.

After cutting, images with an optical microscope (Keyence VHX 5000) were acquired in order to evaluate precisely the realized depth-of-cut and to evaluate the cut qualitatively.

Figure 2. Posalux FP1-SACE machine (modular system)

## III. THEORY

Material removal rate in SACE machining is limited, in case flushing of the machining zone happens easily, by heat propagation in the glass workpiece [4]. In the case of micro-cutting, electrolyte can access freely to the machining zone by appropriate flushing, using side tubes for electrolyte supply in the machining cell (Fig. 1). Further machined material is removed readily from it through the cut. Consequently, as a first approximation, one can discuss the relation between the axial depth of cut  $p$  and horizontal feed rate  $F$  (see Fig. 3 for a schematic) in terms of time needed for the heat to propagate inside the workpiece: one has to give enough time to the workpiece to heat up while one moves the tool.

Consider a tool of radius  $r$ . In the time interval

$$t_F = \frac{2r}{F} \quad (1)$$

the tool will move over its own size. If heat propagates at the rate  $h_r$  inside the workpiece, then the time  $t_h$  needed to heat a distance  $p$  is given by

$$t_h = \frac{p}{h_r} \quad (2)$$

If heat propagation is the rate limiting process, the tool cannot move faster than the feed rate  $F$  at an axial depth of cut  $p$  such that ( $t_F$  and  $t_h$  must be of the same order of magnitude):

$$F \cdot p = 2r \cdot h_r \quad (3)$$

Equation (3) shows that, under the stated hypothesis that machining is only limited by heat propagation, the maximal value of the product  $Fp$  is, for a given tool and workpiece, a constant value. Note that, as the time  $t$  needed to cut a path of length  $L$  and depth  $d$  is given by

$$t = L \cdot d \frac{1}{F \cdot p} \quad (4)$$

in SACE cutting, the time needed to perform a given cut is essentially constant regardless of the values of  $F$  and  $p$  chosen.

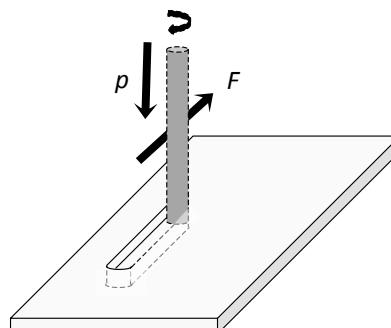

Figure 3. Schematic representation of micro-cutting by SACE process with a rotating tool-electrode (radius  $r$ ) moving horizontally with feedrate  $F$  at an axial depth of cut  $p$ .

The heat propagation rate  $h_r$  is function of the geometry of the problem and the energy put into the system (i.e. energy produced by the spark activity around the tool electrode). Estimations of the heat propagation rate in case of drilling for cylindrical tools are reported in the literature [4] and can be used as a first input.

Explicit calculation of the product  $F \cdot p$  using equation (5.23) from [4] is found to be:

$$F \cdot p = 4a \cdot \frac{\kappa - 1}{\kappa} \left[ 1 - \exp \left( -\pi \left( \frac{\kappa - 1}{\kappa} \right)^2 \right) \right] \quad (5)$$

with  $a$  the thermal diffusivity of the workpiece ( $a \sim 6 \cdot 10^{-7}$  m<sup>2</sup>/s for Pyrex® glass). Relations between the dimensionless number  $\kappa$  and voltage  $U$  are empirically derived in section 5.2 of [4]:

$$\kappa = 0.018 \cdot U + 0.615 \quad (6)$$

Equation (5) and (6) allows to establish a direct relationship between the machining voltage  $U$  and the product  $F \cdot p$  which can be used to define the material removal rate (MRR) when multiplying with the tool diameter.

#### IV. RESULTS AND DISCUSSION

To determine experimentally the maximal depth-of-cut  $p$  at a given tool feed rate  $F$  a series of cuttings of 0.4 mm thick glass slides (Pyrex®) were performed. The cut was considered to be successful if

- a) The tool didn't break, and
- b) The measured depth of the cut was equal or higher than the imposed depth of cut during machining.

From a practical point of view, thanks to the force sensor inside the tool-electrode holder, it was possible to detect none successful cuts due to an increased force acting on the tool (a few mN). Pulsed voltage with 2.5ms pulse high time ( $t_{high}$ ) and 0.1ms pulse low time ( $t_{low}$ ) was used. In such conditions the gas film shows high stability and very few bubbles are observed around the tool-electrode. Cutting experiments were performed at three pulsed machining voltages (high, intermediate and low) as denoted in table 1.

The average input voltage  $U_{avg}$  can be calculated according:

$$U_{avg} = (t_{high} - t_{low}) / (t_{high} + t_{low}) \Delta U_{pulse} + U_{lowlevel} \quad (7)$$

TABLE I. SACE MACHINING SETTINGS

Pulsed Voltage Input				
High Level	Low Level	Period	Duty Cycle	
Low	30 V	17.5 V	2.6 ms	96.15 %
Intermediate	33 V	17.5 V	2.6 ms	96.15 %
High	35 V	17.5 V	2.6 ms	96.15 %

TABLE II. HEAT PROPAGATION IN GLASS WORKPIECE

Machining voltage [V]	F·p [mm <sup>2</sup> /min]
30	1.0
33	1.6
35	2.2

Using these machining voltages (table 1 and equation (7)) as input in equations (5) and (6) we estimate the values for  $F \cdot p$  as outlined in table 2.

As shown in Fig. 4, the maximal depth of cut for a given tool feed follows equation (3). The dashed lines were obtained by least square fits.

The quality of the cut is assessed by optical microscopy for the different machining voltages (low – intermediate – high voltage) and at varying feed rate and depth-of-cut (Fig. 5).

It can be clearly observed that quality of the glass cut generally increases when the machining voltage reduces (indents of  $\sim 75 \mu\text{m}$  –  $60 \mu\text{m}$  –  $50 \mu\text{m}$  for respectively 35 V – 33 V – 30 V at maximum cutting depth for each voltage and feedrate = 5 mm/min.). Decreasing the depth of cut results generally also in higher machining quality. In the extremes, when machining at same feedrate -  $F = 40 \text{ mm/min}$  - and low depth of cut, the machining quality is around the same for all applied machining voltages.

Reasonable quality of cut in glass by SACE technology can be obtained using the derived tool feed vs. depth of cut relations. It should be noted that this model is not optimized for quality of cut surface and other strategies, such as ‘SACE polishing’ by approaching the surface with small lateral increments of the tool-electrode at very low voltage, can be followed to achieve surface qualities in the order of a few microns.

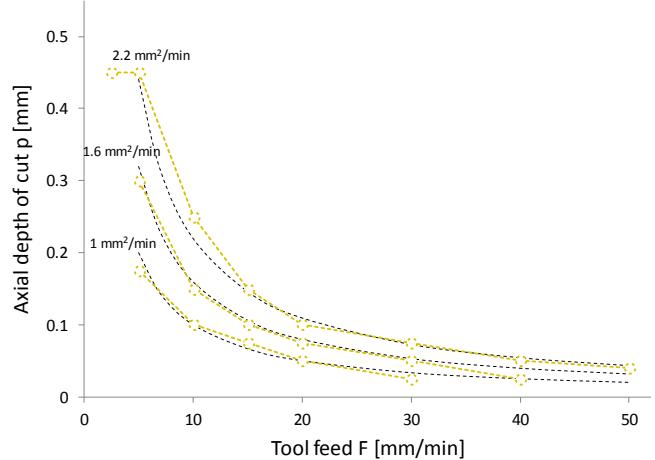

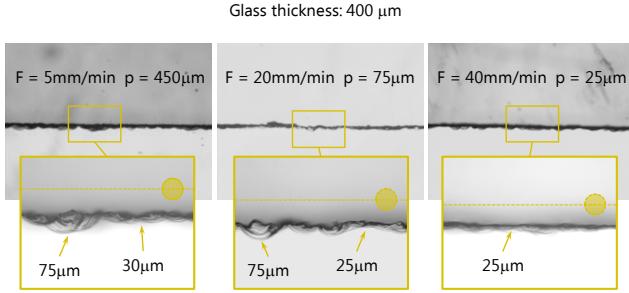

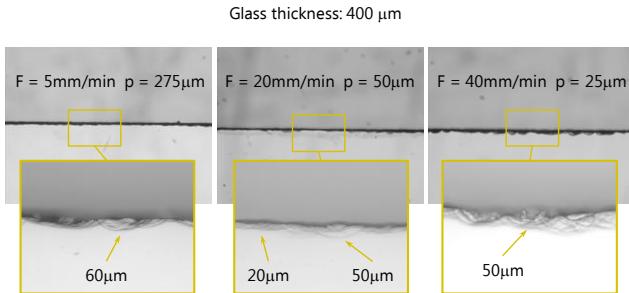

Figure 4. Yellow: Empirical values for maximal depth-of-cut  $p$  [mm] versus tool feedrate  $F$  [mm/min] for tungsten carbide 100  $\mu\text{m}$  diameter tools. Grey dashed lines: Theoretical model values.

Machining voltage – 35 V : 17.5 V / 2.5 ms : 0.1 ms

Machining voltage – 33 V : 17.5 V / 2.5 ms : 0.1 ms

Machining voltage – 30 V : 17.5 V / 2.5 ms : 0.1 ms

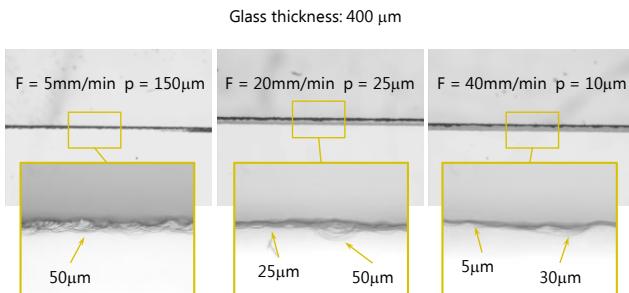

Figure 5. Microscopy (Keyence VHX 5000) analysis of cut quality at different machining voltage, feedrate and depth-of-cut.

## V. CONCLUSIONS

- Cutting parameters for tungsten carbide 100  $\mu\text{m}$  diameter cylindrical tools (with 45° bevel) were determined;
- A simple model relating the lateral tool feedrate  $F$  to the maximum depth-of-cut  $p$  based on the assumption that machining is only limited by heat transfer in the workpiece was presented and matches well the measured data;
- Cut quality was evaluated by optical micro-graphs for different machining voltages (high, medium and low voltage).

The developed model allows to predict the maximum depth of cut for a given tool feedrate, which eliminates time-consuming ‘trial runs’ before machining to determine the best cutting parameters. Hence, this study contributes to further optimization of SACE technology for industrial use.

# A Finite Element Model to Study the Effect of Porosity Location on the Elastic Modulus of a Cantilever Beam

Stephen Handigan

Department of Mechanical Engineering  
Memorial University of Newfoundland  
St. John's, Canada

Sam Nakhla

Department of Mechanical Engineering  
Memorial University of Newfoundland  
St. John's, Canada

**Abstract**— The effect of the location of porosity concentration on elastic modulus of a cantilever beam is investigated. First, two-dimensional investigation with beam theory, Euler-Bernoulli and Timoshenko, was performed to estimate the modulus based on load-deflection curve. Second, three-dimensional finite element model (FEM) in Abaqus was developed to identify the effect of porosity concentration. The use of macro-models such as beam theory and three-dimensional FEM enabled enhanced understanding of the effect of porosity on modulus.

**Keywords**-porosity, elastic modulus, FEA, micro-mechanical, cantilever

## I. INTRODUCTION

### A. Background

It is known that porosity affects the mechanical properties of metals. In many materials, increases in macroscale pore sizes have shown to decrease ultimate strength, yield stress, and fatigue life [1]. However, due to advancements in manufacturing, pores in metals tend to be on the microscale instead of macroscale. This presents new concerns since the effect on a material's mechanical properties due to this microporosity is unknown [2]. This is critical because without understanding how microporosity affects a material, the ability to predict behaviour due to loading throughout its life cycle is difficult. Throughout the life cycle of a structure, exposure to various environmental conditions, sometimes harsh, is possible. Due to these environmental conditions, it is possible that porosity can be increased in the material. As such, structures may be affected in various locations, and in differing amounts, depending on the exposure to the environment. It is critical to understand if the location of porosity has an effect on a structure.

### B. Purpose of Study

It is known that porosity has an effect on elastic modulus. The work of Morrissey and Nakhla [3] presented a literature review on existing models available in literature. These models, mostly empirical, describe the effect of porosity on elastic modulus. Morrissey and Nakhla developed a two-dimensional

finite element model (FEM) that successfully captured the effect of porosity on elastic modulus in tension.

In the current work, a three-dimensional FEM is developed to investigate the effect of porosity on modulus. The effects of uniform distribution or concentrated zones of porosity was investigated. All FEM results were compared to test data reported in literature.

## II. PROCEDURES

### A. Understanding Experimental Setup and Data

The first step in this study was to examine experimental load versus deflection data for micro-cantilevers. For this study, the work by Gong [4] was first analyzed to understand the correct beam theory to apply for determining elastic modulus, as well as to develop the three-dimensional FEM. It is reported in [4], for beam 5, an experimental elastic modulus of 147 GPa. As well, their three-dimensional FE model captured the trend of porosity reduction with an average error in prediction of 38% compared to experimental.

It is reported in [4] that samples were heat treated such that an average grain size of 8-10  $\mu\text{m}$  was obtained. From these samples, the micro-cantilevers were produced at the University of California, Berkeley (UCB) using a focused ion beam (FIB). The FIB was used to cut three trenches using a 7-15 nA beam current – forming a U-shaped trench that had a width of 20-30  $\mu\text{m}$  and a depth of 10  $\mu\text{m}$ . Then using a 1-3 nA beam current, the outline of the beam was refined. Lastly, the sample was rotated 45° both clockwise and counter-clockwise around the length of the beam to allow for cutting of the triangular bottom of the beam. Using a MicroMaterials nanoindenter with a square tip, UCB was able to obtain the load and deflection data for the micro-cantilevers. The depth of indentation into bulk material was removed from the experimental deflection to ensure only the displacement due to bending is accounted. Lastly, the load was applied with a displacement rate of 10 nm/s to the tip of the micro-cantilever until fracture.

The micro-cantilever is approximately 7.5  $\mu\text{m}$  tall, 4  $\mu\text{m}$  wide, and 28  $\mu\text{m}$  long – load is applied at approximately 27  $\mu\text{m}$  from the root, this will be taken to be the length since deflection is also measured at this location. The cross-section is pentagonal shaped, proposed in [5]. The beam is considered to be short and stubby with a length-to-height ratio of less than

four. The beam is not undergoing uniform bending (concentrated load introduces shear forces) and the beam is not rigidly connected to the support. Due to these factors, shear effects may be highly pronounced at the root. Therefore, both Euler-Bernoulli and Timoshenko beam theories were used in the current study.

Using the load-deflection curve reported in [4], the data was extracted and the slope for the linear section was determined to be approximately 1932 N/m. Next, the modulus was calculated using Euler-Bernoulli and Timoshenko beam theory, resulting in 148 GPa and 154 GPa, respectively. This is compared to the reported modulus in [4] in Table I below. Due to the beam geometry, boundary conditions, and the manner at which the load is applied, it is most likely that Timoshenko beam theory is more accurate because the effect due to shear is included. As such, Timoshenko beam theory will be the method of calculating the elastic modulus within this study.

TABLE I. COMPARISON OF CALCULATED MODULUS

Beam Theory	This Study	Reported in [4]
Euler-Bernoulli	148 GPa	147 GPa
Timoshenko	154 GPa	-

For this study, several assumptions are made. Uranium Dioxide is highly anisotropic [6-7]; however, it is assumed that the material acts as an isotropic material since the micro-cantilevers are ideally contained within a single crystal-grain. It is reported in [4] that not all micro-cantilevers are within a single grain; however, without additional information on number of grains and grain orientation, the assumption will remain. The FEM assumes the beam is solid, homogeneous and has a constant cross-section. Lastly, it is assumed that the effect on Poisson's ratio for porosities less than 5% is negligible [8-9]. The FEM assumes uniform porosity distribution across the cross-section.

### B. Finite Element Model – Three-Dimensional Beam

To build the FEM, a three-dimensional, deformable solid part was created in Abaqus. The substrate was sketched and extruded to create a cube. From the front face, the geometry was sketched and extruded to create the beam. The actual beam from [4] and the currently developed FEM is shown in Fig.1. The beam and substrate were then partitioned to allow for separate modification of material properties and mesh development. The beam was further partitioned into three segments of equal length, shown in Fig. 2. This allows for different material properties to be applied to each segment. The next step was to develop the mesh. The mesh was refined differently within the beam than the substrate. The beam had 11,088 3D Stress Hex Quadratic (Reduced Integration) elements, while the substrate had 4,464 3D Stress Hex Quadratic (Reduced Integration) elements.

The next step was to apply boundary conditions to the FEM. The side, rear, and bottom faces of the substrate have fixed boundary condition, while the top and front faces, as well as the beam, are free surfaces, as shown in Fig. 3 (lighter colours indicate free while dark indicate fixed). Next, a tip

load was applied to the beam. The deflection is measured from the bottom side, directly under the location of the applied load, to ensure indentation into the top surface of the beam due to the load was not accounted, thus skewing the deflection data.

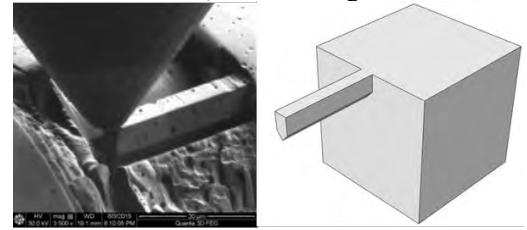

Figure 1. SEM Picture of Experimental Setup [4] (left), Abaqus FEM this study (right)

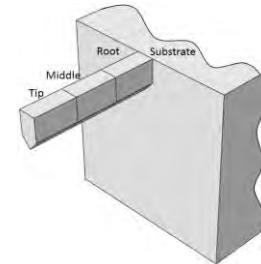

Figure 2. Beam Sections (From left to right: Tip, Middle, Root, Substrate).

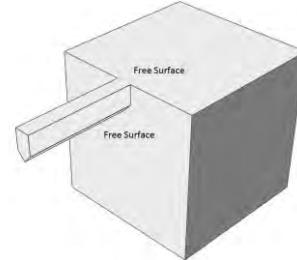

Figure 3. Boundary Conditions (Top, Front, and Beam are free surfaces; all other sides fixed).

Once the FEM was developed, the first test was to determine the calculated modulus of a perfect beam with nominal modulus and zero porosity. This was to provide a baseline for the predicted modulus due to the boundary conditions alone. However, it was unsure if the size of the substrate would have an effect on the results and as such, the FEM was first tested with various substrate sizes.

The substrate was constrained to be a solid cube in each case. Four substrate sizes were considered and the dimensions were scaled due to the beam's largest dimension – height. Sizes were labelled A through D, with A being the smallest and D the largest. Substrate size A was approximately the same size as the height of the beam. Substrate sizes B, C, and D were approximately one-and-a-half times, three-times, and six-times larger than the beam height, respectively. A comparison of the moduli obtained for the four cases is shown below in Table II. As can be seen, the size of the substrate does affect the response of the beam; however, as long as the substrate is at least three-times the height of the beam, the effect is

insignificant. This is expected since when the substrate is small, the fixed boundary condition has a greater effect on the rigidity of the root of the beam, thus, stiffening the beam and over-predicting the modulus. As the substrate size is increased, this effect is reduced to a point such that the modulus is unchanged since the fixed boundary condition is sufficiently far enough away from the root of the beam. For this study, Substrate size D was chosen for the FEM to ensure the fixed boundary condition did not influence the results.

TABLE II. COMPARISON OF SUBSTRATE SIZE

Substrate Size	Modulus Calculated (GPa)
A	186.7
B	182
C	180
D	180

With the size of the substrate determined, the modulus obtained due to the boundary conditions alone was 18% less than the nominal value. This will be considered the base case value and the effect on modulus due to porosity amount and location will be compared.

### C. Finite Element Model – Reduction in Modulus due to Porosity under Bending

Before an analysis can be completed, a FEM must first be developed to determine the percent reduction in elastic modulus versus the position of porosity concentration along the beam, similar to [3]. A two-dimensional FEM was developed to determine this reduction. The FEM was a long, slender beam, with uniform cross-section, and rigidly supported at the root.

The FEM is assumed to have a nominal elastic modulus with zero pores to establish a base case. Next, the elastic modulus is calculated from load and deflection data at the tip. Using this calculated modulus, it was normalized with the nominal value to provide a percent reduction in modulus. This was repeated with various pore locations and pore sizes to simulate various porosities and porosity concentration locations. The results of this FEM are shown below in Fig. 4.

As the porosity concentration moves further away from the root, the percent reduction in elastic modulus decreases. These percent reduction values were applied to the nominal elastic modulus for Uranium Dioxide and new moduli were calculated for when porosity is concentrated within different sections of the beam. A similar process was completed for when the porosity is uniformly distributed over the entire length of the beam. In this case, the percent reduction was approximately equal to the reduction experienced when porosity was concentrated at the tip for both porosities.

Next, these reduced moduli were imported into the three-dimensional FEM for the various setups. These moduli were applied to specific sections of the beam where the porosity was to be concentrated while the remaining sections of the FEM, including the substrate, were considered to be equal to the nominal modulus of 219 GPa for Uranium Dioxide [10].

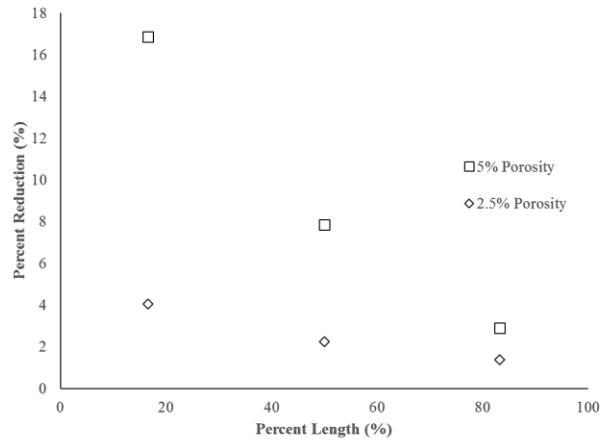

Figure 4. Percent reductions in modulus due to porosity concentration along percent length of the beam.

### III. RESULTS AND DISCUSSION

The results for moving the porosity concentration from the root to the tip is shown in Table III. When the porosity is concentrated at the root, the reduction in modulus is the greatest, while moving towards the tip this reduction decreases. This trend is further supported by the Reduction in Modulus due to Porosity under bending FEM. Furthermore, Gong has successfully demonstrated in [4] that the location of pore concentration does affect the modulus, with the largest effect at the root and decreasing away from the root.

When comparing the percent reductions determined from the two-dimensional and three-dimensional FE models in this study, the values differ. There are several reasons for these discrepancies: 1) different applied boundary conditions, 2) different cross-section, thus different second moments of area – three-dimensional FEM is pentagonal whereas two-dimensional represents rectangular, and 3) general errors converting from two-dimensional to three-dimensional FEM.

When comparing to Gong's results, there is a large difference in the values. There are several reasons for these discrepancies: 1) pore location relative to neutral plane in Single Pore FEM [4] is unknown – pores further away will have a larger effect on reducing modulus, 2) pore distribution is not uniform across cross-section in Cluster Pore FEM [4] – pores constrained within rectangular-portion of the beam (no pores located in the triangular section), and 3) uncertain boundary conditions – Gong initially completed a substrate-size sensitivity-analysis, but for the FEM of the reconstructed beam, the substrate appears to be approximately the same size as the beam which would greatly influence the results due to the boundary conditions stiffening the beam.

In Fig. 5, the Abaqus FE models completed for this study are compared with experimental load versus deflection data reported in [4]. From this, it is evident that the FE models capture the trend of the experimental results from [4] with average error of 14.8%. However, there is some error which can be contributed to the assumptions made in this study. The FE models completed in this study assumed a uniform, constant cross-section, free of imperfections, which is not the

case when observing SEM images of the beam in [4]. As well, the FE models were isotropic due to the single-grain assumption, but as reported in [4] this was not true. Lastly, the porosity concentration in the FE models completed in this study do not include the effect of pores away from the neutral plane – it is assumed the porosity is concentrated uniformly across the cross-section with no bias away from the neutral plane.

In Fig. 6, all FE models by this study and by Gong are compared with the experimental data. It is evident that Gong's Single Pore Root FEM has the largest effect, comparable to this study's FEM for 5% porosity concentrated at the root. The placement of this single pore from the neutral plane is unknown and as such it is difficult to compare to the FE models completed in this study.

In Fig. 7, all 2.5% porosity models are compared with the experimental data. Again, Gong's Single Pore Root FEM has the largest effect on the load-deflection response. However, when comparing the Cluster Pore FE models from [4] to the FE models completed in this study, it is evident that the Cluster Pore FE models are over-predicting the elastic modulus. This may be due to the orientation chosen by Gong to model the cluster of pores. This orientation differs from the assumed uniform porosity concentration for the FE models completed in this study, hence the lower reductions.

In Fig. 8, a comparison is shown between Gong's experimental data and FE models. Gong's FE models show a much better agreement to the experimental data than is reported in [4] with an average error of 21.8% with experimental.

The FE models completed in this study, which assume uniform porosity distribution across the cross-section, show with certainty that porosities of 5% have a large effect on the behaviour of the beam when concentrated close to the root. However, if these large porosities are uniformly distributed over the length, or concentrated in a location away from the root – at or beyond half the beam length – the effect decreases drastically. Whereas, for porosities of 2.5% and lower, it can be concluded that there is minimal effect on the beam's modulus regardless of distribution and concentration throughout the length.

#### IV. CONCLUSIONS

This study has proven that the amount of porosity and the location of said porosity has an effect on the elastic modulus. Several cases were analyzed and it was determined that porosities concentrated at the root have the largest effect on the elastic modulus of a cantilever, while porosities uniformly distributed over the length, or concentrated away from the root, have minimal effect on elastic modulus.

# Microfluidic Method of Viscosity Measurement in Propane-Saturated Bitumen

Mira Kim

University of Toronto  
Toronto, Canada

**Abstract**—In this paper, the viscosity propane-saturated bitumen was measured through a microfluidic chip. Property measurement of propane-saturated bitumen has been traditionally done on a heavy-duty PVT cell, and the application of microfluidics in high temperature and pressure conditions to measure the properties of bitumen is a novel technique. There are two steps in the viscosity measurement of propane-saturated bitumen. First, the propane saturated bitumen is prepared in a high-pressure piston cylinder through propane injection in bitumen at a pressure above its saturation pressure. This propane-bitumen sample is left to saturate till it there is no further pressure drop. Then the propane-saturated bitumen is pushed through the microfluidic chip and the viscosity of the bitumen is measured by the pressure differences and the imaging of the fluid end, as an application of the Poiseuille's law.

**Keywords-Bitumen, Oil sands, Microfluidics, Propane, PVT, Viscosity, Diffusion**

## I. INTRODUCTION

Steam-assisted-gravity-drainage (SAGD) is a commercially successful oil recovery method for Canadian oil sands, also known as bitumen, by utilizing the heat transfer from steam condensation process to mobilize the highly temperature sensitive bitumen. Solvent-SAGD process is a modification of the SAGD process, where solvents are used as additional components to reduce the viscosity of bitumen through mass transfer. [1] Vapor extraction technique (VAPEX) is an oil extraction process primarily using the effect of viscosity reduction through mass transfer by injecting light hydrocarbons as propane into bitumen. [2]

As the solvent saturation in bitumen is a crucial part of the VAPEX process, measurement studies to determine the saturation of solvents have been conducted. Pressure-decay method is a popular technique to measure the diffusivity in the gas-liquid systems. [3-7] The first step in the calculation of the diffusivity is to define the appropriate mass-transfer equations. [3] A simplified model of this is the unsteady one-dimensional mass diffusion equation, also known as the Fick's second law of diffusion. Fick's second law of diffusion can be written as below:

$$\frac{\partial c}{\partial t} = D \frac{\delta^2 c}{\delta z^2}$$

where  $c$  is the solvent concentration in bitumen,  $z$  is the distance from the bottom of the diffusion cell, and  $D$  is the diffusion coefficient of the solvent in bitumen.

The application of Fick's law to the diffusion process in solvent-bitumen has been an interest to many scientists. Tharanivasan et al. [4] published a paper, applying three different boundary conditions to solve this equation. First is the equilibrium boundary condition, where the boundary condition assumes that the heavy oil-solvent interface is saturated with the solvent under the so-called equilibrium at all times. Second is the quasi-equilibrium boundary condition, where the heavy oil-solvent interface is assumed to be saturated with the solvent at the existing pressure in the solvent phase. Third is the nonequilibrium boundary condition, where the solvent mass-transfer flux across the interface is proportional to the difference between the solvent saturation concentration under the equilibrium pressure and the existing solvent concentration at the surface. According to Tharanivasan's paper, the mass transfer across the heavy oil-propane interface is best described by applying the quasi-equilibrium boundary condition.

The study of solvent diffusion in bitumen has been conducted using experimental methods as well. Etminan et al. [5] published a paper on the constant pressure technique for gas diffusivity and solubility measurements in heavy oil and bitumen where the boundary conditions were set experimentally to an equilibrium state. This was accomplished by continuously injecting the required amount of gas into the gas cap from a secondary supply cell to maintain the pressure constant at the gas-liquid interface. Additionally, Behzadfar et al. [6] measured the diffusivity of carbon dioxide in bitumen in a pressure-decay method coupled with rheometer. Mixing due to shear imposed by a rheometer allows rapid direct measurement of the equilibrium pressure in the carbon dioxide-bitumen system.

Microfluidics methods of measuring diffusivity has been studied by Fadaei et al. [8] In Fadaei's paper, toluene was injected to a partially bitumen filled microfluidic chip, and one-dimensional diffusion of toluene and bitumen was quantified by through-plane visible-light transmission imaging. Then, by fitting the experimental data to the concentration profiles obtained using a numerical model, diffusion transport dynamics were quantified. The results showed that for intermediate toluene-mass fractions (0.2-0.8), a constant diffusion coefficient of  $2.0 \times 10^{-10} \text{ m}^2/\text{s}$  was measured. However, at low toluene mass fractions (<0.2),

significantly reduced diffusive transport was observed, and endpoint analysis indicated diffusion coefficients trending towards  $4.3 \times 10^{-11} \text{ m}^2/\text{s}$ . At high toluene mass fractions ( $>0.8$ ), the values trend towards  $1.5 \times 10^{-10} \text{ m}^2/\text{s}$ .

Fadeai et al. [9] also measured the diffusivity of bitumen-carbon dioxide by using a cross-channel glass microfluidic chip. The device was initially filled with carbon dioxide at low pressure (<1.0 bar). A plug of bitumen was injected into the central (50  $\mu\text{m}$  wide and 20  $\mu\text{m}$  deep) channel and subsequently exposed to high-pressure carbon dioxide on both ends. One-dimensional oil swelling in response to carbon dioxide diffusion was imaged over time. A simple mathematical approach was applied to calculate the diffusion coefficient based on the oil-swelling data. Measurement results are reported here at a range of pressures (1-5 MPa) and room temperature (21 °C). The measured diffusion coefficients in this range are on the order of  $10^{-10} \text{ m}^2/\text{s}$ , in good agreement with the relevant published data using conventional methods. The biggest advantage of this method was that it required up to 10 min of time and a 1 nL plug of sample in comparison with conventional methods that require hours or days and up to 0.5 L of sample.

In this paper, measurement of bitumen viscosity with propane saturation was conducted using a microfluidic method. Though viscosity measurement through a microfluidic device has been previously done in biological research, [10-13] the property measurements of solvent saturated bitumen have traditionally been done in macroscale experimental apparatus. [14-22] The use of the glass microfluidic chip in this work allows experiments to have advantages in sample size reduction and miniaturization of system design, bringing the heavy-duty petroleum PVT research on lab-on-a-chip scale.

## II. EXPERIMENTAL METHOD

The preparation of propane saturated bitumen was done on a high-pressure piston cylinder. Bitumen was filled in one end of the cylinder and water was filled on the other side. Then a certain volume quantity of liquefied propane was injected to the bitumen filled cylinder. Liquefied propane was used to quantify the amount of mass fraction in bitumen. Propane gas was liquified by drawing propane gas from the cylinder tank (Praxair) to a high-pressure syringe pump (ISCO 100D), and compressing the gas in the high-pressure syringe pump. Then the propane was injected to the bitumen filled side of the piston cylinder at a pressure quite above the saturation pressure, so that the propane saturation in bitumen could be achieved. Pressure was measured after the propane was injected in bitumen, and saturation was determined when the pressure drop was below the accuracy of the pressure gauges ( $\pm 1 \text{ kPa}$ ). The pressure drop rate showed a gradual decrease until eventually there was no pressure further pressure drop. The theoretical saturation pressure values were derived from equality of fugacity between the liquid and vapor phases. If the vapor phase is pure propane, the equation for the saturation pressure  $P$  is

$$P = x_{\text{c3}} \gamma_{\text{c3}} P_{\text{Vc3}}$$

where  $P_{\text{Vc3}}$  is the vapor pressure of propane in kPa, and  $\gamma_{\text{c3}}$  is the activity coefficient of propane in bitumen. According to literature, the best fit value of the activity coefficient was 1.158. This equation primarily indicates that higher pressure is needed to achieve a higher volume fraction of saturation. [2] Figure 1 shows the experimental setup to prepare the propane-saturated bitumen with the thought of connecting it to the microfluidic chip after the saturation. A high-pressure valve was used to close the system after the injection of propane to later connect it to the microfluidic chip.

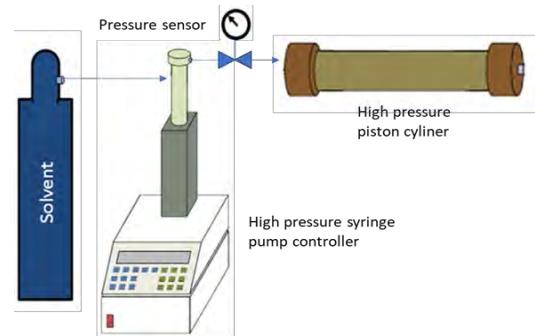

Fig. 1 Setup for propane saturation in bitumen

After the propane saturated bitumen sample was prepared, it was pushed to go through the microchannel in the microfluidic chip. The hydraulic diameter of the microfluidic chip was calibrated to be 76  $\mu\text{m}$  by reading the pressure and flowrate of a calibration fluid. The propane bitumen sample was pushed by applying a constant pressure on the other end of the cylinder by the ISCO pump. The pressures were 1.5 and 1.7 MPa, both values above saturation pressures. Poiseuille's law was used to measure the viscosity of the solvent-saturated bitumen through imaging the flow. Poiseuille's law is described as below

$$\frac{dx}{dt} = \frac{\Delta P r^4}{8 \mu x}$$

where  $x$  is the length of the fluid,  $r$  is the tube radius,  $\mu$  is the viscosity of the fluid, and  $\Delta P$  is the total effective pressure. Figure 2 depicts the experimental setup for the viscosity measurement of propane saturated bitumen.

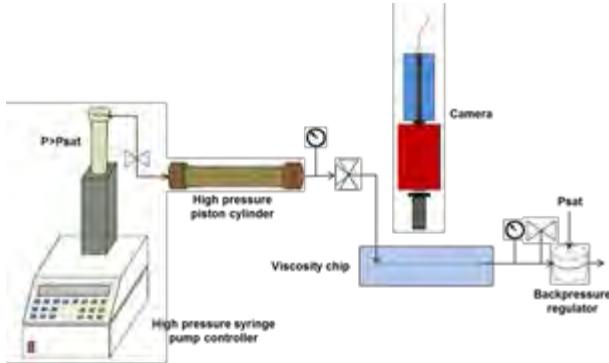

Fig. 2 Schematic for the viscosity measurement of the propane-saturated bitumen.

The experimental conditions of the two runs are summarized in Table 1. The propane fraction values were selected to compare a higher propane fraction ratio to a lower propane fraction ratio with the objective to demonstrate the effectiveness of solvent saturation in bitumen viscosity reduction.

Table 1 Experimental conditions and the measured viscosities for viscosity measurement of propane-saturated bitumen

Run#	Bitumen mass(g)	Propane mass fraction	Temperat ure (°C)	Pressure (MPa)	Measured Viscosity (cP)
1	2.83	0.10	20	1.5	65,000
2	2.83	0.25	20	1.7	565

### III. RESULTS AND DISCUSSIONS

In this section, two runs were done with different mass fractions of propane in bitumen. The experiments were captured using a video camera, and the video file was converted using a video to image converter. Figure 3 shows the movement of the bitumen in the first run by putting it into a sequence of frames in a time frame of frame per 10 seconds.

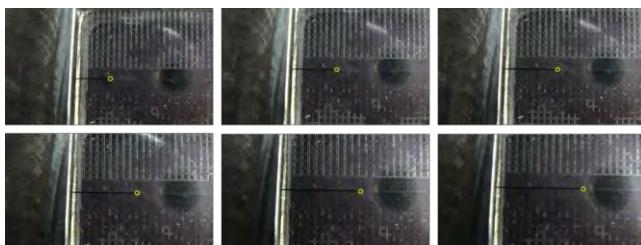

Fig. 3 Sequence of images of run #1 in every 10 seconds.

Figure 4 is an image capture from the higher propane mass fraction component run. The images were extracted to be 1/3 second per frame from the video to image converter.

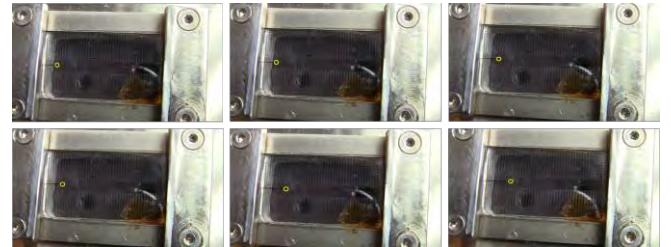

Fig. 4 Sequence of images of run #2 in every 1/3 second.

Figure 5 shows a comparison of run #1 and run #2 in a fuller time frame. Run #1 had a significantly slower advancement in the flow, and it took 8-9 minutes for the propane-saturated bitumen sample to completely fill the channel. In run #2, the propane saturated bitumen sample filled the channel in just 7 seconds, resulting in flow speed 2 order of magnitude higher than of run #1, indicating a significantly lower viscosity.

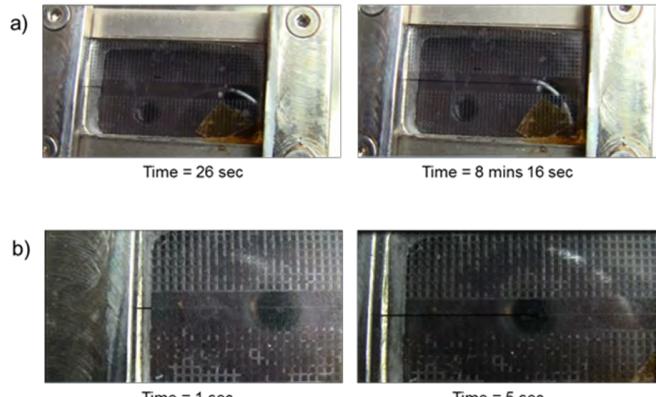

Fig. 5 Images of propane-bitumen flow captured at different times during a) run #1 and b) run #2.

These images were converted manually into two datasets by calculating the distance of the bitumen front advancement. The grids in the microfluidic chip was a useful standard for this calculation, each grid providing a 1 mm scale. Then, an excel linear curve fitting function was used to calculate the slope of the plots, and through the calculated linear constant, the viscosity was calculated. Figure 6 shows the graphs depicting the location of the bitumen front in time.

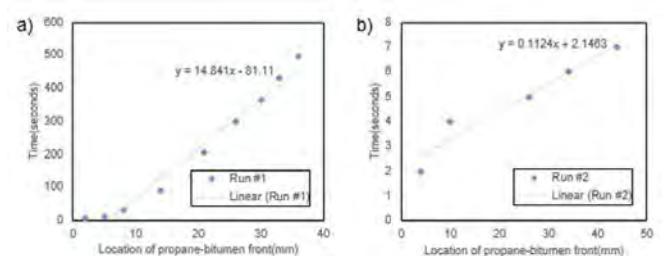

Fig. 6 Location of propane-bitumen flow front and time for a) run #1, and b) run #2.

While the viscosity measurement of solvent-saturated bitumen is still under study, various numerical methods have been developed to estimate the viscosity of bitumen. Here, the measured viscosity was compared with the modified Shu correlation equation. The modified Shu equation for the mixture is:

$$\mu = \mu_{\text{Bit}}^{x_{\text{Bit}}} \times \mu_s^{x_s}$$

$$x_{\text{Bit}} = \frac{\alpha V_{\text{Bit}}}{\alpha V_{\text{Bit}} + V_s}$$

$$x_s = 1 - x_{\text{Bit}}$$

$$\alpha = \frac{0.000375 \Delta \rho^{-8.56653} \rho_{\text{Bit}}^{4.567001} \rho_s^{-5.27094}}{\ln(\mu_{\text{Bit}}/\mu_s)}$$

where  $\mu$  is the viscosity of the mixture,  $V_{\text{Bit}}$  is the volume fraction of bitumen,  $V_s$  is the volume fraction of solvent. The original equation for  $\alpha$  is an empirical estimate based on 17 different crude oil and solvents. [22] The  $\alpha$  for the Shu equation was modified for propane-saturated bitumen, as it was found that the original empirical estimate by Shu was not appropriate for liquified propane. [2] Furthermore, in this equation, the viscosity estimate was very parameter sensitive, and it is fair to say that an exact analytical solution for the viscosity of the propane-saturated bitumen does not exist, due to the multi-component structure of bitumen, and especially with its asphaltene components. Nevertheless, it is possible that some escape of propane gas and asphaltene deposition during the run could have resulted in a higher viscosity measurement than its actual viscosity.

Figure 7 depicts a graph of the Shu equation and the measured viscosity values. The line depicts the Shu equation and the red points are the measured values.

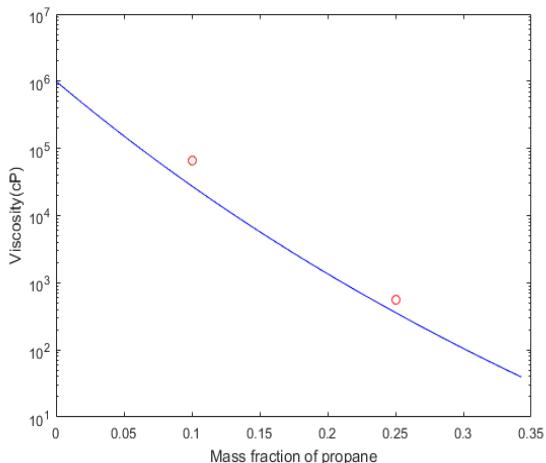

Fig. 7 Viscosity of propane-saturated bitumen through the Shu equation and experimental values. The line indicates the Shu equation and the red points are the measured values.

#### IV. CONCLUSION

In conclusion, viscosity measurements of propane-saturated bitumen showed a significant improvement in viscosity reduction. This indicates the effectiveness of the alternative

method of viscosity reduction through mass transfer as a comparable method or combined method to viscosity reduction through heat transfer. Additionally, the application of microfluidics was important because it brought visualization of the sample flow, reduction of sample size, and miniaturization of the experimental setup.

Furthermore, this shows that microfluidics can be applied for PVT measurements in petroleum research. An important tool of the PVT measurements in petroleum research is a piston cylinder, and a development of a microfluidic piston cylinder that is capable of withstanding the conditions required for petroleum research, such as high temperature and pressure conditions, [23] and compatibility to harsh solvents would be the next possible direction to bring the heavy-duty petroleum research system to lab-on-chip scale.

**Abstract**—*Numerical simulations for the effect of body forces due to aircraft acceleration on the airflow and contaminant dispersion in a model for a passenger aircraft cabin are performed in this study. It was found that those body forces have a significant impact on the contaminant dispersion phenomena and concentrations, especially during the climb leg, where the concentration was almost triple its counterpart during the steady level flight case at the two monitoring locations. Air velocities, on the other side, increased noticeably during the climb and descent legs leading to evident changes in the airflow patterns, vorticity magnitudes, and at some locations, vorticity directions, as well.*

## I. INTRODUCTION

Nowadays, billions of people every year prefer to use air travel rather than other means of transport because of the fast and reliable service the airliners provide. However, the environment inside a commercial aircraft cabin provides a fertile ground for deterioration of air quality and disease transmission among passengers if proper measures are not taken [1].

In the past two decades, numerous studies with different research approaches have investigated air quality in aircraft cabin environments using air distribution systems as a control measure. These approaches range from purely experimental [2–6] to entirely computational (numerical simulations) [7–9], or combinations of both [10–14].

Despite this large number of airflow and air quality studies in aircraft cabins, and although aircraft are moving with high speeds and accelerations accomplishing distinct flight mission legs (or intervals) with different dynamic conditions, such as takeoff, climb, cruise, descent, and landing [15], no study has considered the effect of the resulting body forces from these accelerations on the flow of ventilation air and contaminant dispersion inside aircraft cabins.

The main objective of this work is to fill the gap in the literature that always considered that the passenger aircraft are at rest or under cruise conditions, and that the ventilation airflow, buoyancy effects due to the occupants-generated thermal plumes, and contaminants dispersion within their cabins are only influenced by the gravitational acceleration. Moreover, the effect of the accelerations induced by the body forces acting on a typical modern passenger aircraft (Boeing 767-300), such as the lift and drag, in addition to the thrust of the jet engines and the weight of the aircraft itself, on the air distribution and gaseous contaminant dispersion inside an economy cabin section is to be investigated through computational fluid dynamics (CFD) simulations using the ANSYS FLUENT software. The mission legs, during which the simulations are performed, are climb, steady level cruise, and descent.

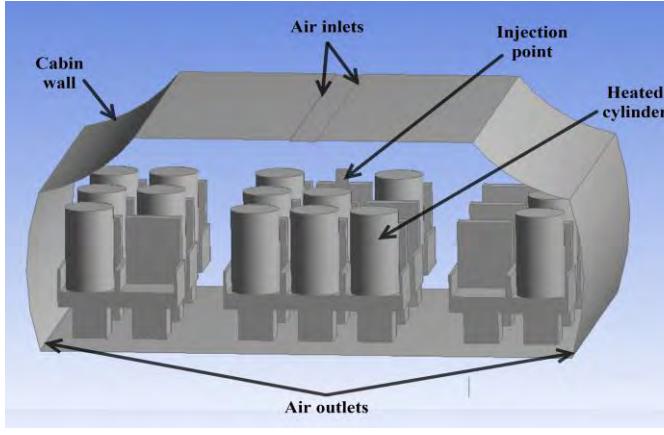

## II. METHODS

### A. Simulated cabin geometry

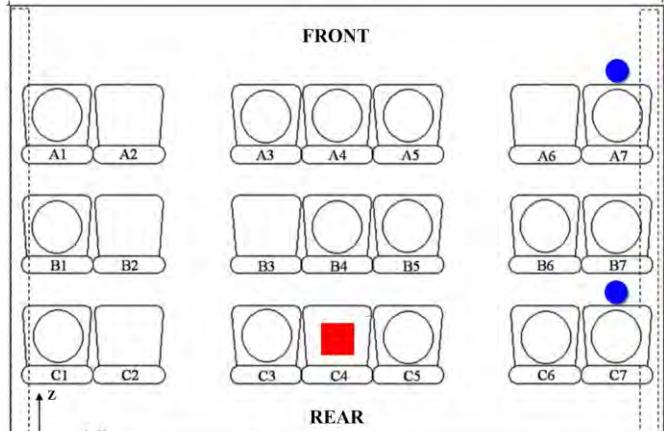

The aircraft cabin model used for the current study is adopted from the literature, and more specifically the experimental study in [4], and the numerical simulation follow-up work in [8].

The model resembles an actual size sectional economy-class cabin of a Boeing 767 passenger aircraft with 21 seats arranged in three rows (the seven abreast or 2-3-2 seat arrangement). The external dimensions of the cabin mockup are 4.9 m by 3.2 m by 2.1 m (W, L, H). The cabin mockup is located at the International Centre for Indoor Environment and Energy, Technical University of Denmark, Lyngby, Denmark. The cabin mockup appeared for the first time in the literature in [3] where more details about its configuration and control systems can be found. Fig. 1 shows a three-dimensional view for the created cabin model in the current study to the exact dimensions using the design software DesignModeler included in the commercial CFD package ANSYS 17.0, and a plan view for the seats.

(a)

(b)

Figure 1. The computational cabin model used in the current study; (a) three-dimensional view of the geometry built in ANSYS 17.0, and (b) plan view for the cabin with the cougher/injector position (red square), and the SF<sub>6</sub> concentration monitoring points (blue circles)

### B. Model and boundary conditions

The model's boundary conditions found in [4] and [8] were closely followed and implemented in the numerical solver FLUENT for the case of 200 L s<sup>-1</sup> supply air flow rate, which was the only supply air flow rate considered. SF<sub>6</sub> gas was released in the cabin to mimic the injection and transport of the cough's smallest size droplets (typically 1.6 to 3.0 μm), and which formed the largest number concentration of the injected droplet ensemble in the experiments. This was performed for the sake of model validation. Table I shows the boundary and inlet conditions for the current model.

The simulation time for the transient airflow part is 350 s at the start of which the cough (SF<sub>6</sub> release) was introduced for 1 s with released air volume of 0.4 l. Before this transient run, the airflow domain only was completely solved in the steady mode.

TABLE I. BOUNDARY AND INLET CONDITIONS FOR THE MODEL

Boundary/inlet Conditions	Value
Supply air temperature	24 °C
Supply air flow rate	200 l s <sup>-1</sup> (corresponds to a supply velocity of 2.61 m s <sup>-1</sup> )
Supply air absolute humidity	0.92 g kg <sup>-1</sup> (corresponds to 5% RH at supply air temperature)
Cabin wall temperature	18 °C
Heating cylinder heat release	60 W per cylinder
SF <sub>6</sub> (cough) injection location	Seat C4
Air velocity at injection location	10.6 m s <sup>-1</sup>

The flow turbulence in the cabin was modeled using the renormalization group (RNG) k-ε model of the Reynolds-averaged Navier-Stokes (RANS) group based on recommendations for similar airflow simulation cases in closed spaces found in the literature [16–19].

### C. Grid independence test

For defining the degree of independence of the obtained solution (airflow velocity and time-averaged SF<sub>6</sub> concentration) from the grid size changes, a grid independence test is conducted. In the present work, three levels of grid fineness (sizes) were created, namely: coarse grid (4,704,751 elements), medium grid (5,522,517 elements), and fine grid (7,375,800 elements), in the order of grid element size decrease or fineness increase. The mesh refinement ratio ( $r$ ) between each two consecutive grid levels was kept constant at 1.1.

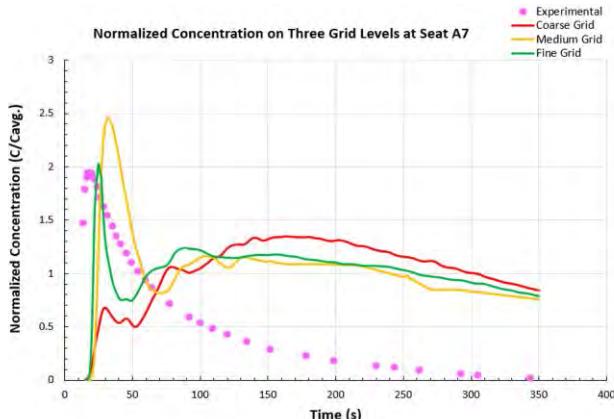

Transient simulation runs were performed for airflow and SF<sub>6</sub> dispersion in the cabin on each grid level with the identical boundary conditions mentioned previously in section B. Fig. 2 presents the normalized SF<sub>6</sub> concentration time series (real-time concentration divided by time-averaged concentration) as they change with the simulation time for the three grid levels with respect to the experimental data (see section D). The real-time SF<sub>6</sub> concentration was monitored at the breathing level of the occupants (1.17 m) at seats A7 and C7 (blue circles in Fig. 1).

In addition to the graphical comparison of solution on the three grid levels, the grid convergence index (GCI) is calculated to indicate the amount of asymptotic convergence that the solution achieves through determining the uncertainty in solution between two consecutive grid levels [20,21].

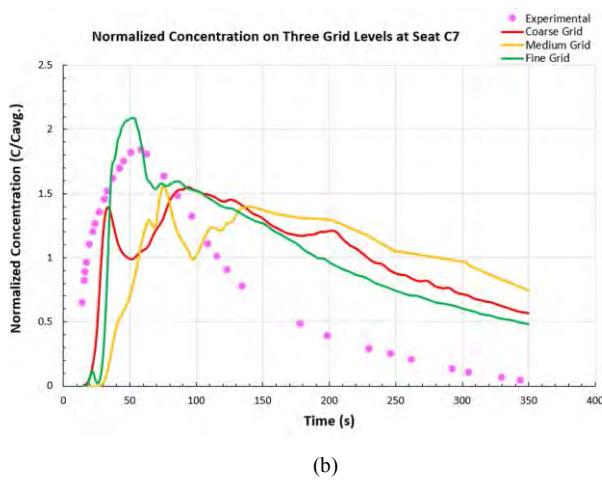

In the current study, the GCI is calculated using the following formula:

$$GCI_{mn} = \frac{F_s |\epsilon_{mn}|}{r^p - 1}, \quad (1)$$

where,  $F_s$  is a factor of safety recommended to be 3.0 for comparisons of two meshes and 1.25 for comparison of three meshes (such as in the current model),  $\epsilon_{mn}$  is relative error between the two solutions obtained on two consecutive grid levels, and  $p$  is the order of convergence. For more information on the calculation procedure followed refer to [21,22].

(a)

(b)

Figure 2. Normalized SF<sub>6</sub> concentration change with the simulation time on the three grid levels; (a) at seat A7, and (b) at seat C7

The GCI for SF<sub>6</sub> concentration calculations from the coarse to the medium grids was 3.13%, and from the medium to the fine grids was 1.26% at seat A7. On the other hand, at seat C7, the GCI was 3.55% from the coarse to the medium grids, while it was equal to 1.41% between the medium and the fine grids. Based on these results, the fine grid level was found to exhibit enough grid independency of the solution, and therefore, will be used further.

#### D. Model validation and error estimation

The experimental data used for the aircraft cabin model validation was mainly extracted from the original study [4] considering the smallest particle size range (1.6-3.0 μm) to be compared with the SF<sub>6</sub> (passive tracer) concentration time series monitored at the two seats A7 and C7 over the simulation time. This is based on the findings of multiple studies in literature that indicate that the smallest size droplets (3 microns in diameter and less) behave like the gaseous substances (especially SF<sub>6</sub>) when dispersing in the cabin space [5,10]. Fig. 3 depicts the compared normalized concentration time series at seats A7 and C7 using the numerical solution obtained on the fine grid only.

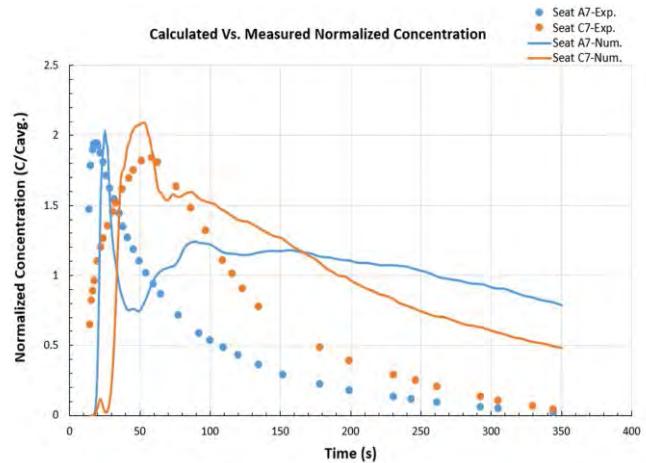

Figure 3. Comparison of the normalized concentration time series between the experiment and numerical simulation on the fine grid level

The error estimation in the current CFD model predictions for airflow velocity and concentration time series are calculated using a procedure which was first proposed by Steven Hanna in [23], and used by him and others later in multiple studies to express the error between the observed and predicted concentrations in atmospheric air quality models [24–26]. This procedure uses two performance measures to express the error, namely: the fractional mean bias (FB), and the normalized mean square error (NMSE), defined as follows:

$$FB = \frac{2(\overline{C_o} - \overline{C_p})}{(\overline{C_o} + \overline{C_p})}, \quad (2)$$

$$NMSE = \frac{\overline{(C_o - C_p)^2}}{\overline{C_o} * \overline{C_p}}, \quad (3)$$

where,  $C_o$  and  $C_p$  are the observed and predicted concentrations, respectively.

Table II gives the FB and NMSE values calculated for the velocity magnitudes and normalized concentration time series between the experimental measurements and numerical predictions in the current study.

From Table II, it can be remarked that both error measures are noticeably lower for the air velocity magnitude than for the normalized concentration calculations. On the other hand, the NMSE values for normalized concentration at seat C7 are about 50% less than at seat A7, while FB values are almost the same at both seats. This shows that the shift between the observed and predicted concentration values is similar, but the spread of the predicted data with respect to the observed ones is two times higher at seat A7, which indicates less accurate predictions.

The decrease in prediction accuracy from seat C7 to seat A7

TABLE II. FB AND NMSE VALUES FOR THE NUMERICAL PREDICTIONS

Air Velocity		Normalized Concentration			
FB	NMSE	FB (Seat A7)	NMSE (Seat A7)	FB (Seat C7)	NMSE (Seat C7)
0.07977	0.02743	0.09705	0.96112	0.06922	0.42384

can very well be attributed to the condition of airflow, and therefore that of the surrogate SF<sub>6</sub> gas, from the emission source (at seat C4) to each seat. From C4 to C7 the flow is mainly lateral which is less susceptible to the bulk flow turbulence than the primarily longitudinal flow experienced from C4 to A7 (see Fig. 1).

Generally, the calculated FB and NMSE figures agree well with the graphical presentation for the measured and calculated concentration time series (Fig. 3).

#### E. Calculation of aircraft body acceleration components

The aircraft vertical acceleration ( $a_v$ ) and horizontal acceleration ( $a_h$ ) components were calculated during climb and descent legs using a basic approach adapted from different sources in aircraft dynamics literature [27] and online [28,29].

The calculation procedure relies on applying Newton's second law ( $\sum \vec{F} = m\vec{a}$ ) on two axes passing through the center of gravity of the aircraft; one is vertical and the other is horizontal. The forces in action are the lift (L) and drag (D) on the aircraft, in addition to the aircraft's weight (W) and the thrust of the jet engines (T). More information on the calculation procedure followed can be found in appendices A and B at the end of this paper.

### III. RESULTS AND DISCUSSION

#### A. Effect of aircraft body forces on contaminants dispersion

The climb and descent simulations were run for the same time span of the steady level flight simulations (350 s), but with the new acceleration components, resulting from the climb and descent calculations, implemented in the numerical solver. Fig. 4 shows a comparison of the calculated concentration time series of SF<sub>6</sub> during steady level flight, climb, and descent at the two set monitoring locations at seats A7 and C7.

It can be clearly noticed from Fig. 4 that the tracer gas concentration is significantly higher (up to 250% more) during the climb leg than the steady level flight case for most of the simulation time at the two locations. Consequently, the level of exposure of passengers sitting at any of the two seats to the contaminant, which can be interpreted from the area under the curves, significantly increases throughout the aircraft climb time. This poses greater infection risks on the health and well-being of most passengers in the cabin upon exposure to hazardous gaseous substances, in-cabin contaminants, or some infectious particulates during the aircraft climb leg that can take up from 20 to 30 minutes for some flights and aircraft models.

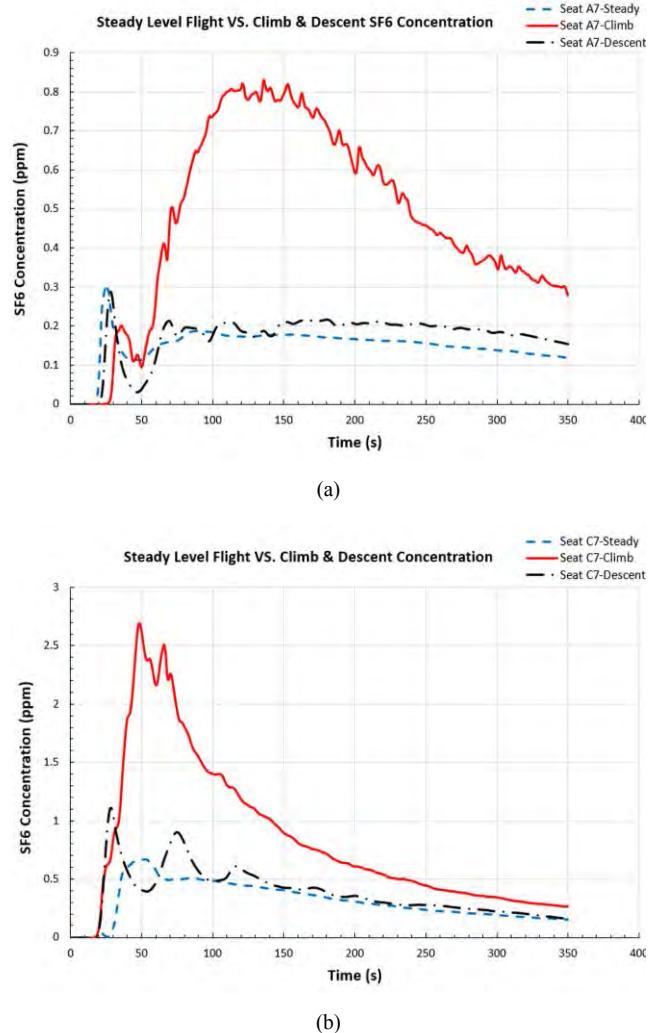

Figure 4. Comparison of the predicted SF<sub>6</sub> concentration time series among steady level flight, climb, and descent scenarios; (a) at seat A7, and (b) at seat C7

On the other hand, the SF<sub>6</sub> concentration time series during the descent leg does not noticeably differ from that for the steady level flight time, and the former can be seen increasing slightly over the latter at the beginning or near the end of the simulation run depending on the monitoring point location. This indicates that the level of passengers' exposure to contaminants is almost identical between the descent and the steady level flight scenarios at the breathing height. However, such similarity in the exposure between the two cases can be altered by changing the contaminant injection point or direction and/or varying the number of concentration monitoring sites and their locations, such factors is beyond the scope of the current study.

One factor that may have contributed to the considerable difference in the SF<sub>6</sub> concentration time series between the climb and the descent legs is the difference between climb and descent rate of velocity change and the corresponding accelerations. The climb speed for most modern jet-powered passenger aircraft can reach up to 600 km hr<sup>-1</sup> (324 knots) or more, while the full-powered descent rate is limited to around

250 km hr<sup>-1</sup> (135 knots) only to ensure passengers' comfort. This large difference in aircraft speed between the two mission legs yield dissimilar aircraft accelerations, and therefore, distinct effect of the generated body forces on the contaminants dispersion rates and patterns inside the cabin.

Another factor in play is the difference between the climb and the descent (inclination) angles. During the take-off and climb legs, most jet-powered passenger aircraft adopt an inclination angle from 15° to 20°, such an angle is much steeper than the small descent angle restricted mostly to 3° to perform comfortable descents. As much as the rise in aircraft speed, the increase of the climb angle over the descent angle very well contribute in enhancing the dispersion rate of contaminants and changing their distribution contours within the cabin. This is because changing the flight path angles significantly alters the values of body force components acting on the aircraft in motion and the contained air on the vertical and horizontal lines, and therefore, the aircraft acceleration components in each of those two directions.

#### B. Effect of aircraft body forces on airflow patterns and vorticity

In addition to the effect the body forces have on the contaminant dispersion inside the cabin, they also affect the airflow velocity and patterns, which can be quantified using vorticities.

Airflow velocity magnitudes in all directions inside the cabin were in general greater during climb and descent than that throughout steady level flight. The monitored airflow velocity magnitudes for the simulated flight time increased anywhere between 1% and 45% during climb and between 6% and 42% during descent with respect to the steady level flight air velocity magnitudes. On the other hand, the air velocity components ( $V_x$ ,  $V_y$ , and  $V_z$ ) exhibited different values of increase and decrease between climb and steady flight, and descent and steady flight, with no fixed trend.

The increase in airflow velocity magnitudes throughout the climb and descent legs changed the airflow patterns in the cabin to some degree. One form of this change is the increased air boundary-layer thickness adjacent to the cabin walls due to the tendency of the air to separate from the walls as it moves downward during climb and descent. In other words, the increased downward airflow velocities (0.9 m s<sup>-1</sup> for climb and 0.8 m s<sup>-1</sup> for descent compared to 0.65 m s<sup>-1</sup> during the steady level flight) led to reduce the airflow attachment to the walls. Consequently, the strongest downward flow separation (thickest airflow boundary-layer) is noticed during climb.

Another effect the airflow velocity changes have on airflow patterns is the alteration of the vorticity magnitude and direction in the cabin. For rotational (non-zero vorticity) flows, such as the highly turbulent airflow in the cabin space, the vorticity vector ( $\vec{\omega}$ ) is defined as the curl of the velocity as follows:

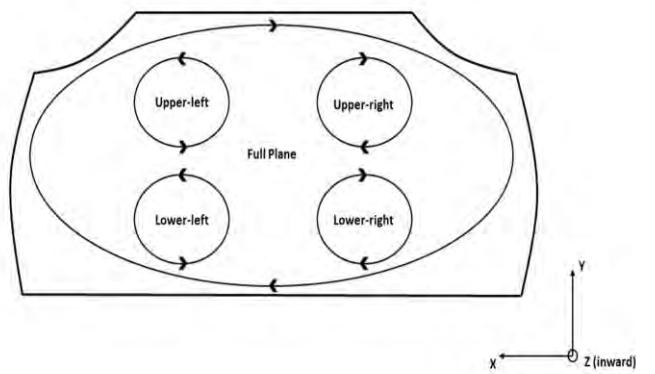

Figure 5. Example of the followed notation for estimating the z-component airflow vorticity ( $\omega_z$ ) on the full x-y plane and its four side corners

$$\vec{\omega} = \nabla \times \vec{V} = \omega_x \hat{i} + \omega_y \hat{j} + \omega_z \hat{k}, \quad (4)$$

Fig. 5 shows an example of the airflow vorticity on the x-y plane set at the middle of the cabin. From the figure, it can be clearly seen that the airflow vorticity is used to approximate circulation on the full planes, such as x-y, x-z, and z-y (not shown in the figure, but corresponding to  $\omega_z$ ,  $\omega_y$ , and  $\omega_x$ , respectively), and also at the four side corners of each plane, namely: the upper-left, upper-right, lower-left, and lower-right corners. This was made possible by calculating the average airflow velocities on separate line segments located at the top, bottom, right, left, and the center (horizontally and vertically) of each of the mentioned planes. Afterwards, the difference in magnitude between each pair of those velocities, and the distances between each two parallel lines on which they were calculated, are used to yield the vorticity vector components as follows:

$$\omega_x = \frac{\Delta v_z}{\Delta y} - \frac{\Delta v_y}{\Delta z} \quad (5a)$$

$$\omega_y = \frac{\Delta v_x}{\Delta z} - \frac{\Delta v_z}{\Delta x} \quad (5b)$$

$$\omega_z = \frac{\Delta v_y}{\Delta x} - \frac{\Delta v_x}{\Delta y} \quad (5c)$$

Table III presents the calculated vorticity vector magnitudes and components on the full planes and the four side corners of each during the steady level flight, climb, and descent legs, and also, the percentage change of those values when each of the climb and descent legs is compared to the steady level flight case.

Studying Table III, it can be noticed that the vorticity vector magnitudes during climb and descent are always greater than those during steady level flight either on the full plane or any of

a. The unit for vorticity magnitude and components is  $s^{-1}$ 

b. (+) is in clockwise direction and (-) is in counterclockwise direction

c. (+) indicates an increase and (-) indicates a decrease from steady flight

d. Accompanied with a change in the direction of rotation

the four corners. This rise is mainly caused by the increased airflow velocity gradients everywhere in the cabin during climb and descent. This indicates stronger circulation of air in the cabin for each zone identified. Between climb and descent, the former has higher vorticity magnitudes at the corners, while this was not the case on the full plane only, where circulation patterns on each corner cancel each other out on the full plane. The greatest increase in vorticity magnitude, taking the steady level flight case as a reference, is seen on the full plane during descent with around 164% of increase. This was followed by the climb on the full plane, as well, with 64% increase, while, for the corners, the amounts of increase were relatively close in value and in the favor of climb, as previously mentioned.

On the other hand, the vorticity vector components exhibited both increases and decreases during climb and descent, with respect to the steady level flight case, with increases occurring slightly more frequently. However, those increases are not exclusive to one flight leg, and occur almost equally between climb and descent. One unique characteristic

of vorticity components is that they can show the change in the vorticity direction between steady flight and climb, and steady flight and descent, in addition to the increase or decrease in magnitude. This is shown by a change in the sign of the vorticity component from positive (clockwise direction) to negative (counterclockwise direction), and vice versa. Those cases are also clearly demonstrated in Table 3 tagged by the footnote (d) to show that a change in the direction of airflow rotation occurs even if the vorticity intensity (magnitude) increases or decreases.

#### IV. CONCLUSIONS

In this study, numerical simulations for the effect of body forces due to aircraft acceleration on the airflow and contaminant dispersion in a model for a passenger aircraft cabin are performed. The steady level flight leg which takes most of the flight time is taken as the reference case, to which the contaminant concentration and airflow changes during the climb and descent flight legs are compared.

It was noticed that the concentration of the contaminant surrogate ( $SF_6$ ) at the two set monitoring locations, and therefore the passengers' exposure, increased substantially during the climb leg from the steady level flight. However, this was not the case during the descent leg, throughout which the  $SF_6$  concentration did not considerably differ from that during the steady level flight time.

Airflow velocity magnitudes, on the other hand, increased everywhere in the simulated cabin during climb and descent from the steady flight case. But, this was not the case for the airflow velocity components ( $V_x$ ,  $V_y$ , and  $V_z$ ) which showed different levels of increase and decrease with no fixed trend.

The change in airflow velocities had a significant effect on the airflow patterns and vorticity (approximation for circulation) in the cabin. Downward airflow coming from supply slots was less attached to the cabin walls during climb and descent than through the steady flight time. Additionally, airflow vorticity magnitudes always exhibited an increasing trend when the steady flight case was changed to either the climb or descent scenario, indicating greater air circulation in the cabin. This increasing trend, however, was not followed by the vorticity components on the full plane and its corners in each direction which showed various percentages of increase and decrease, and also displayed changes in the vorticity direction from steady flight to either climb or descent.

The findings indicate the potent effect the body forces have on the airflow behavior and contaminate dispersion inside the cabins of passenger aircraft and calls for more research attention to this topic to unveil some ventilation design remedies to the negative effects this may have on the health of aircraft occupants.

#### ACKNOWLEDGMENT

The authors thank the Government of Ontario, Canada, for providing the funding for this work in the form of the Ontario Trillium Scholarship (OTS) for the lead author. They also thank Christopher Y. H. Chao (Department of Mechanical Engineering, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China), and Man Pun Wan (Department of Mechanical & Aerospace Engineering, Nanyang Technological University, Singapore) for providing their full research data. Finally, the authors recognize CMC Microsystems for providing the Academic Research license of ANSYS, and the Centre for Advanced Computing (CAC) at Queen's University (Kingston, ON, Canada) for providing the Frontenac Compute Cluster to run the simulations.

## APPENDIX (A): PROCEDURE FOR DETERMINING THE AIRCRAFT ACCELERATION COMPONENTS DURING CLIMB

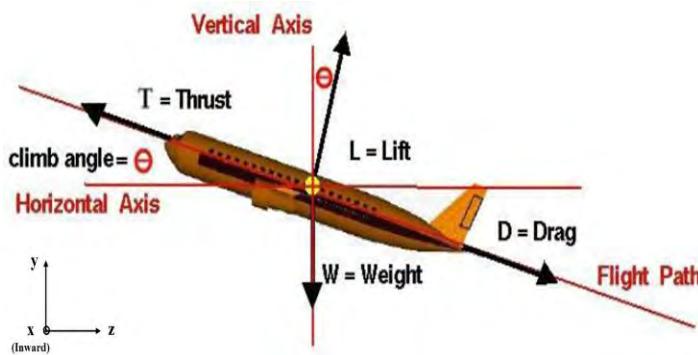

Figure 6. Forces on a passenger aircraft during climb with the two axes (horizontal and vertical) set for the calculation of acceleration components

Newton's second law is applied on the vertical and horizontal axes shown in the above figure,

$$\sum \vec{F} = m\vec{a} \quad (1)$$

On the vertical axis:

$$T \sin \theta - D \sin \theta + L \cos \theta - W = m\vec{a}_v \quad (2)$$

and, on the horizontal axis:

$$T \cos \theta - D \cos \theta + L \sin \theta = m\vec{a}_h \quad (3)$$

where  $\vec{a}_v$  and  $\vec{a}_h$  are the vertical and horizontal acceleration components, respectively.

The unknowns ( $T$ ,  $\theta$ ,  $D$ ,  $L$ ,  $m$ ) are estimated based on industrial specifications and dimensions for the Boeing 767-300 aircraft.

$T = 462.6 \text{ KN}$  (for a twin-jet engine)

$\theta = 20^\circ$

$m = 159,210 \text{ kg}$  (max. takeoff weight)

$W = mg$

$$D = C_D * 0.5\rho V^2 A, \quad (4)$$

$$L = C_L * 0.5\rho V^2 A, \quad (5)$$

where  $C_D$  and  $C_L$  are the drag and lift coefficients, respectively,  $\rho$  is the air density,  $V$  is the aircraft velocity (taken as  $155 \text{ m s}^{-1}$ ), and  $A$  is the reference (wing) area.

$$C_D = C_{D_0} + kC_L^2 \quad (6)$$

where  $C_{D_0}$  is the part of drag coefficient due to friction and pressure on the aircraft body, and  $k$  is a constant that incorporates the other part of the drag coefficient due to lift (lift induced drag).

$C_D = 0.06$  (approximation for the majority of aircraft aerofoils)

$$k = \frac{1}{\pi AR e} \quad (7)$$

where  $e$  is a constant equal to 0.85 for twin engine wide-body aircraft, and  $AR$  is the wing aspect ratio which is determined from:

$$AR = \frac{(\text{wing span})^2}{\text{wing area}} = \frac{(47.57)^2}{283.3} = 7.987 \quad (8)$$

These yield  $k = 0.04688$

Taking  $C_{D_0} = 0.017$  for twin engine wide-body, and substituting in equation 6, yields  $C_L = 0.96$

Substituting in equations 4 and 5, and assuming the density of air to be  $1.2 \text{ kg m}^{-3}$  (aircraft still close to sea level), the drag and lift forces on the aircraft during climb are determined to be:

$$D = 229.473 \text{ KN},$$

and

$$L = 3671.568 \text{ KN}.$$

Substituting in equations 2 and 3 yields the vertical and horizontal components of the aircraft acceleration, respectively:

$$\vec{a}_v = 13.79 \text{ ms}^{-2} = -1.4 \vec{g},$$

and

$$\vec{a}_h = -7.14 \text{ ms}^{-2} = 0.73 \vec{g}.$$

Lastly, the absolute acceleration components got are expressed in the form of relative acceleration components on the air inside the aircraft cabin before being implemented in Fluent. This is attained by reversing the sign of each acceleration component and superimposing it on any acceleration(s) that may exist in the same direction (e.g. gravity). This yield the relative acceleration components as follows:

$$\vec{a}_y = (-13.79 - 9.81) = -23.6 \text{ ms}^{-2} = 2.4 \vec{g},$$

(or  $23.6 \text{ ms}^{-2}$  acting downwards)

and

$$\vec{a}_z = 7.14 \text{ ms}^{-2} = -0.73 \vec{g}.$$

(or  $7.14 \text{ ms}^{-2}$  acting toward the tail of the aircraft)

## APPENDIX (B): PROCEDURE FOR DETERMINING THE AIRCRAFT ACCELERATION COMPONENTS DURING DESCENT

For descent, the same procedure and parameters for climb apply, but the aircraft velocity ( $V$ ), descent angle ( $\theta$ ), and the density of air ( $\rho$ ), at the chosen descent elevation (10000 ft. or 3050 m), are adjusted to the new case.

$$V = 70 \text{ m s}^{-1} \text{ (full-powered descent)}$$

$$\theta = 3^\circ$$

$$\rho = 0.9 \text{ kg m}^{-3}$$

With the aircraft tilted downward, equations 2 and 3 in Appendix (A) are changed to:

On the vertical axis:

$$L \cos \theta + D \sin \theta - T \sin \theta - W = m\vec{a}_v, \quad (9)$$

and, on the horizontal axis:

$$L \sin \theta + T \cos \theta - D \cos \theta = m\vec{a}_h \quad (10)$$

Substituting in equations 4 and 5 of Appendix (A) with the new velocity and air density, and using the same values for  $C_D$  and  $C_L$ , yields:

$$D = 37.481 \text{ KN},$$

and

$$L = 599.69 \text{ KN}.$$

Substituting the  $D$  and  $L$  values got (keeping  $T$  and  $m$  the same) in equations 2 and 3 of Appendix (A) yields the vertical and horizontal components of aircraft acceleration during descent, respectively:

$$\vec{a}_v = -6.1883 \text{ ms}^{-2} = 0.63 \vec{g},$$

and

$$\vec{a}_h = 2.86 \text{ ms}^{-2} = -0.29 \vec{g}.$$

Finally, the relative acceleration components are calculated for the descent leg using the same approach previously followed for the climb leg:

$$\vec{a}_y = (6.1883 - 9.81) = -3.622 \text{ ms}^{-2} = 0.37 \vec{g},$$

(or  $3.622 \text{ ms}^{-2}$  acting downwards)

and

$$\vec{a}_z = -2.86 \text{ ms}^{-2} = 0.29 \vec{g}.$$

(or  $2.86 \text{ ms}^{-2}$  acting toward the head of the aircraft)

# Quantitative Natural Gas Discrimination For Pipeline Leak Detection Through Time-Series Analysis of an MOS Sensor Response

Matthew Barriault, Mahyar Mohaghegh Montazeri, Allen O'Brien, Homayoun Najjaran, Mina Hoofar

School of Engineering  
University of British Columbia  
Kelowna, Canada

**Abstract**—In order to detect natural gas pipeline leaks, ethane in the natural gas must be discriminated from background methane emissions. Our gas detection apparatus is well-suited for this application due to its flexibility and low cost. We present a comparison of machine learning models for quantitative estimation of concentrations of both methane and ethane in a target gas sample, using a response over time from a single sensor in our apparatus. We also demonstrate that the use of synthetic data is very effective for training a model to discriminate between methane and ethane.

**Keywords**-machine learning; gas detection; microfluidic; diffusion simulation; pipeline leak detection

## I. INTRODUCTION

Natural gas pipeline leak detection can be broadly categorized into “internal” and “external” methods, depending on whether the detector resides inside or outside the pipeline. Internal methods include acoustic measurement, pressure/flow monitoring, and statistical analysis. These methods also often make use of one of several mathematical modeling options to predict when a leak has occurred. External methods are more hardware-based, relying on, for example, acoustic, optical, soil monitoring, or vapor sampling sensors [1]. These hardware solutions can either be permanently installed in a fixed location, or used in conjunction with a mobile monitoring apparatus, such as a handheld detector or even a drone. We present here the application of a small, cost-effective, and highly flexible gas sensing apparatus that can be used in either permanent or mobile applications.

Leak detection requires differentiation between methane and ethane, since natural gas will typically contain ~5% ethane and must be detected in the presence of background methane emission from, for example, nearby agriculture. However, the difference between the sensor’s response to methane and ethane may not be immediately clear. We employ machine learning techniques to discover patterns that will enable this discrimination. To offset the requirements of some algorithms that a large dataset be provided, we also test the performance of our estimation models using synthetic data. Using simulations, we will be able to generate predictions of the sensor’s responses to wide ranges of concentration, temperature, pressure and humidity. All of this can be used to train the pattern recognition system to be able to take into

account the effect of these parameters and give more accurate results.

## II. SENSING APPARATUS AND DATA COLLECTION

The sensing apparatus consists of a Figaro 2610 metal oxide semiconducting gas sensor embedded in a 3D-printed microchannel, which is coated with chromium, gold, and parylene-C to increase selectivity. Full fabrication details are given in [4]. This apparatus is quite flexible, and target gases can be altered simply by changing which MOS sensor is included. This is made easier by the fact that Figaro manufactures sensors with similar dimensions, but for a variety of target gases. Parallel work in our lab has demonstrated the suitability of this apparatus for nuisance sewer gas detection [2], wine identification [3], and breath analysis. Its small size enables it to be used for both stationary and mobile applications, which is extremely beneficial in the context of pipeline leak detection, where both types of devices may be needed, depending on the individual situation. Figure 1 displays a model of the microchannel sensing apparatus.

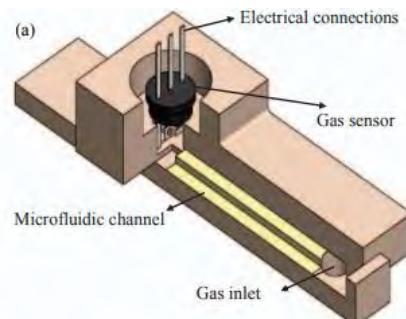

Figure 1. Gas sensing apparatus. Figure from [4]

Our dataset consists of time-series curves from our sensing apparatus in response to a variety of target gas concentrations. These targets are created through the use of a mass flow controller, and contain known concentrations of methane or ethane. We have not yet collected enough data with mixtures of both gases to make meaningful predictions, but this is the focus of ongoing work, primarily on using simulations to create synthetic mixture data to alleviate the time required to perform manual tests. Therefore, in the current work, the goal of the model is to not only determine which gas it has been exposed to, but also to estimate the concentration of that gas.

The time-series curves are generated by exposing the sensor to the target gas for 40 seconds, then allowing the sensor to recover by placing it in fresh air for 150 seconds. An example curve is shown in Figure 2. The exposure and recovery phases are clearly distinguishable. Some of the curves' features are also shown, which will be discussed in Section IV-A.

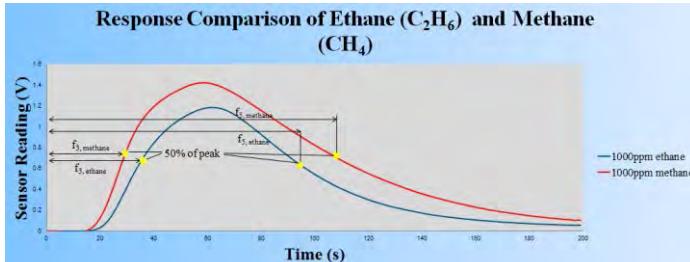

Figure 2. Comparison of responses to 1000ppm methane and 1000ppm ethane, with features #3 and #5 shown

### III. SIMULATION METHODOLOGY

One of the main challenges of developing microfluidic-based gas detectors is calibration of the sensor, based on wide ranges of different parameters such as changes in the mixture concentration, temperature, pressure and humidity. This requires a vast number of experiments to generate enough data to be able to take into account the effect of each parameter accurately. Simulation of the gas sensor can help solve this problem as it reduces the number of experiments needed for calibrating the sensor, saves time, reduces human and instrument errors, and removes many limitations.

In the current study diffusion of a target gas inside the sensor's 3D printed micro-fluidic channel is studied. The simulation is done in a three dimensional model and the effect of gas adsorption to the channel walls is also applied to the simulation results.

This methodology does not take into account the individual differences between each sensor. To use the simulation data to train a model used to estimate real data, the simulations need to be tailored to account for the fact that the real sensor does not exactly match the theoretical model. However, we present here a proof of concept that synthetic data is well-suited to training a discriminative model such as those discussed in Section IV-B and IV-C. Such a calibration procedure that would allow the model to be trained on synthetic data and tested on real data is the focus of ongoing work.

The synthetic dataset was generated by simulating a target gas with concentrations from 100ppm to 1000ppm in increments of 100ppm, with five repeats for each. To make our predictions more robust to day-to-day variations in the sensor, and to make our data more realistic, we introduce some randomness in the simulations. The actual simulated target concentrations were sampled from Gaussian distributions with means equal to the ideal target concentrations, and standard deviations of 10ppm. Since this randomness is unknown to us in a real situation, the estimation targets for these tests are kept as the ideal targets i.e. 100ppm, 200ppm, etc. The simulated

curves for different concentrations of methane are shown in Figure 3.

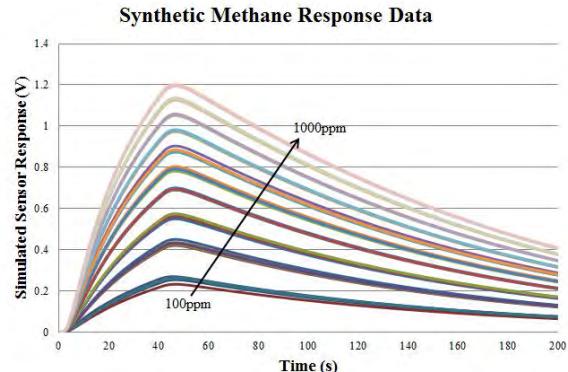

Figure 3. Simulation results for methane, with actual concentrations sampled from a Gaussian centered on the ideal concentration

#### A. Diffusion model

As in this study, diffusion of a mixture of gas into another is the governing transport phenomena. For this, the Maxwell-Stefan equation, which is an accurate model for multicomponent diffusion for low density gases, is chosen:

$$\nabla x = - \sum_{\beta=1}^n \frac{c D_{\alpha\beta}}{N} (x_\beta N - x N_\beta), \quad (1)$$

where  $x_i$  is the mole fraction,  $N_i$  the flux,  $C$  the total concentration and  $D_{ij}$  the diffusion coefficient of component  $i$  in component  $j$ . It worth mentioning that, in a binary system, the well-known Fick's law can also be used to simplify the model. [5]

#### B. Surface adsorption model

As the gas diffuses inside the micro-fluidic channel, some of the molecules adsorb to or desorb from the channel walls which affects the transport phenomena rate. In this simulation the adsorption is taken into account using the Langmuir adsorption model, which considers the phenomena an equilibrium reaction and provides the adsorption and desorption rate as:

$$r_{ad} = k_{ad} p_A [s] \quad (2)$$

$$r_d = k_d [A_{ad}] \quad (3)$$

Where  $k_{ad}$  and  $k_d$  are the adsorption (forward) and desorption (backward) reaction rates,  $p_A$  partial pressure of  $A$ ,  $[S]$  empty sites concentration and  $[A_{ad}]$  is the concentration of compound  $A$  molecules adsorbed on the surface. [6]

#### C. Model assumptions and boundary conditions

In this model we assume that there is no flow, and the diffusion is the governing transport phenomena. Also, there is no diffusion of gas molecules to the bulk of channel walls and the adsorption is occurring only on surface. The simulation model is shown in Figure 4.

As the experimental test consists of two steps, exposure and recovery, the simulation is also designed in two different steps which have different initial and boundary conditions. In the exposure phase, there is no target gas inside the channel and it is filled with air. At time=0s the sample concentration is introduced as the boundary condition at the opening of the channel and during this step the diffusion happens for 40s, at which point the recovery phase starts. The initial concentration is derived from the last time point of the previous step and the boundary condition will be set to zero concentration of the target gas.

It is worth mentioning that many other model assumptions are inherited from the diffusion and the surface adsorption models which can be found in the previously mentioned references.

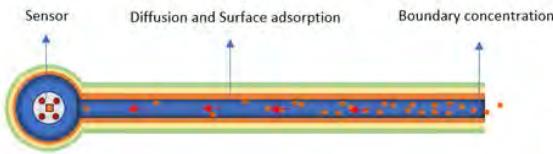

Figure 4. Diffusion simulation model

#### IV. CONCENTRATION ESTIMATION

In this work, we evaluate the performance of both feature-based and feature-less classifiers. In the case of a feature-based model, the input to the classifier is a set of pre-designed features that are extracted from each of the time-series curves. In other words, the input is a set of training vectors  $x_i \in \mathbb{R}^d, i = 1 \dots n$ , where  $n$  is the number of samples in the training dataset, and  $d$  is the number of features extracted from each sample. For the feature-less models, the input is simply the raw data, so the training vectors are  $x_i \in \mathbb{R}^t, i = 1 \dots n$ , where  $t$  is the length of each time-series sample. In both cases, the targets  $y$  are the known concentrations of both methane and ethane:  $y_i \in \mathbb{R}^2, i = 1 \dots n$ . Feature-based methods have found extensive use with electronic noses, and a considerable effort has been made in past decades to design features that will produce good classification results [1]. However, it is desirable to use a classifier that does not require the hand-designing of such features. For this reason, we investigate the performance of a recurrent neural network, which can take the raw sensor data as input, without the need for any feature design.

Preliminary hyperparameter selection for each model (including model depth, width, and regularization parameters) was done using a common held-out test set consisting of 5% of the total data. Once hyperparameters were identified that maximized performance on the test set, the final performance of the model was evaluated by predicting the methane and ethane concentrations for each sample, using a leave-one-out method. Leave-one-out can be considered a special case of k-fold validation with  $k = n$ , where  $n$  is the total number of samples. This means that  $n$  models were trained, with one sample excluded from each, giving the best possible prediction

for each sample. The leave-one-out method becomes impractical for even moderately-sized datasets, for which standard k-fold validation should be used instead, with  $k$  chosen such that the held-out test data in each case would be about 5% of the total dataset.

##### A. Feature extraction

In order to get an idea of which features will discriminate well between methane and ethane, we examine the comparison of the sensor's response to 1000ppm of each gas in Figure 2. The significant difference in speed of response, especially between 20 and 50 seconds, suggests that features such as the time at which the signal reaches 50% of its peak value might be useful. Along with good discrimination between gases, it is also important for the magnitudes of predicted concentrations to be accurate. For this reason, features such as the peak value and the area under the curve will also be useful because these features relate directly to the magnitude of the target gas concentration. Table 1 provides a full description of the features used.

Once the features have been extracted, they must be processed to ensure that the models can learn properly from them. This processing is to make the distributions of each of the features have a mean of zero, and a standard deviation of one. This is done so that one feature with a much larger magnitude than the others does not completely dwarf the contributions of the rest.

Table 1. Extracted features used for feature-based classifiers

Feature Number	Feature Description
1	Peak value
2	Area under the curve
3	Time to 50% of peak value (exposure phase)
4	Time to 75% of peak value (exposure phase)
5	Time to 50% of peak value (recovery phase)
6	Time to 75% of peak value (recovery phase)

##### B. Feature-based models

Many machine learning models perform poorly with time-series data if the entire time-series is naively given to the model to use as training/testing data, due to their difficulty in learning temporal relationships. Multi-layer perceptrons (MLPs) and support vector machines (SVMs) are two such models. Therefore, we evaluate the performance of these model using extracted features.

A multilayer perceptron is a type of feed-forward neural network consisting of at least three layers, all but the first of which apply a nonlinear transform to a weighted sum of the previous layer's activations. The first layer is called the input layer, and it is where the features are input. The last layer is called the output layer, and it is where the network's predictions appear. Any layers in between these two are called

hidden layers. Since a nonlinear transform is applied at every layer, the addition of more hidden layers means that the network can learn more complex functions [7]. The activation  $z$  of layer  $j$  is given by:

$$z = \sigma(W_{ij}z_i + b) \quad (4)$$

where  $z_i$  is the activation vector of the previous layer,  $b_j$  is the bias vector for layer  $j$ ,  $W_{ij}$  is the weight matrix between layers  $i$  and  $j$ , and  $\sigma$  is a nonlinear transform function, usually either the logistic sigmoid or the hyperbolic tangent function.

MLPs are supervised models, meaning that for the network to predict the correct output values, it must be allowed to learn on a training dataset for which the correct outputs are already known. The goal of this learning is for the network's predictions to be as close to the true outputs as possible. This is accomplished by altering the network's weights and biases ( $W_{ij}$  and  $b_j$  for each layer) through a process known as backpropagation. It involves updating the weights and biases along a gradient that maximally decreases the error. The weights and biases are updated according to:

$$W_{i,new} = W_i - \delta \frac{\partial \varepsilon}{\partial W_i} \quad (5)$$

$$b_{,new} = b - \delta \frac{\partial \varepsilon}{\partial b} \quad (6)$$

where  $\delta$  is a constant called the learning rate, and  $\varepsilon$  is the error function, such as the mean-squared loss function. The learning rate controls how large the weight and bias updates are. If it is too small, the network will train slowly, but if it is too large, the algorithm may not converge.

In our case, the network must have five input units, and two output units, since we are using five features to predict two concentrations. Preliminary testing indicates that three hidden layers with 50 units each performed best on our data.

A support vector machine is a binary classification model that can construct a very complex classification surface through the use of a kernel function. They are based around the idea of achieving the maximum margin separation between classes. They achieve non-linear classification by mapping the inputs into a higher-dimensional space, where linear classification may be able to be accomplished. This idea can also be extended to regression analysis by fitting a regression hyperplane to the training cases. This allows for a highly non-linear regression surface. In our case, we actually have to fit two SVMs, one for each concentration target, since the standard SVM is applicable only to single targets [11].

### C. Feature-less models

Recurrent neural networks (RNNs) differ from traditional neural networks in the fact that they incorporate memory. Each new data point in a time-series that is given to an RNN will produce not only an output, but also an update to the network's internal memory state. At each time step, the network's hidden units see not only the input data, but also the

memory state. Using the training data, the network will learn how best to use this memory state throughout the duration of a single time series data vector [8]. A simple recurrent neural network is shown in Figure 5.

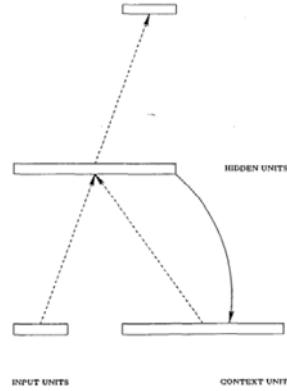

Figure 5. Simple recurrent neural network, with connections from the hidden units back to themselves. Figure from [8]

The hidden layer outputs for an RNN are similar to those of an MLP, except that the outputs are now indexed by time due to the fact that the output changes for every time point in each series. Also, there is an extra term in the expression, since the hidden layer's output at the previous time point influences the output at the current point:

$$z_{,t} = \sigma(W_{ij}z_{i,t} + W_h z_{,t-1} + b). \quad (7)$$

In the above equation,  $W_h$  represents the weight matrix from the previous hidden activation to the current hidden activation.

## V. RESULTS

### A. Real data prediction

As mentioned in Section IV, we are using a leave-one-out validation method for determining the quality of our models. Our quality metric is the mean-squared prediction error over our entire dataset. The error  $\varepsilon$  is given by:

$$\varepsilon = \sum_{i=0}^n \sum_{j=0}^d (y_{ij} - y_{pred,ij})^2 \quad (8)$$

where  $y_{ij}$  refers to the  $j^{th}$  concentration target for the  $i^{th}$  data sample,  $y_{pred,ij}$  is the network's prediction of  $y_{ij}$ ,  $n$  is the number of samples, and  $d$  is the number of concentration targets per sample. In our case,  $d$  is equal to two, since we are predicting methane and ethane. The error rates for the real data are presented in Table 2.

Table 2. Mean-squared error comparison for the models studied

Model	Mean-squared Error	Mean Error (ppm)
MLP	1,845	43.0
SVM	3,079	55.5
RNN (1 layer)	22,781	150.9
RNN (4 layers)	8,276	91.0

While the RNN requires less effort in feature engineering, it did not perform as well as the more traditional feature-based models. This can be attributed to the fact that the RNN's performance increases significantly with a deep model (four layers vs one), and deep models tend to require much more training data than shallow models [9]. This makes the possibility of using synthetic data particularly attractive.

### B. Synthetic data prediction

For the tests with synthetic data, there was no additional model parameter tuning; the same values were used on both the real and synthetic datasets. However, since we have 100 simulated examples, k-fold validation with  $k=20$  was used instead of the leave-one-out method. This significantly reduced the training time. The error rates for the synthetic dataset are presented in Table 3.

Table 3. Mean-squared error rates for the synthetic dataset

Model	Mean-squared Error	Mean Error (ppm)
MLP	74	8.6
SVM	288	17.0
RNN (1 layer)	4,120	64.2
RNN (4 layers)	6,025	77.6

As predicted, all of the models saw an improvement when using the synthetic dataset instead of the real data. This is likely due to the fact that the synthetic data is cleaner and contains less variance than the real data. In future tests, the randomness added to the synthetic data should be increased to match the distribution of the real data.

The deep RNN did not see as much of an improvement as the other models, which might mean that it requires additional training time since more data samples were used.

## VI. CONCLUSION

Even though the RNNs failed to outperform the feature-based methods, the overall results show that the quantification of methane and ethane with a single MOS sensor is very feasible, even when the identity of the target gas is unknown. Once a large volume of simulation data has been accumulated, the application of the models described in this work, along with the integration of our sensing apparatus with a stationary or mobile platform will be viable, low cost, and non-invasive method of detecting natural gas pipeline leaks.

## VII. FUTURE WORK

The estimation results presented here have been limited to the discrimination between two different gases, and

concentration estimation of the target gas. Future work will include extension to estimating the concentration of both methane and ethane in an arbitrary mixture. To accomplish this, we anticipate the need for more information than a single time-series. For example, multiple different sensors can be used with one microchannel, and ideally one of them would be more sensitive to either methane or ethane than the other. Electronic noses typically do contain more than one type of sensor, but since methane and ethane are so similar, the approach of adding different types of sensors will not likely make a big improvement. The more promising approach is to use multiple identical sensors, each with a microchannel of a different length. This will accentuate the differences in diffusion between the two gases, rather than the difference in how they affect the sensor.

Future work will also include the extension of the algorithms described here to other projects in our lab, as described above [2][3]. In addition, we will be investigating a variant of the RNN called the long short-term memory (LSTM) network, which tends to learn longer-term dependencies better than regular RNNs [10].

**Abstract**— Metal powder properties in Selective Laser Melting (SLM) is among one of the most important factors when implementing new alloy developments for the equipment. In fact, not all commercially available metal powder alloys are ready to be implemented without a comprehensive set of tests. Besides the powder properties, we have a large number of building and environmental parameters that demands extensively research prior implementation. Although selected alloys are commercially available and documented to be used in SLM, including Ti6Al4V, SS316L and In718, the majority of it still not ready to be utilized in this system. The focus of this study is to use a thermal model in order to predict the thermal distribution of the process regarding different aspects of the powder properties, especially the thermal conductivity, when different powder packing densities and diameters are used. A Stainless Steel 304L will be utilized in this work, since it is not yet available to be commercially used. The main goal is to show the capabilities of the Finite Element Method in the pre-definition of optimal parameters for the process using a new alloy development. Our findings can be used as a pre-evaluation guideline when printing SS304L, since the comparison with similar experimental work in the field showed significant resemblance and outcomes. The temperature distributions show that the packing density has greater sensibility on the final temperature distributions, compared to the powder diameter variance. Two different power inputs are compiled and the temperature outcomes demonstrate that a power input of 100 Watts is recommended to use when printing SS304L, rather than 400 Watts that brings high temperature into the powder bed.

## I. INTRODUCTION

Selective Laser Melting (SLM) is an Additive Manufacturing process that utilize metal powder in order to build full dense parts in a layer fashion. Currently, the technology is commercially distributed by few manufacturers

around the world, with a selection of alloys available, including Titanium, Stainless Steel, Aluminum, Cobalt-Chrome and Nickel-based alloys [1][2].

The fact that SLM uses a lower space, entitled bed, which is filled with fine metal powder, resulted in the association of this process with the Powder Bed Fusion (PBF) classification. Among them are Direct Laser Melting Sintering (DLMS), Electron Beam Melting (EBM) and Selective Laser Sintering (SLS). It is important to emphasize that all these processes were developed by different entities and timelines, and although some similarities, they have quite different set of parameters and mode of operations [3].

The main objective of this study is to demonstrate the high capability of FEM in this field, utilizing for that a low computational cost thermal model able to predict the temperature distributions when scanning a single layer and track of the powder bed. Some of the aspects of discrete method will be implemented, however only in the thermal conductivity implementation method. We start with the laser power input modeling, by using double-ellipsoidal as the heat flux input into the FEM model. Next the material is modeled, considering the state (solid, liquid, powder) and the temperature effects. Special attention is devoted to the thermal conductivity of the powder and for that a special effective thermal conductivity formulation is used to determine the variance in all conditions (packing density and powder diameter). Important devotion is given to the phase change and emissivity of powder as well. Finally, the model is built and compiled, leading to the results and analysis sessions. The powder diameter and the packing density are the main focuses here, in order to determine the impact on the temperature profile during two set of power input sources.

## II. EFFECTIVE THERMAL CONDUCTIVITY OF POWDER BED

The contact of two adjacent spherical particles is essential when calculating the thermal conductivity, since the major heat exchange is done through conduction [4]. The respectively radius of contact is calculated by the Hertz theory applied for contact interaction of solid bodies [5]. This contact area is very small, especially in the present study, since no plasticity is

considered and the only force acting among particles are gravity forces.

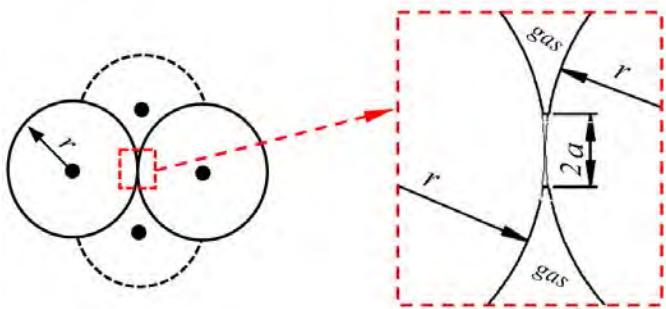

Figure 1 - Particles in contact (right) and the contact region (left)

The material used in the model is Stainless Steel 304L. This alloy has considerably low cost and yet still not available for the process in the industry. The data is extracted from Choong report, including Specific heat, density and the thermal conductivity, which are specified as temperature-dependent properties, essential when simulating high change in temperature distribution over small time increments [6]. To accommodate the phase transformation, the latent heat is included as well, which will modify the capacity heat during the powder melting [3].

The packing density affects the contact radius, consequentially influencing the emissivity and finally the final effective thermal conductivity of the powder bed. Below are the porosity-dependent emissivity for all packing densities and the final effective thermal conductivity of all cases from 300K until  $T_{Solidus}$  of SS304L [7].

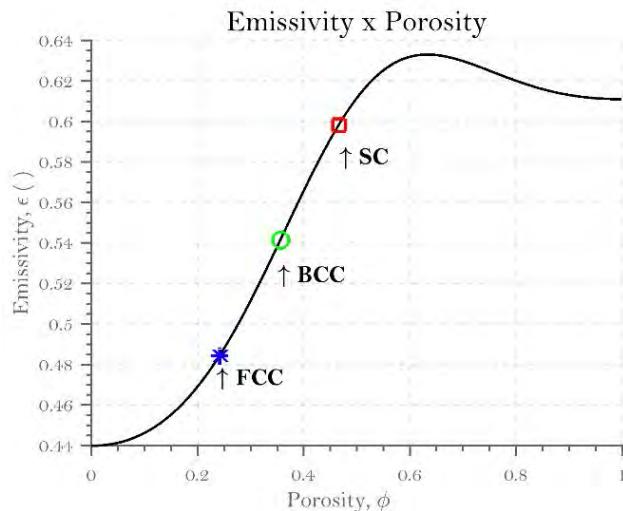

Figure 2 - Porosity-dependent emissivity of SC, BCC and FCC for SS304L [7]

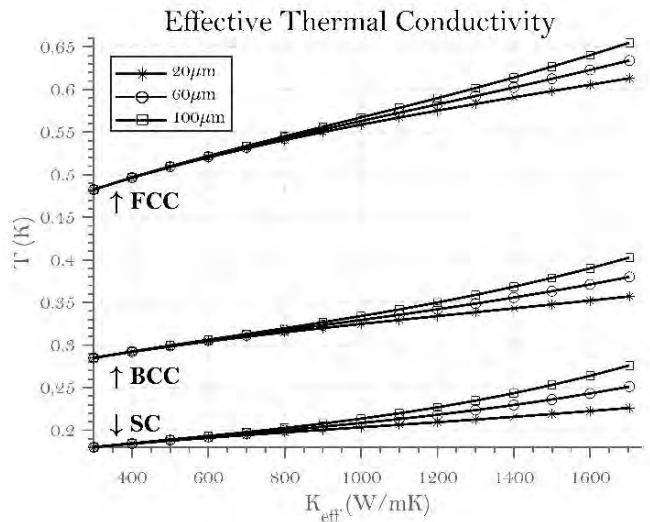

Figure 3 - Effective thermal conductivity of powder for SC, BCC and FCC with 20, 60 and 100 $\mu\text{m}$  of powder diameter for SS304L [7]

In this study, it is considered three different packing densities, SC, BCC and FCC, with porosity of 0.2424, 0.3571 and 0.467 respectively, along with three powder diameters analysed, 20, 60 and 100 $\mu\text{m}$ . On previously work the effects of powder packing in the bed was not analyzed and a general value of 0.400 in porosity was adopted [3]. The thermal radiation term is highly influenced by the powder diameter, temperature and emissivity of the powder bed. In the other hand, the thermal conductivity due the contact between particles will vary according to the contact ratio and the initial solid thermal conductivity, since the value of the fractional contact area,  $A$ , is less than  $3 \times 10^{-4}$  [7].

It is noticeable that the powder diameter does not affect significantly the value of  $k_{eff}$  for temperatures between 300K and 800K. However, for higher temperatures, due the radiation term, there is a perceptible difference. For FCC, as example, there is around 7%  $k_{eff}$  increase when using 100 $\mu\text{m}$  instead 20 $\mu\text{m}$ . The margin increases to 22% when doing the same comparison with SC, due the higher emissivity of SC compared to FCC. When comparing between the different packing densities, the  $k_{eff}$  increase margin is even bigger, reaching up to 267%.

### III. THERMAL MODELING OF SLM HEAT SOURCE

The thermal model is defined in a way to handle different material phase (liquid, solid and powder state), as well for their variance during different temperatures. A three-dimensional model is established using DC3D8 hexahedron element with 25 $\mu\text{m}$  of size and a total domain of 1500x1500x75 $\mu\text{m}$  (1.5x1.5x0.075mm). A small domain is justifiable, given the small laser spot diameter, 50  $\mu\text{m}$ , used in the model and the very low thermal conductivity present on the bed.

The material is modeled as temperature and state dependent, allowing to proper account more accurately the temperature

distributions. There are some considerations that were made to preserve a low computational time/cost.

#### Principal assumptions:

- thermo-fluid effects were not considered, so Marangoni effect and fluid flow in the melt pool is not accounted;
- vaporization of the material is not implemented as well, but the phenomena only occur when utilizing considerably high laser power input ( $P = 400\text{W}$ );
- a single track of the laser is observed and the influence of the hatch distance is neglected in order to only focus on the effect of the packing structure and particle diameter in the temperature distributions.
- only average powder (particles) diameter is considered when calculating the effective thermal conductivity of powder state.

ABAQUS is the software used to perform the analysis, since its subroutines allow to model the moving heat source and keep track of the material state. The subroutines DFLUX and FILM were implemented in this study for Gaussian heat flux and convection/radiation definition respectively. The solution given is the temperature distribution of the process, described as  $T(x,y,z,t)$ . The problem is described by the three dimensional heat conduction equation (8), with the respective manufacturing and chamber environmental boundary conditions [3,7].

#### IV. RESULTS AND DISCUSSION

The numerical analysis was conducted for two laser power input (100 and 400 Watts), combined with three packing densities and three different powder diameters, giving 18 compiled result models that ran for 9,5 hours in total (average of approximately 30 min for each simulation). The temperature distribution was acquired in four central nodes through the thickness located in the middle of the powder bed.

The contact powder and substrate is neglected, however the pre-heat temperature from the substrate is entered as a boundary condition, with a defined pre-defined temperature of 643K. We have found that different powder diameters within the same packing density have no impact in the final temperature distributions on the model. However, between the three different packing densities the temperature differs. When using  $P=100\text{W}$  (Figure 10), the maximum temperature achieved is around 1575K at the surface, not enough to reach the melting point of the alloy utilized. However, it is essential to consider that powder can still melt in certain amount due necking between the small particles. The only concern here is at  $-75\mu\text{m}$ , which achieved a temperature of 1100K.

On the same temperature distribution plot, is noticeable that the temperature raises at the same rate for all the packing densities, but as soon as the temperature reaches the maximum amount and the laser scan moves forward, the temperature loss differs from each of the configurations. On the highlighted secondary plot in the same graph, it is shown that SC loses less heat than BCC and FCC. This is justifiable by the fact that SC

has a smaller effective thermal conductivity among all, thus exchanging less heat. The biggest difference reaches up to 45K between SC and FCC at the surface of the powder bed, representing 3%.

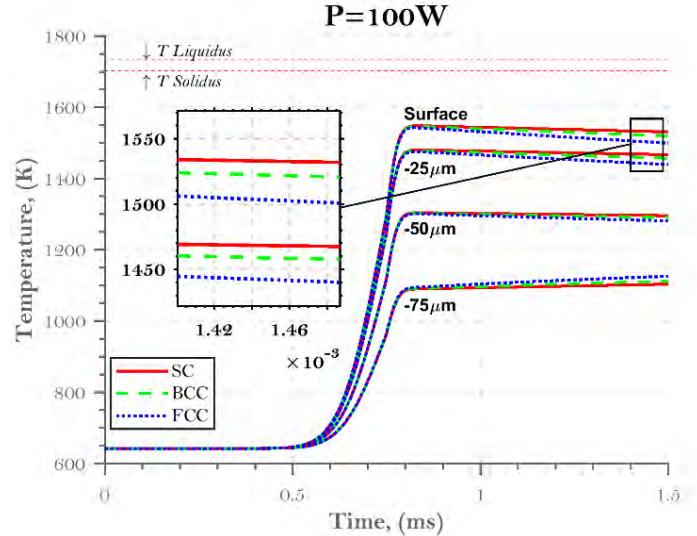

Figure 4 - Temperature distribution of Power input of 100W [7]

Another feature from the first analysis is the fact that the rate of change is very small after the temperature reaches its maximum. This happens because of the domain still on powder state, thus having low thermal conductivity overall. It is important to notice as well that the effective thermal conductivity, although not validated experimentally, followed the same trend experienced by the study of Alkahari *et al* [23]. In their study the thermal conductivity of SS316L was measured by laser flash technique and the outcomes show a tendency of superior thermal conductivity of  $100\mu\text{m}$  particles when comparing to  $20\mu\text{m}$ , the same tendency happens when increasing the packing density.

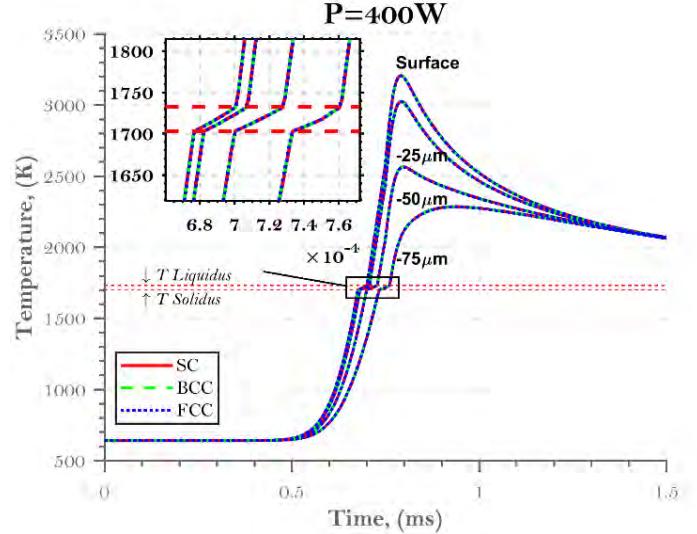

Figure 5 -Temperature distribution of Power input of 400W [7]

The second power input ( $P=400\text{W}$ ) is the one which the whole depth of the powder bed layer reaches the

melting point. However, the maximum temperature achieved at the surface is around 3250K, which is an undesirable condition that can lead to evaporation of the metal [8]. The bottom reaches around 2100K, which will most likely induce the melting of some area of the substrate or increase the heat affected area of the same. It is noteworthy here to observe that a gradient of around 1150K between the top and bottom layer is induced, whereas at P=100W the gradient is 475K. This fact alone is extremely important when analysing residual stresses during SLM. The higher temperature gradient and respectively the cooling rates induced by the process, higher is the residual stresses occurrence.

In the secondary plot of Figure 12, it is highlighted the melting point area between solidus and liquidus temperature (dashed red line). The change of rate of temperature during this interval proves the model is capable of interpreting the different properties states and the phase change by the latent heat of fusion, even with a small time incrementation used.

Furthermore, the results show a very close behaviour with the experimental studies using SS304L found in the literature. Abd-Elghany and Bourel had performed the closest testing to our set-up. They have conducted tensile specimens printing using a machine with 100W and 30/50/70 $\mu\text{m}$  layer thickness, concluding that higher layer thickness produced low density and poor mechanical properties specimens [9]. This can be used as an reference to our set-up of P=100W and layer thickness of 75 $\mu\text{m}$ , which the laser input was not enough to bring the temperature to the melting point, thus consolidation between powder particles are poor.

## V. CONCLUSIONS

In this research it is proposed a low cost FEM thermal model capable of measure temperature distributions through the powder bed and consequentially the temperature gradient, of a single layer and track of the laser scanning using SLM process. Although the packing density and powder diameter impact the final value of effective thermal conductivity of the powder bed, the only considerable effects in the temperature distribution was observed for lower power input (P=100W) and only for different packing densities. The reason why the powder diameter did not show major impact in the model is related to the minor effective thermal conductivity change regardless of the diameter and the fact that the model is based in the total volume occupied by the particles as a whole.

The significance of the results demonstrate that a proper compaction and density distribution of the powder bed is important to keep the cooling rates and temperature distributions within the desirable range, however these impacts are only perceivable outside the melt pool zone. In the other hand, by looking to the power input, we can see that 400W with the current speed of 1m/s induce high temperature at the surface and through the layer thickness, very close to evaporation point.

This by itself brought a temperature gradient of around 1150K through the layer thickness, which is the main cause of warping and residual stresses. For P=100W the temperature did not reach the melting point at all, which could affect in the consolidation of the particles and in the final porosity of the built part.

Future research is necessary in order validate the model experimentally using different powder diameters and measure on which extent the powder bed is compacted or not.

**Abstract**— In borehole mining and oil and gas drilling, the drilling process is invisible from the surface, which is why a two-way communication method between the drill head and the surface is a must. The popular industrial instrumentation technique, widely known as measurement while drilling (MWD), has enabled industries to save costly employee hours and gain more control over the drill bit direction. There are four major methods used throughout history, where the mud pulse telemetry technique has become the state of the art because of its simplicity and convenience. However, like other methods, it has a major drawback of having a slow data transmission rate. Moreover, other methods have different issues which include large attenuation of the data that is transferred through drill pipes. Acoustic telemetry is the most recent method of transferring data through a solid medium, a technique using continuous wave propagation of forces in the wall of the pipe. A proper use of this new method is expected to become popular in the mining and oil-gas industries because of its faster data transmission rate and ability to ignore most attenuating parameters. This method is still in its optimization stage, and the use of a convenient tool to match the transducer with the parameters of the drill pipe and surroundings is still a challenge to overcome. This paper will propose a simulation model to simulate the transmission of data through drill pipes, and will show experimental results of such arrangement justifying the opportunities ahead in this field.

## I. INTRODUCTION

Experts involved in surveying or extracting fossil fuel and minerals face a great challenge of drilling without seeing, which is why their usual methods include measuring real time

data while drilling. This is commonly known as measurement while drilling (MWD) or logging while drilling (LWD). In addition, these operations involve large assemblies of equipment and inconveniences due to invisibility, complex well patterns, long operation times, high costs etc. The initial goal is to determine ore location, drilling orientation, properties of rock, dimensions of cavity and other parameters using sensor data assembled in the borehole assembly (BHA). This data is then transmitted to the surface from the wellbore (or the hole). Using basic trigonometry, a three-dimensional plot of the path of the well can be produced thus enabling an operator to measure the trajectory of the hole as it is drilled in real time. Therefore, it becomes easy to follow the preplanned direction of the drilled hole. Also, measurements to determine properties of the rock is done by taking natural gamma ray emissions from the rock [1]. Other information such as density, porosity, rock fluid pressures are taken by sensors based on sound or electricity [2]. All of this information helps to broadly determine what type of rock formation is being drilled, which in turn helps confirm the real-time location of the wellbore by comparing to seismic data. MWD downhole tools also allow the wellbore to be directed in a chosen direction, therefore known as directional drilling.

Historically there are four communication methods used, namely cable operated communication, mud pulse telemetry, vibration/pressure wave transmission and electromagnetic communication [3]. Among these, the most popular is mud pulse telemetry (MPT) which is a binary coding system and is the first of its kind to be used in the industry. It uses drilling fluid to transmit the pressure pulse created by a poppet type valve. The valve changes the drilling fluid's pressure thus the pressure wave propagates through the drilling fluid. At the surface the pressure differences are recorded and analyzed. This method, however, has its own issues such as

non-homogeneity of the mud fluid and is only operational when the drilling fluid is running. Most importantly, due to signal attenuation in the fluid, its data transmission rate is slow on the scale of 1-10 bits per second. As a result, exploring other methods such as communication via structural vibration have become necessary [3].

Acoustic telemetry includes the use of piezo transducers to produce compression, torsion, or shear waves that propagate through the drill strings to the other end where they can be picked up using another piezo transducer or another type of sensor. The medium of pressure wave transmission is the solid steel pipe rather than viscous liquid as in mud pulse telemetry. The information picked up by different sensors is converted into digital data and is recorded into the memory and broadcast by the transducers as vibration or acoustic wave through the drill string. The transducer generates this vibration within the steel drill string by means of a high frequency ferroelectric ceramic piezoelectric material with the combination of two different masses [4]. The captured signal is transferred to a computer where a program decodes the digitized sensor signal and extracts the downhole information; this method can give faster data rates up to 100 bits per second [5]. The vibrational method and theories have been known from the beginning of the MWD, but because of the lack of an efficient transducer, the method did not flourish. Currently, because of advancements in piezoelectric ceramic technology, the method has resurfaced and is beginning to gain commercial popularity [6-9].

Acoustic telemetry uses the solid medium of the drill string itself and not the mud fluid which is why it has different attenuation. For typical oil and gas applications, the attenuation for acoustics systems varies from 2-10 dB/1000 feet and up to 30 dB/1000 feet if the pipe is badly worn [10-12]. Along with a number of patents, the work published in academic journals are found to focus on wave transmission of different types through mass jointed pipe strings [13-14]. Drumheller has done a considerable amount of work which included investigations of the basic theory of wave propagation, the hardware of communication tools, and collecting and explaining a history of industrial experimental results on attenuation. [15]. Carcione introduced a time-domain algorithm for the propagation of one-dimensional axial, torsional, and flexural stress waves, which also includes transducer sources and sensors [16]. Based on this work some other works were modified and justified by experimental verification. Among the modifications include avoiding lateral vibration at the neutral point and a method to avoid them by a new approach of MPT and summarization of many more applications, such as wave loadings on offshore platforms, classical problems in wave propagation, and extensions to modern kinematic wave theory [17].

Most of the research work regarding drill bit communication focuses on communication through drill strings in the oil-gas industry but none address borehole mining, which has a number of important differences. In borehole mining, drill stems tend to be shorter, and larger in diameter and the whole pipeline can be within hundreds of meters, consisting of hundreds of pipes. Moreover, the impedance mismatch at each

pipe joint is much less, because the pipe joints are screwed to each other with no extension in outside diameter as seen in the pipe joints of the oil-gas drill pipe. So, the associated reflection and resonances at the pipe joints are less.

In this paper a universal simulation model will be proposed that can account for any types of drill string along with the transmitter and receiver for acoustic wave propagation. The simulation model will be verified by experimental data, which will justify the model. A simulation model will be a convenient approach to understand the characteristics of the pipelines for different applications, which include the attenuation and frequency shifting of the system. Moreover, this will lead to the optimization and modification of the transducer and sensors to be used with any specific application. If the frequency response of the system is known then a particular communication scheme can be chosen beforehand which can employ different frequency contents for a faster data transmission. Future research works will be to optimize the transducer based on the application and convenience in the communication scheme and also to choose a particular communication scheme.

## II. EXPERIMENTAL MODELING

An experimental apparatus was assembled for data transmission through drill strings as shown in Fig. 1. This experimental model includes Tonpilz-type piezoelectric transducers as both the transmitter and receiver. These transducers were designed for sonar applications. It is possible to use an accelerometer sensor at the receiving end, but in this experiment an identical transducer was used as the receiver. This configuration allows for two-way communication to occur if needed.

### A. Frequency Response of the Transducer

First, the experiment is performed attaching the transducers face to face with bolts. This experiment gives the frequency response of the two transducers shown in Fig. 2.

All control and data measurements are done by a National Instruments data acquisition system (NI-DAQ). A maximum length sequence (MLS) is a digital pseudorandom binary sequence that has a perfectly white, flat spectrum. This signal is used as an input signal into the driver transducer through an amplifier. The MLS is generated using linear feedback shift registers (LFSR) using Matlab® code created by Wiens [18] and

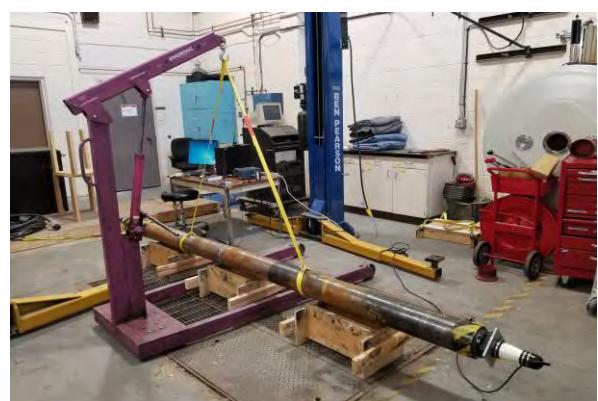

Figure 1. Arrangement for three pipes connected with transducers.

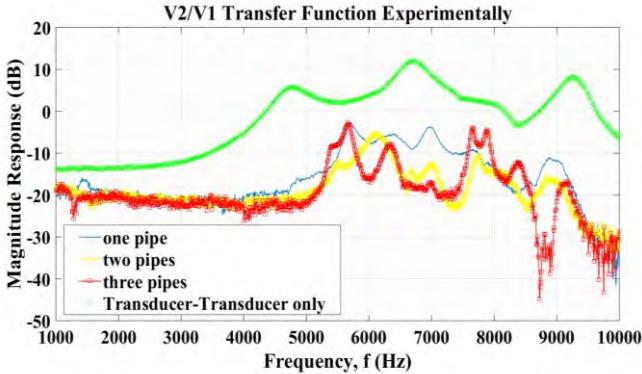

Figure 2. Frequency Response of the transducers only connected face to face and transducers connected with one, two and three drill strings.

LSFR feedback values from Koopman [19]. The output is measured from the receiver transducer through a voltage divider which is recorded as voltage  $v_2$ . The input voltage  $v_1$  is taken from the amplifier output through the voltage divider. The voltage divider is used here so that NI-DAQ device stays within the rated range of  $\pm 10$  V, while the amplifier outputs  $v_1=100$  V. The MLS used has a sampling frequency of 20 kHz.

The measured data was then used to obtain transfer function

$$ETFE = \frac{V_2}{V_1} \quad (1)$$

where  $V_1$  and  $V_2$  are the fast Fourier transform (FFT) of the measured voltage ( $v_1$  and  $v_2$ ) signals. This experimental method works well for pressure measurements of fluid transmission line [20] and is believed to be a good experimental approach for measuring vibration along any transmission line.

#### B. One, Two and Three Drill Strings

The transducers are connected with one drill string through the end caps. The drill string used for this experiment is collected from a mine site (in this application they are called jet rods). The transducers are then connected with two and three drill segment strings through end caps as shown in Fig. 1.

Fig. 2 shows the frequency response for different pipe arrangements with the transducers. It is clear from the figure that the frequency response range of the transducers is 4000 Hz to 10000 Hz. For ease of understanding, the peak natural frequencies are extracted and Fig. 6 is formed to show that with the increase of pipes the natural frequencies of certain modes are reducing and more frequency contents become visible in the range.

### III. PROPOSED SIMULATION MODEL

A model shown in Fig. 3 is proposed in this section for simulation that can represent the experimental apparatus previously shown. A successful model that can account for a certain number of drill strings and comply with the experimental results must be able to account for a large number of drill strings connected together. The model includes a driver/transmitter transducer, then a block for a number of drill strings and a receiver transducer to act as a sensor.

To obtain an effective and more practical simulation model, the linearized one-dimensional piezoelectric ceramic equations found in Sherman [21] are used. Also, the transducer is considered as a simple mass-spring-damper model where piezoelectric stack materials are placed between the head mass and tail mass. The pipeline of a finite number of drill strings can be modeled using a number of transmission line models [22] connected together. This accounts for the input and output forces and displacements in terms of transfer functions that can calculate the system more in a computationally inexpensive way.

In Fig. 3,  $v_1$  is the input forcing voltage at the driver transducer,  $u_1$  is the displacement at the driver transducer,  $F_1$  is the output mechanical force of driver transducer and also the input of the pipeline.  $F_2$  is the input force at the outlet of transmission/pipeline and also the output from the receiver transducer. Similarly,  $u_1$  and  $u_2$  are the displacements at the inlet and outlet of the transmission line.  $v_2$  is the output voltage from the receiver transducer.

#### A. Piezoelectric Transducer

A piezoelectric transducer is an electromechanical device that converts mechanical energy into electrical energy or vice versa. A lot of previous research has been performed on the design of an effective transducer, among them is a 50 kHz Tonpilz type transducer developed by Baylis [23]. A detailed discussion on the basic design analysis of this type of transducer is made in the book by Sherman and Butler [21]. This particular transducer is comprised of a combination of two masses bolted together with piezoelectric ceramic placed in between.

The basic governing equations of piezoelectric ceramics are the combination of mechanical and electrical characteristics which are dependent on each other. The constitutive relations are usually called piezoelectric equations that apply the theory of piezoelectricity. The equation, describe the interaction effects of stress, strain, electric displacement, and the electric field. In the case where the strain and electric fields are approximately uniform, the mass of the piezoelectric material can be assumed negligible, and the amount of free charge is small, the behavior of the transducer can be modelled by the simplified constitutive equations given in [21]

$$S = s^E T + d^t E \quad (2)$$

$$D = d T + \epsilon^T E \quad (3)$$

where  $T$  is the stress,  $S$  is the strain,  $E$  is the electric field, and  $D$  is the electric displacement. All of these variables are functions of position and time, where  $T$  and  $S$  are both symmetric second rank tensors. In these equations,  $S$  and  $T$  are  $6 \times 1$  column matrices,  $E$  and  $D$  are  $3 \times 1$  column matrices,  $s^E$  is a

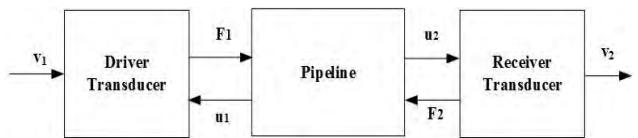

Figure 3: Proposed model

$6 \times 6$  matrix of elastic compliance coefficients,  $d$  is a  $6 \times 3$  matrix of piezoelectric coefficients ( $d^T$  is the transpose of  $d$ ), and  $\epsilon^T$  is a  $3 \times 3$  matrix of permittivity coefficients [24].

### B. Pipeline

To model the drill string, a different approach is taken in this research by using a transmission line model which is often used in the hydraulic circuit design for fluid flow through a pipe. The transmission line model was initially developed by Krus [22] and is based on the assumption of a four pole equation and approximating the response with a number of transfer functions, as shown in Fig. 4. This model reduces to a compact transfer function model which only calculates the states at inlet and outlet thus reducing the computational effort. There is other research done on the modification of this transmission line model in order to gain better accuracy and apply to other transmission line problems [25-27]. However, all of these are used in the application of fluid mechanics. For this research, pressure and flow are replaced with analogous force and velocity.

From analogy, in this model the pressure  $P$  and flow rate,  $Q$ , can be replaced with force,  $F$ , and velocity  $u$ . They are related by the following equation [22]

$$F_1 = C_1 + Z_c u_1 \quad (4)$$

$$F_2 = C_2 + Z_c u_2 \quad (5)$$

where,  $Z_c = A c \rho$  is the characteristic impedance of the drill string,  $c$  is the local speed of sound in the transmission line,  $A$  is the cross-sectional area of the pipe, and  $\rho$  is the material density of the drill string.

The transfer functions in Fig. 4 are as follows. They are calculated in the laplace domain,  $s$ .

$$H_1(s) = \frac{R}{kTs + 1} \quad (6)$$

$$H_2(s) = Z_c \frac{-RA}{s^2 + kTe^{2pc}} \quad (7)$$

$$G_f(s) = \frac{kTe^{2pc}s + 1}{kTs + 1} \quad (8)$$

where,  $k$  is an empirical factor. It was determined in [22] that  $k = 1.25$  is an acceptable value. The wave propagation time,  $T = \frac{L}{c}$ , is related to length of the pipe,  $L$ , and local speed of sound,  $c$ . The distributed line resistance,  $R = \frac{\mu\pi d}{h} L$ , assuming ideal laminar flow. This model neglects unsteady friction, and assumes a distributed resistance across the transmission line.

The  $e^{-Ts}$  term with the  $(s)$  transfer function is a time delay of time,  $T$ , simulating wave propagation.

### IV. RESULTS OF SIMULATION MODEL AND COMPARISON

The simulation model for the two transducers connected face to face show similar frequency response to that of experimental results except in the 1<sup>st</sup> mode shown in Fig. 5, which is expected given the assumptions in the model. The assumptions are taken as the model consists of two mass spring damper system where the mass of the piezo ceramic is ignored and it is considered as a spring damper connection in between two masses [21]. Also, the actual transducer has masses bolted together at an unknown preload and the whole assembly is covered with neoprene type rubber material. So, these factors played an important role of moving the first mode of the experiment from the simulation model value.

Fig. 5 shows the frequency response of different pipe arrangements for the simulation model. The frequency response of different pipes have similar trend to that observed in the experimental result shown in Fig. 2.

Fig. 6 compares the resonant frequencies between the experimental apparatus and simulation model. The simulation model has a different range than the experimental model as shown in Fig. 5, which is why a different range is seen in the

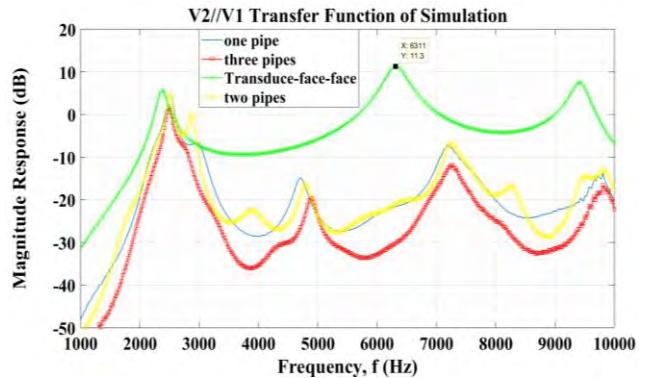

Figure 5. Frequency Response of the transducers only connected face to face and transducers connected with one, two and three drill strings.

### Natural Frequencies vs Modes for different pipes

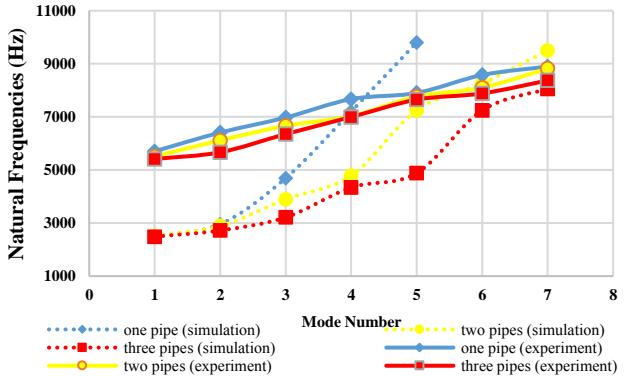

Figure 6. Comparison of Natural Frequencies of different Modes of different pipe arrangements of simulation model and experimental model.

simulation model for the frequency response of different pipes than the experimental results. Also because the experimental apparatus is a drill string that has a construction of concentric inner and outer pipes supported by spacers of different materials, whereas in the simulation model a cylindrical type of pipe is considered with a similar mass matched with the experimental apparatus. However, a similar trend of decreasing natural frequencies of different modes with the increase of number of pipes is observed in both experimental and simulation model results. This is expected because the natural frequencies of a system change disproportionately with the square root of its mass.

## V. CONCLUSION

The comparison of results between the simulation model and the experiment indicates that the simulation model is able to explain the wave propagation in long drill strings. Thus this can help with developing a communication scheme for data communication in drill string using methods that employ wide range of frequency content in a single transmission.

## ACKNOWLEDGMENT

The authors would like to acknowledge the help of Mr. Douglas V. Bitner of University of Saskatchewan for his help with this research. The authors also acknowledge the support given by the Saskatchewan Research Council, SK, Canada for the experimental assembly and equipment, as well as financial support of this work.

**Abstract:** The mechanical properties of 3D-printed parts have been extensively studied and the effects of printing parameters on them have been investigated. However, there are limited reliable data for the thermal properties of the materials used for printing, which can impede the development of additively manufactured heat exchangers made from either pure polymers or composites. In the current study, the effect of the layer height and width have been investigated experimentally and numerically to explore the thermal anisotropic nature of unidirectional printed parts printed using fused deposition modelling (FDM). The results show that increasing the layer height and width causes deterioration in the thermal conductivity, which may reach 65% of reduction compared to the pure polymer.

**Keywords:** FDM, FFF, printing parameters, thermal conductivity, PLA, numerical modelling

## I. INTRODUCTION

Polymers have many advantages—such as corrosion resistance, low weight, and smooth surfaces—which make the class a notable competitor to exotic metals in heat exchanger applications. Nevertheless, their low thermal conductivity narrows their application [1]. The addition of conductive fillers inside the polymer matrix is an effective remedy to this issue. Polymer composites are conventionally produced by an injection process [2]. However, controlling the injection process parameters, such as injection flow conditions, filler volume concentration, their distribution, and their orientation state inside the polymer matrix, is not practically achievable.

Additive manufacturing (AM) is an alternative approach to produce composite polymer components [3], [4]. It depends on laying the material layer by layer according to the designed 3D CAD model. Compared with subtractive methods, it has many advantages, such as shortening the production time cycle and reducing cost [5], [6]. AM has many techniques, such as stereo-lithography (SLA), fused deposition modeling (FDM), selective laser sintering (SLS), and laminated object manufacturing (LOM) [7].

Recent studies show the ability to produce a final prototype of polymer heat exchangers using either one of the previous methods. For example, Jia et al. [8] employed the FDM process to produce a heat sink made of thermally conductive graphite polymer composite for a 3D printer extruder. Their results showed that it achieved a similar energy dissipation effectiveness compared with the conventional aluminum one. In the same direction, Hymas et al. [9] established a new hybrid approach of FDM and embedded metallic strips to fabricate a composite polymer heat exchanger (CPHE). Kalsoom et al. [10] exploited the stereolithography process to produce an electronic heat sink from composite resin made of synthetic diamond fillers and acrylate polymer. In this context, the current work is dedicated to studying the effect of the FDM process parameters on the thermal properties.

FDM is the most commonly used process parameter due to its ability to produce low cost products with negligible waste, the wide availability of various plastic filaments, and because there is no need for chemical post-processing. The process theory is based on laying the material layer by layer on a heated bed using a continuous filament of thermoplastic that passes through a hot nozzle moving in the X-Y plane. The nozzle motion is controlled according to the data generated by slicing software which is responsible for dividing the CAD model into separate layers. Once one layer is completed, the bed is lowered in order to begin the other one and so on until

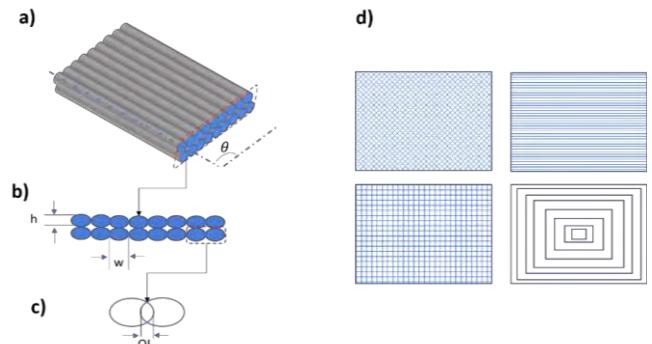

Figure 1: FDM process parameters; (a) raster angle,  $\theta$ ; (b) layer height,  $h$  and width,  $w$ ; (c) overlap,  $OL$ ; (d) infill pattern.

the whole product is built. This process has many parameters, such as layer height, layer width, overlap between layers, infill pattern, and raster angle, as shown in Fig. 1.

Due to the low mechanical and thermal properties of the FDM 3D-printed parts, many studies have focused on producing composite filament. However, this composite should have specific properties to be easily processed with FDM, such as viscosity, flexibility, stiffness, strength, and conductivity. Thus, for some cases where the filler concentration is high, additives—such as surfactants—are needed to produce homogeneous distribution of the filler inside the matrix. Some of these studies are presented here.

Nikzad et al. [11], [12] could increase the mechanical and thermal properties of Acrylonitrile Butadiene Styrene polymer (ABS) by including some metallic fillers—iron or copper—to produce a composite filament for FDM applications. They were able to successfully find the appropriate mixture percentage that meets the desired properties without facing processing issues during printing. They utilized the transient line source technique and the Differential Scanning Calorimetry (DSC) to measure thermal conductivity and the thermal capacity of the resulted mixture of composite polymer, respectively. Their results show the thermal conductivity achieved marked improvement above 30 vol %. However, the thermal capacity deteriorated by incorporating the metallic fillers at any volume percentage. Furthermore, they examined the dynamic mechanical properties of the composite and demonstrated that high filler percentage reduced the material strength due to poor filler distribution, agglomeration, and the development of voids. Laureto et al. [13] used the guarded heat flow meter TCA300 to quantify the through-plane thermal conductivity of 3D-printed parts made from the commercially available Polylactic acid (PLA) filament and its metal composites. Similar attempts were carried out, but with different metallic composites such as in the studies by Hwang et al. [14] and Masood et al. [15].

Ning et al. [2] examined experimentally the influence of process parameters such as nozzle temperature, raster angle, fill speed, and layer thickness on mechanical properties of carbon fiber reinforced polymers (CFRP). The adopted filament was made of an Acrylonitrile Butadiene Styrene (ABS) matrix with a volume concentration of 5% of chopped carbon fiber. They concluded that the optimum parameters are 220 °C, [0/90], 25 mm/s and 0.15 respectively in terms of the tensile properties. However, regarding the ductility and toughness, the optimum values remain the same, except for the layer thickness and raster angle which have values of 0.25 mm and [45/45], respectively. Furthermore, they investigated the effect of adding these carbon fibers on the porosity of the FDM-printed parts using an SEM micrograph. Shemelya et al. [16] utilized the Transient Plane Source (TPS) to address the anisotropic thermal properties of the 3D-printed ABS composites filled with graphite, carbon fiber, and silver. Flaata et al. [17] developed a steady-state apparatus designed specifically to measure the thermal conductivity of 3D-printed composites and exploited it to test some feed stock materials

available commercially for FDM such as PLA, ABS, brass PLA, bronze PLA, and stainless steel PLA. However, there is a large discrepancy between the values measured by Laureto [13], Shemelya et al. [16], and Flaata et al. [17]. For instance, ABS has a thermal conductivity of 0.35 according to [17] while it was tested by [16] and suggested to have a value ranging from 0.15 to 0.2, depending on the direction of measurements; this represents a deviation of 57%–75%. The same situation applies for PLA and its composites. Also, some studies addressed the manufacture of piezoelectric ceramics and ceramic composites via FDM [10], [18], [19].

In summary, the mechanical properties of 3D-printed parts have been extensively studied and the effects of printing parameters on them have been investigated. However, to the best of our knowledge, there are limited studies about their thermal properties. The achievement of creating a thermally efficient composite polymer heat exchanger (CPHE) hangs on investigation of the anisotropic nature of the printed parts to produce reliable thermal conductivity data and exploration of the effects of process variables on their performance. Therefore, in order to achieve this goal, two objectives must be met:

- Develop an accurate experimental facility for measuring the thermal conductivity of low conductive materials.
- Characterize the effect of the layer height and width on the thermal conductivity of unidirectional printed parts experimentally and numerically.

## II. MATERIALS AND METHODOLOGY

### A. Preparation of Samples

To examine the effect of the process variables on the thermal anisotropic nature of unidirectional printed parts, the specimens need to be fabricated in three different configurations of the same size, as shown in Fig. 2. The first one is for quantifying the thermal conductivity in z-direction ( $k_{zz}$ ), while second one is for y-direction ( $k_{yy}$ ) and the last one is for x-direction ( $k_{xx}$ ). However, only the first direction was printed and measured experimentally, while the other directions were investigated numerically and analytically. The experimental measurement was utilized as a validation step for the numerical model. The influence of the layer height was studied by printing the samples in these configurations with

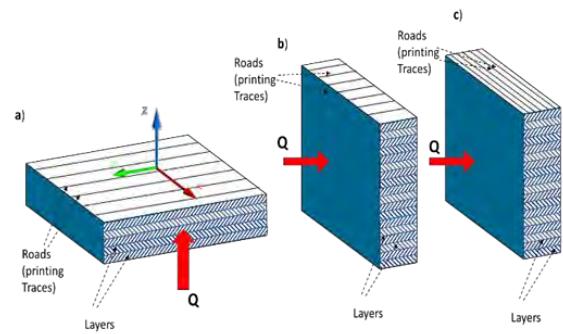

Figure 2: Different Configurations to measure the thermal conductivity in;  
(a) z-direction,  $k_{zz}$ , (b) y-direction,  $k_{yy}$ , (c) x-direction,  $k_{xx}$ .

different values ranging from 0.05 mm to 0.3 mm, while keeping the layer width and overlap constant at 0.4 mm and 0 mm, respectively, which are the default printer setting. As for the layer width, its value was varied from 0.4 mm to 0.8 mm, while maintaining the layer height and overlap at 0.15 mm and 0 mm. The printing temperatures were 200 °C for the nozzle and 60 °C for the bed. All the samples were printed with line patterns with a raster angle of 90 °C in order to be unidirectional.

All samples were printed with 100% fill from PLA filament using the Ultimaker® 2 printer. Each sample was printed to the size 40 mm x 40 mm x 3 mm, which is the same cross section area of the test rig. An automatic ULTRAPOL polishing machine was utilized to ensure that the sample surfaces were parallel and its surface roughness was very small. The sample surface roughness was measured after polishing by means of a profile meter and its Ra value was about 0.462 µm.

### B. Microscopic Study

Determining the thermal conductivity for the other directions numerically or analytically requires an investigation of the pattern of layers after printing, which was carried out using a microscopic study. Also, this study was used to obtain the air volume fraction inside the matrix. Fig. 3a depicts the effect of changing the layer height from 0.15 mm to 0.3 mm while keeping its width at the default value of 0.4 mm. Similarly, Fig. 3b shows the layer width effect while keeping the layer height at 0.15 mm. As can be seen from this figure, increasing the layer height increases the air volume fraction and the same effect happens for the layer width. Fig. 3 indicates that the pattern is homogeneous, except for some roads which are not connected to each other. This phenomenon is more probable to occur at small layer heights. This is because the melt flow sometimes finds low resistance in one direction more than the other when squeezed against the printer bed. Another important feature which appears in this figure is that the roads starts to completely disconnect when layer width is more than 0.5 mm. This additional air gap between the roads most probably happens because the printer is not able to provide the correct amount of extrusion during the printing time which is controlled by the travelling speed. The printing speed was held constant at a value of 60 mm/s for all the samples. Each photo was then converted into an 8-bit image type in order to perform thresholding. ImageJ software was

employed to do the thresholding and calculate the air volume fraction. Another method was employed to measure the volume fraction of air which depends on weighting the sample while postulating that the air mass inside the gaps is negligible, and then applying the following equation:

$$v_f = \frac{v_s - v_p}{v_s} \quad (1)$$

$$v_p = \frac{m_s}{\rho} \quad (2)$$

where  $v_f$ ,  $v_p$ ,  $v_s$  are the volume fraction of air, the volume that the polymer occupies inside the printed part, and the printed part volume.  $\rho$  is the polymer density which was measured for the PLA feed stock filament. Table 1 and 2 show a comparison between the air volume fraction resulting from the ImageJ method and weighting method. As can be seen from these tables, there is a large deviation between the two methods, especially for the layer height. The reason for this is that the tested sample under the microscope is broken only at one section and the photo captured part of this section which cannot be considered representative of the whole sample, especially in given the layers' disconnection problem. Therefore, the second method was assumed to be more accurate; however, the photos give a better insight into the pattern happening inside the printed part and will help to develop the numerical model.

### C. Numerical Modeling

The effective thermal conductivity in z or x directions can be predicted by simplifying the problem into a 2D model which resembles a unit cell that was extracted to represent the overall geometry. ANSYS fluent 18.2 software [20] was used to predict the heat flow by conduction through printed parts. The unit cell had a dimension of  $h/2$  in the z-direction and  $w/2$  in the x-direction, as shown in Fig. 4a. A temperature boundary condition was applied at the right and left boundaries of the domain, while insulated and symmetry conditions were adopted for the top and bottom boundaries, respectively, as shown in Fig. 4b. This configuration was employed to predict  $k_{xx}$ . As for the other direction, the boundary conditions were reversed, where the temperature gradient should be in the same direction as the thermal conductivity measurement direction. The energy equation solution results in the heat transfer which is used to calculate the effective thermal conductivity by exploiting Fourier's law of conduction. The simulation was repeated several times to find the layer height and width influence on the thermal properties. The same range stated in

$h=0.15 \text{ mm}$ ,  $w=0.65 \text{ mm}$  and  $\text{OL}=0$

b)

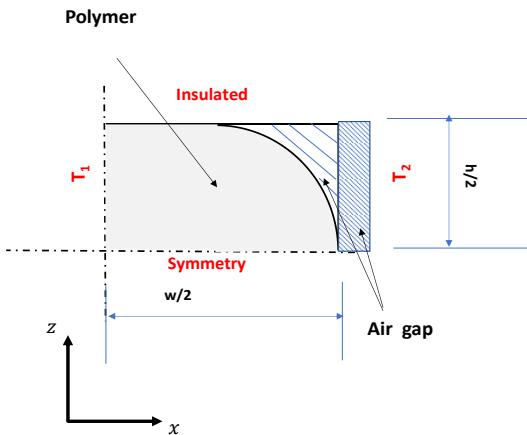

Figure 5: Numerical Model (a) unit Cell (b) domain.

Section A was used here for the numerical simulation. The employed temperature difference,  $T_1 - T_2$ , was set equal to 1 for all cases. The volume fraction calculated by weighting the samples in the previous section was used to determine the air gap distance between the roads.

### D. Experimental Methodology

Fig. 5 shows the suggested design which is mainly composed of two sides; one is serving as the heat source and the other one represents the heat sink, where the sample is sandwiched between them. The hot side is composed of two isothermal blocks manufactured from copper material,  $k = 391.2 \text{ W/m K}$ , with a small thickness to produce a uniform temperature field through them. The function of the first block is to supply the heat into the sample under testing. The secondary hot block was designed to surround the main one in order to guarantee that all the heat coming from the source flows into the sample only and there is no heat loss from the main block either from its sides or its top surface. The secondary block's power was controlled to ensure that the two blocks have the same temperature which was monitored at three different locations. It was assumed that the secondary power was adequately tuned when the temperature difference did not exceed  $0.001^\circ\text{C}$  at steady state.

Similarly, the cold side consists of two blocks, which were also manufactured from copper material. Both have a U channel which permits the chilled cooling water to flow through

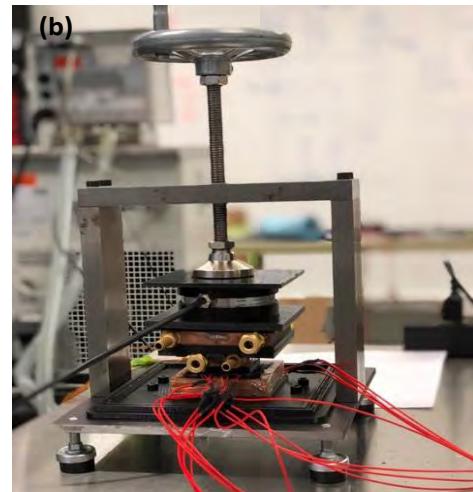

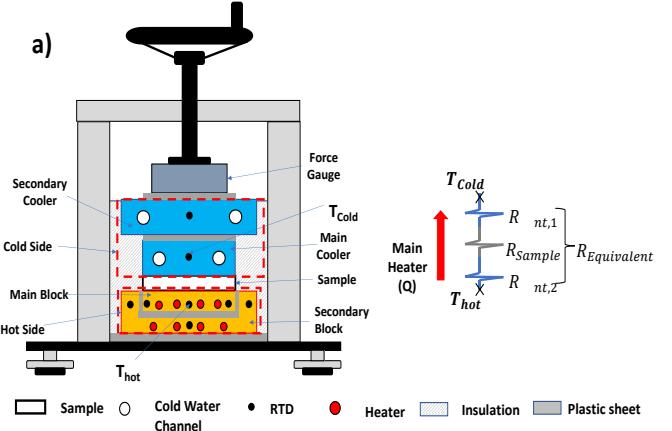

Figure 4: Experimental apparatus (a) Schematic (b) real rig.

them. All the blocks and the sample were stacked above each other and forced against a force gauge using a clamping system. The secondary cold block function is to isolate the system from the clamping system base. All parts were confined into a large block filled with silica aerogel with a thermal conductivity of 0.014 w/m k.

The thermal conductivity can be easily calculated by measuring main block input power and temperature difference between RTD, as given by:

$$k = \frac{Q \Delta t}{A_c(T_{hot} - T_{cold})} \quad (3)$$

where  $k$  is the measured thermal conductivity,  $\Delta t$  is the specimen thickness,  $A_c$  is the sample cross section area and  $(T_h - T_c)$  is the temperature difference between the main hot block and main cold one. Some aspects were considered while doing the testing to make sure that the contact resistance effect is negligible. Thermal interface material was applied at both sides of the sample and the clamping pressure was kept high at about 3 bars for all measurement. Moreover, the contact resistance value was calculated by testing the total thermal resistance for three samples, at the same operating conditions, with similar geometrical and printing parameters, except for the thickness which was different. The contact resistance value can be extracted by drawing its value against its thickness and performing a linear curve fitting. Its value was less than 2% of the total resistance, which can be discarded.

### III. RESULTS

#### A. The effect of layer height

The thermal conductivity in z-direction ( $k_{zz}$ ) was measured experimentally and compared to the numerical model, as shown in Fig. 6. Each sample was measured three times and averaged to guarantee the reliability of the test rig. It is indicated that there is a good agreement between both of them which supports the possibility of using the numerical model to predict the thermal conductivity in x-direction ( $k_{xx}$ ). The analytical parallel was employed to predict the thermal conductivity in the third direction ( $k_{yy}$ ) which is given by the following equation:

$$K_e = (1 - V_f)K_m + V_f K_a \quad (4)$$

where  $k_e$  is the effective thermal conductivity and  $k_m$  and  $k_a$  are the conductivities for the matrix and air respectively.  $V_f$  is the air volume fraction inside the PLA matrix. The numerical model requires the thermal conductivity of pure polymer and this has been measured by printing a sample with a small layer height of 0.06 mm and a high percentage of overlap to ensure that there are no air gaps generated inside the part. Its value was 0.2207 w/mk. The experimental results in Fig. 6 indicate that increasing the layer height reduces the thermal conductivity in z-direction until a value of 0.133 w/m k at layer height of 0.3 mm is reached, due to the increase of air volume fraction. This represents a percentage of reduction of about 40 % compared with pure PLA polymer. Figs. 6 and 7 illustrate that the effect of layer height is more significant in z and x directions, while it is nearly constant for y-direction. The

thermal conductivities are higher in directions z and y than x-direction. This is because the heat path in x-direction is a series which increases the heat's overall resistance while it is parallel for the other directions. For x-direction, the thermal conductivity decreases and then increases because when the layer height is small, the layers are not connected. In summary, the layer height increase causes a decrease in the thermal conductivity, which reaches values of reduction of 42%, 14%, and 28% for x, y, and z, respectively, compared with the pure polymer at a layer height of 0.3 mm. The previous percentages were calculated based on the numerical model predictions.

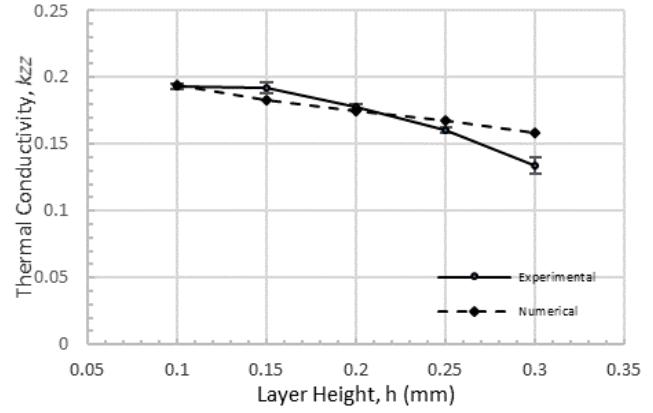

Figure 6: Comparison between the experimental results and numerical model for studying the effect of layer height on the thermal conductivity,  $k_{zz}$  at constant layer width of 0.4 mm.

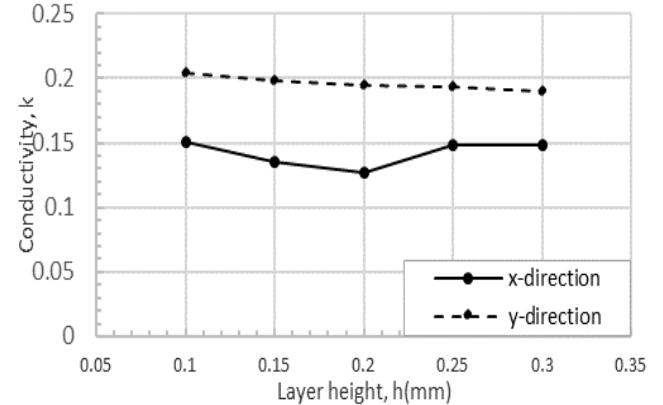

Figure 7: The effect of layer height on the thermal conductivity in y-direction ( $k_{yy}$ ) and x-direction ( $k_{xx}$ ) at constant layer height of 0.15 mm.

#### B. The effect of layer width

The influence of the layer width on thermal conductivity in x and z directions was predicted numerically while the parallel model was employed for y-direction, as shown in Fig. 8. Similar to the layer height, increasing the layer width causes

deterioration for the thermal conductivity in all directions. Also, the thermal conductivity is higher for y and z directions than x-direction, because of the same reason mentioned before. The layer width has a severe effect on the thermal conductivity in x-direction because the layers are completely disconnected in that direction.

The thermal conductivity in x-direction reaches a low thermal conductivity value of 0.077 w/mk at a width of 0.8 mm, which represents a 65% reduction compared with pure polymer, while the reduction is 28% and 25% for y and z directions, respectively. This highlights the importance of studying these parameters and demonstrates the possibility of tailoring the thermal properties of the printed parts, especially in the case of continuous fiber printing.

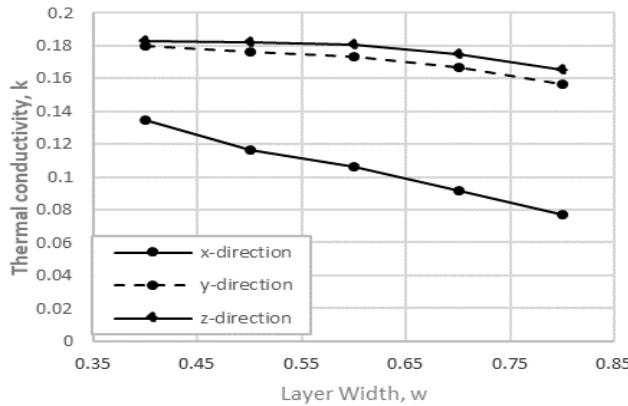

Figure 8: The effect of layer width on the thermal anisotropic nature of 3D-printed parts.

#### IV. CONCLUSION

This work examined the influence FDM process parameters on the anisotropic thermal properties of unidirectional 3D-printed parts. An experimental facility was developed to measure the effect of the layer height on the thermal conductivity in one direction, which was used as a validation step for the developed numerical model. The numerical model used in parallel with the analytical model was able to quantify the thermal conductivities in all directions. The main outcomes can be summarized into these points:

- Increasing either the layer height or width reduces thermal conductivity in all directions as a result of porosity generation.
- The effect of layer width is more significant than the layer height, especially when the layer disconnection problem exists.
- Increasing the layer height, while keeping the layer width constant at 0.4 mm, results in a drop in the thermal conductivity which reaches a value of 42%, 14%, and 28% in x, y, and z directions, respectively, at a layer height of 0.3 mm compared with pure polymer.
- Increasing the layer width, at constant layer height of 0.15, leads to a decline in thermal conductivity, reaching reduction percentages of 65%, 28%, and

25% in x, y, and z directions, respectively, at a layer width of 0.8 mm.

**Abstract**— Recent investigations using image-based computational flow dynamics (CFD) have revealed turbulent-like blood flow instabilities (hemodynamics) within intracranial cerebral aneurysms and surrounding vasculature, which may contribute to aneurysm initiation, growth, and rupture. We describe a method derived from spectral decomposition of flow for inspecting and characterizing these “turbulent-like” hemodynamic structures in intracranial aneurysms by sonification of CFD generated data. Motivated by auscultation techniques, the current research seeks to address the limitations of conventional CFD animations by allowing the user to listen to complex flow patterns that are often difficult to discern visually. In the process, the proposed method of sonification is successfully applied to a series of datasets resulting from high-fidelity numerical simulations of intracranial aneurysms. The resulting framework is shown to be highly efficient in performing parametric sonification in real time.

**Keywords-** *CFD; biomedical; sonification; signal processing*

## I. INTRODUCTION

A cerebral aneurysm is the localized bulging of a weakened artery wall within the brain. Rupture occurs when the stresses exerted on the artery wall exceed the strength of the wall.

Blood flow instabilities (hemodynamics) are thought to contribute to the initiation, growth, and rupture of intracranial aneurysms [1], by stimulating degenerative remodeling (weakening) of the artery wall. The forces associated with these unstable flows are difficult to measure non-invasively using current technologies, thus, medical image-based CFD has been used to investigate these hemodynamic forces retroactively [1][2][3].

The initiation, growth, and rupture of these aneurysms is a complex, multifactorial process, but it is known that remodeling occurs according to flow conditions [4]. At Reynolds number of less than 500, turbulent-like flow has been observed in glass models of human intracranial aneurysms [5], starkly contrasting the commonly accepted threshold value of  $Re=2300$ .

Using digitized patient-specific vasculature models extract-

ed from clinical 3D angiography images, blood flow is simulated using advanced numerical methods. The results of such simulations are typically visualized as part of the process of data analysis.

These investigations have revealed turbulent-like flow instabilities within aneurysms or the vessels that host them, with implications for aneurysm rupture and initiation [1][2]. Such instabilities are typically represented through conventional visualization paradigms (glyphs, streamlines, isosurfaces), and though these can provide tangible and intuitive representations of the hemodynamics, visual differences among unstable laminar, transitional, and turbulent flow regimes in complex vascular geometries are often difficult to discern.

Auscultation refers to the established medical technique of listening to the sounds of the body for evaluation purposes [6]. For example, clinicians are trained to identify turbulent blood flows by recognizing auditory properties of duration, quality, and timing during examination of bruits in the carotid artery [6]. Doppler auscultation has been used in preliminary stages to listen to valvular movements and blood flow velocity sounds during cardiac examination, resolving sounds undetected by stethoscope [7], though to our knowledge, this technique has not been demonstrated on intracranial aneurysms.

Intracranial saccular aneurysms have been observed to emit acoustic signals (bruits) as a result of fluctuating hemodynamic flows thought to be characterized as turbulent-like, if not necessarily turbulent in the strict fluid mechanical sense [8][9][10]. These vibrations are difficult to measure in vivo due to difficulty differentiating these bruits from other bodily sounds, and as such are not a reliable source of diagnostic information [9].

Visually communicating spatiotemporal flow instabilities ignores the existing strengths of the human auditory system for resolving frequencies as compared to visual perception of spatial frequencies. For example, attempting to visually distinguish a difference of pitch between vibrating strings ignores the auditory ability to distinguish subtle pitch differences, of which [11] indicates can be as small as 0.2%.

This lack of visual acuity is not only a problem of aneurysm visualization, but flow visualization in general. High frequency fluctuations require video or animation with an appropriately high frame rate (at least twice the fluctuation rate, in agreement with Nyquist's theorem) or greatly slowed video (thereby in-

This research was funded by the Canadian Natural Sciences and Engineering Research Council, the Social Sciences and Humanities Research Council, and the Heart & Stroke Foundation.

creasing time required to analyze data). This limitation becomes increasingly apparent as frequency of fluctuation increases.

Sonification is “the data-dependent generation of sound, if the transformation is systematic, objective and reproducible” [12]. The most common method of sonification, parameter mapping, involves careful mapping of data dimensions to auditory dimensions [13].

Sonification in the current work begins by decomposing the time domain values (velocity) in the frequency domain in order to discriminate regions of unstable flow. The current method allows inspection of individual frequency bands independently. Although point vector values remain the basis for our current work, the frequency domain processing between these vector values and the audio output distinguishes the current research from previous works. By sonifying the spectrogram, the envelope shape (percussive or smooth nature) is communicated along with spectral content.

In this context, a novel method originally inspired by Doppler ultrasound auscultation is presented for communicating the nature of the flow by augmenting conventional flow visualizations with data-driven sound (sonification) for the purposes of more easily identifying hemodynamic flow quality.

## II. METHOD

High-fidelity CFD data sets produced using cases from the open-source Aneurisk database [14] serve as the basis of this methodology. These simulations were performed with a high-resolution strategy where a high-fidelity Navier-Stokes solver was used in combination with fine spatial and temporal resolutions. Fully developed Womersley velocity profiles were applied at the inlet, and zero pressure was specified at the outlets.

The density of the fluid was 1.025 g/cm<sup>3</sup> and its corresponding viscosity 0.035 Poise was used. The computational mesh consisting of tetrahedral elements is generated using the open-source Vascular Modelling Toolkit (VMTK) [15] from segmented and preprocessed CT angiograms. A second-order-accurate, minimally dissipative, and energy-preserving open-source CFD solver (Oasis) is used. Number of elements range from hundreds of thousands to millions of elements, with a time-step resolution on the order of 0.1 ms [16][17].

Within an interactive visualization environment (ParaView - an opensource scientific visualization tool), the average power spectral density of velocity-time traces is computed for a probed sample volume, defined by centre point and radius, in order to evaluate a local region of flow within the aneurysm sac. The probe radius is chosen based on two considerations: first, the real-time computation must support interactivity, and second, the probe should not be too spatially localized or too global. To define this balance of local and global volume, the upper bound of probe radius should neck diameter of the aneurysm, while the lower bound will be considered small enough to separate coherent Q-criterion structures. The frequency content and time-varying power of the resulting spectrogram are sent to a real-time audio server (SuperCollider sound server) to control the frequency and loudness of a bank of audio-rate sound generators. The summation of these generators results in

a harmonically rich signal representative of the probed location.

This on-the-fly implementation is contained (though not constrained) within the ParaView Python shell and intended to run alongside a synchronized animation. Sound networking protocol Open Sound Control (OSC) is used to communicate the spectrogram data between the live ParaView environment and audio server. The audio presentation of the signal is highly configurable while maintaining audio-rate synthesis, allowing the user to pitch, slow down, or threshold by frequency band in real-time, synchronized to the visualization. Fig. 1 provides an overview of this process.

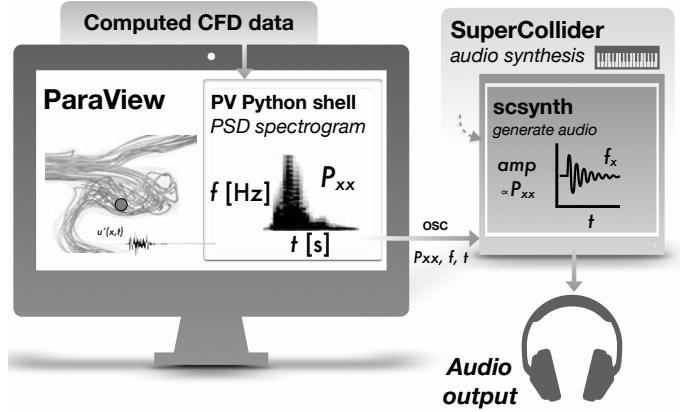

Figure 1: An overview of the method of implementation.

The structure of the sonification “instrument” was designed such that any aneurysm dataset (or any collection of spatiotemporal data) may be used as input with little manipulation (only requiring a transpose of velocity vectors). As the user probes the data, varying audio outputs are generated local to the probe. As such, different frequency content and amplitude envelopes are readily generated for each new sample of the dataset.

A guiding philosophy of sonic aesthetics was to caricature the existing physiological phenomena by generating sound inspired by fluid sounds existing in nature, and not necessarily to recreate the full acoustic field tied to the flow.

The basis of our parameter mapping was generated as simply as possible: the spectral content of velocity is mapped with auditory frequency values, while magnitude of spectral content is mapped with loudness. Use of spatial audio was considered to represent “space” of the mesh, but was ultimately found more useful for communicating the kinetic directionality of flow within the sample volume.

### A. Implementation

Data is stored in binary data frames and accessed interactively from the Paraview render view. SuperCollider is used to generate the sonification from the flow data. The real-time selection, filtering, and spectral processing of flow velocity is described below.

The chosen probe radius used is 0.25 mm, containing approximately 50 discrete points within the volume. A list of point identifiers is generated for a 20 uniformly distributed random points within this local volume. The velocity values for these points through time will serve as the basis for the sonification, to be discussed in subsequent sections. This sonification is intended to accompany a synchronized visualization with time duration chosen by the user. As such, this pipeline is updated once for each period of flow. The data has temporal resolution of 0.004s (2500 samples/second) and about 500 000 points.

As shown in Fig 2, the velocity content for each point is extracted and filtered by criteria of spectral power index (SPI) to isolate flow instabilities.

SPI is a frequency domain decomposition method introduced by Khan et al as a means to quantifying the transient instabilities of turbulent-like pulsatile flows without cycle-to-cycle variations [18]. This decomposition separates the pulsatile carrier signal from the turbulent-like flow instabilities. By using a high pass filter to remove the 99% most energy-carrying frequencies (corresponding to a cutoff frequency of 25 Hz), flow instabilities can be isolated. SPI is defined as the ratio of energy contained within the flow instabilities as a fraction of all signal energy.

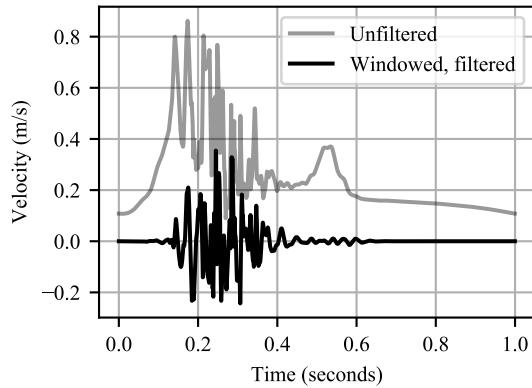

Figure 2. Isolation of velocity fluctuations by high-pass filtering the pulsatile signal according to SPI criteria. A Blackman window is used prior to filtering.

The local Power Spectral Density (PSD) spectrogram for the filtered velocity data associated with each point is calculated using a window length of 256 samples with 192 sample overlap, resulting in a smooth, temporally shifting view of the power content for each frequency bin. The average spectrogram for the sample volume is then computed. This matrix of power content corresponds to 128 frequency bins  $\times$  36 time bins.

A synthesizer template used for creating synth nodes (a synthdef) was generated in the SuperCollider environment and stored on scsynth (a real-time SuperCollider audio server). Using sound networking protocol Open Sound Control (OSC), the power matrix is sent to scsynth.

The frequency content and time-varying power of the computed spectrogram are fed to a bank of sound generators. Each

frequency bin of the spectrogram corresponds to the frequency of a generator. The time-varying power values of the spectrogram are used to modulate the loudness (amplitude) of each generator in time.

The power associated with each bin corresponds to the temporal loudness (amplitude envelope) of the sound as well as a “complexity” parameter, while the frequency value corresponds to the resonant frequency of a constant skirt gain filter (Ringz generator) with noise input. The “complexity” parameter controls the cutoff frequency and modulation depth of a resonant high-pass filter. By pseudo-randomly shifting the cut-off frequency of the high pass filter near the resonant frequency of the Ringz generator, and with a shift depth proportional to the temporal power, sound textures resembling bubbles are generated to indicate a higher level of flow complexity.

The apparent directionality of flow is communicated by rotating an ambisonic B-format sound field around the user. Given the position of the aneurysm model onscreen, the directionality of flow relative to the user is determined and used to spatialize the sound; for flow visually moving left-to-right, the sound rotates correspondingly, and vice versa. The perceived rotation angle indicates the relative velocity orthogonal to the user.

This on-the-fly generation is intended to accompany a conventional flow visualization in ParaView. All computed data (signal filtering and extraction of PSD) is computed within the Paraview python shell.

### III. RESULTS AND DISCUSSION

A current example of the interactive implemented method can be found at [19].

The present framework of sonification results in a highly configurable audio representation allowing on-the-fly exploration of flow instabilities within CFD data. Frequency bands can be individually emphasized or extracted for closer inspection. Different sound textures, ranging from Doppler-inspired sounds to bubbly flow sounds, exist within the instrument framework. This sonification runs in real time next to a simplified conventional visualization on consumer grade hardware, allowing for flexible inspection of data.

Fig 3. illustrates a variety of flow conditions existing within an aneurysm. Velocity of flow is high entering the neck of the aneurysm, but contains minimal fluctuation. Entering the sac, it is observed that fluctuations increase substantially. The intensity of the spectral content is presented on a logarithmic color scheme and normalized for presentation. High-frequency fluctuations present within the aneurysm sac indicate disturbed flow, which may have implications for aneurysm initiation, growth, and rupture as described previously. Contours of Q-criterion for a time instant during the systole are shown for each point on a constant y-z plane, where discrete locations of intense Q-criterion are observed.

The prototype has been tested with five aneurysm datasets, each of similar temporal and spatial resolution but varying flow complexity. Further exposure to new datasets will confirm the

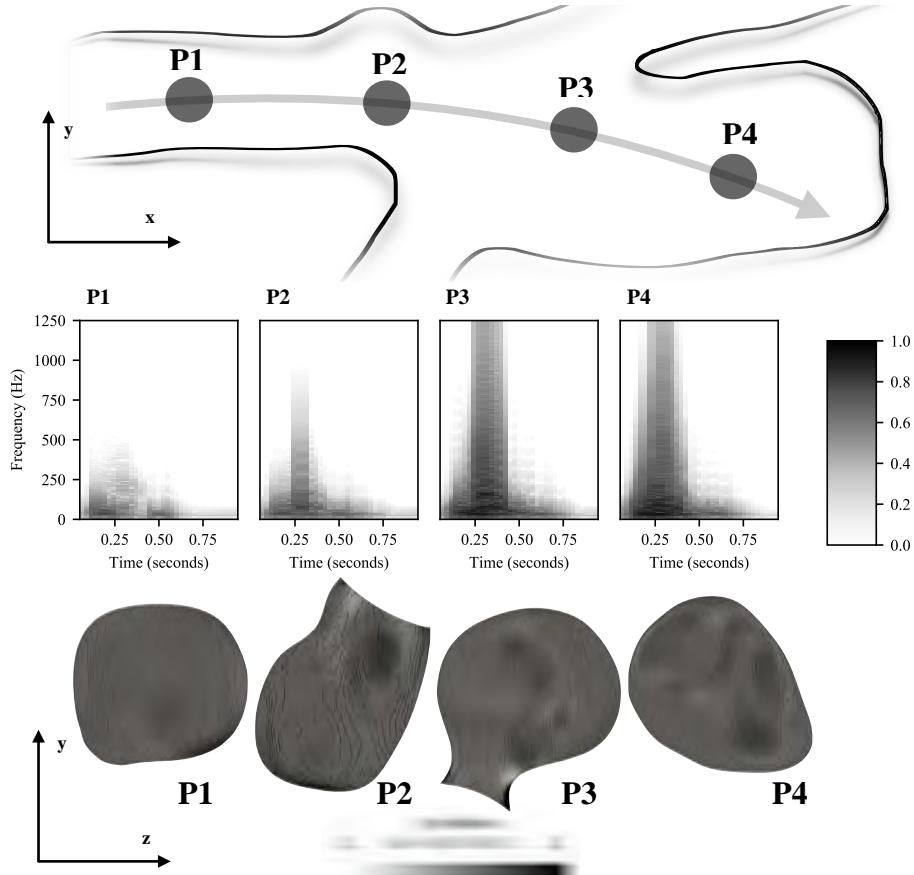

Figure 3. A comparison of spectral content and intensity of Q-criterion through the aneurysm neck and into the sac

existing method of psychological scaling, or suggest further refinement to accommodate a broader range of flow conditions.

The biological and clinical implications of high frequency content from a decomposed velocity signal are not in the scope of the current investigation; these effects are discussed in greater depth in CFD literature. The physiological presence of high frequency fluctuations, along with frequency-specific amplitude envelopes, are to be communicated to the user for interpretation. Other simplified strategies such as directly communicating Q-criterion to indicate turbulent flow were sonified, but in omitting so many dimensions of the underlying data, this simple feedback system was found too simplistic for anything other than locating regions of instability. The strength of this sonification lies in maintaining the nuance of the original signal.

The frequency resolution of the calculated PSD is limited by the temporal resolution of the data. By windowing the data, variation in time is gained at the expense of frequency resolution. This is a reasonable balance if the signals often approximate noise; broad temporal and spectral characteristics are communicated. From this balance, there are two potential dis-

advantages. First, the hard-set designation of frequency bands results in similar timbral properties between datasets. Secondly, and perhaps more importantly, if the signals have strong harmonic content, greater frequency resolution may be required to explore spectral relationships. Given the existing knowledge of spectral content in turbulent-like flow, the current chosen windowing parameters are acceptable.

The proposed method for interpreting cerebrovascular flows is not limited by application, and may be useful for other time-series spatial datasets containing instabilities. For example, we implemented a similar approach in the 3D creation suite Blender, for visualizing and sonifying flow around a vertical wind turbine, placing third in WestGrid's Visualize This! 2017 Challenge [20].

#### IV. CONCLUSION

A novel method for sonifying CFD data for the purpose of better communicating high frequency fluctuations within simulated intracranial aneurysmal flows is described. This frequency-domain method is intended to augment conventional visualization in order to ease the interpretation of dense spatio-temporal datasets by allowing the user to visually concentrate on one field while listening to another. This method for data

inspection builds on established analysis of intracranial hemodynamics with a focus on real-time inspection inspired by the existing field of auscultation.

**Abstract** - Ice formation and accumulation can lead to operational failure and risks for structures, including power transmission lines, aircraft, offshore platforms, marine vessels, and wind turbines. Liquid repellent and icephobic surfaces can reduce ice accretion and improve asset integrity and safety in harsh environments. There are significant needs to probe how wettability affects the droplet impact, ice nucleation and ice accretion processes on different kinds of micro-structured surfaces. This paper presents experimental results of droplet impact, icing delay time and ice accumulation on metallic surfaces with varying wettability. Several different designs of the hydrophobic surfaces are considered. A commercial hydrophobic coating is also used to enhance liquid repellent features and reduce ice accumulation. The results demonstrated that when the static contact angle increases, the total icing time increases, suggesting desirable icing delays. The total icing time decreases with lower surface temperature, higher impact velocity or smaller droplet diameter.

**Keywords** - superhydrophobic, anti-icing, wetting, freezing, icing-delay time

## I. INTRODUCTION

In cold and harsh environments, the formation and accumulation of ice may cause significant hazards and hinder the field operations, for example, with power transmission lines, airplanes, offshore platforms, marine vessels, and wind turbine [1-4]. There are many ways to remove ice from structures, for example, with a high-frequency high-voltage short-circuit to melt the ice but it requires the operator to shut off power during de-icing operation [5-7]. Workers use hammers to remove the ice on wellhead platforms and chain bridges. These methods are inefficient, difficult, expensive, and often have safety and environmental issues [8]. In order to achieve a more effective way to reduce ice formation and adhesion, extensive research has been directed to develop hydrophobic metallic surfaces with water repellent and anti-icing properties for applications in harsh environments [8, 9-10].

Superhydrophobic phenomena were first related to surface roughness by Dettre and Johnson [11]. Subsequently, the unique hydrophobic properties of lotus leaves have become an active research area because of the fundamental interests in

wetting and directional flow of water [11]. The lotus effect has various advantages such as water repellent action, small flow resistance, and self-cleaning property from dirt. The static contact angle of a liquid droplet on a smooth surface is related to the following interfacial energies at the three phase contact line,

$$\cos \theta = \frac{\gamma_{sv} - \gamma_{sl}}{\gamma_{lv}} \quad (1)$$

where  $\theta$  is the static contact angle.  $\gamma_{sv}$ ,  $\gamma_{lv}$ , and  $\gamma_{sl}$  represent the solid-vapor, liquid-vapor, and solid-liquid interfacial tensions, respectively. The contact angle hysteresis is also a key property to define the surface wettability. It is the difference between the advancing angle and receding angle when the solid surface is tilted, and the droplet starts to roll off [12-14]. The key properties of superhydrophobicity include the static contact angle larger than  $150^\circ$  and small contact angle hysteresis (less than  $10^\circ$ ).

For droplet impact dynamics, Ted Mao et al. [15] developed a semi empirical model to predict the maximum spread as a function of the Reynolds number ( $Re$ ), the Weber number ( $We$ ), and the static contact angle. Ice nucleation sub-model is also considered as heterogeneous ice nucleation at liquid-solid interface and the free-energy barrier ( $\Delta G$ ) is also estimated by N. H. Fletcher [16].

$$T_{interface} = T_{droplet} + (T_{substrate} - T_{droplet}) \frac{erfc\left(\frac{h}{2\sqrt{a_{ns}t_c}}\right)}{erfc\left(\frac{h}{2\sqrt{a_w t_c}}\right)} \quad (2)$$

where  $a_{ns}$  and  $a_w$  are thermal diffusivities of solid-air and water domain, respectively and  $t_c$  is the total time that the droplet in contact with substrate.

In this paper, experimental studies are conducted to determine the effects of sample surface temperature, droplet impact speed, surface wettability, and droplet diameter on the total icing time of a single water droplet.

## II. EXPERIMENTAL APPARATUS AND PROCEDURE

An experimental apparatus was designed to investigate liquid droplet impact and icing on surfaces with varying wettabilities. Fig. 1 shows the experimental setup. It consists of a support stand (Fisher Scientific) with a tilt base (World Precision Instruments) of adjustable inclination angles, a cold plate (AAVID Thermally) that is mounted on the tilt base and controls the temperature of sample surfaces, and a thermal electric cooler (TE Technology). A small copper tube (Sigma-Aldrich, Stainless steel capillary tubing 1/16 in) is buried for generating the liquid droplets with controllable temperatures. To generate a small water droplet, several needles of different inner diameters were used at the bottom end of the droplet generator tubing. The liquid comes from a syringe pump (Harvard). The cold plate is connected to a thermal bath (Fisher Scientific) which provides control of the surface temperature of the material sample being tested.

With this setup, water droplets are emitted with controlled temperatures impacting on different surfaces under different temperatures. High speed imaging was conducted with a high-speed camera (Vision Research). The high-speed camera was connected to a laptop for video and photo. An LED light and a light diffuser (Edmund Optics) were used to provide light while capturing droplet impact and nucleation processes. The response of the oscillation time, droplet dynamics and total icing time were determined from the video taken by the high-speed camera. The uncertainty analysis of the equipment used is shown in table 1.

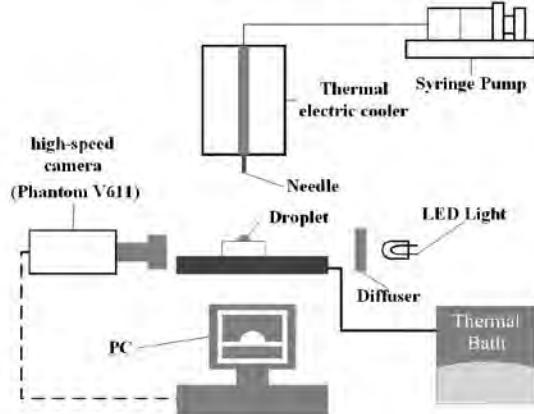

Fig. 1 Liquid droplet impact and icing experimental systems

Table 1. Experimental uncertainties of the experiments

	Operating Range	Uncertainty
Thermal Electric Cooler	-20 to 80°C	$\pm 0.1^\circ\text{C}$
FLIR E60 Infrared Camera	-20 to 650°C	$\pm 2^\circ\text{C}$
Isotemp Heated Bath Circulators	-25 to 200°C	$\pm 0.01^\circ\text{C}$
Measure tape	MAX 25'	$\pm 0.5 \text{ mm}$
Measure ruler	MAX 15 cm	$\pm 0.5 \text{ mm}$
High Speed Camera	MAX 6242 fps with full resolution	$\pm 20 \text{ ns}$

Several machined and coated sample surfaces with various wettabilities were used in the experiment. The contact angles of various samples are between  $77.2^\circ$  and  $145.5^\circ$  including hydrophilic and hydrophobic surfaces. The surface material is stainless steel (17-4 PH) for all samples. The smooth sample is a normal stainless-steel surface with no mechanical machining and coating. Some samples have microscale surface structures fabricated by wired electrical discharge machining, laser machining [17], or sandblasting. Other samples are coated with low surface energy material to further increase the surface hydrophobicity. The coating used for the samples was a Metal Repellency Treatment coating from Aculon.

## III. RESULTS AND DISCUSSION

The droplet dynamics and ice nucleation experiments on a flat surface were conducted under different conditions and captured by high-speed camera. The temperature of the sample surface was varied between  $-10^\circ\text{C}$  and  $-13^\circ\text{C}$ . The droplet diameters were varied from 1.80 mm, 2.82 mm, to 4.11 mm. The droplet impact speeds were varied from 0.77 m/s, 0.99 m/s, to 1.17 m/s. The droplet temperature was kept at  $5^\circ\text{C}$ . The surface wettability was changed from a hydrophilic smooth stainless-steel surface to a hydrophobic textured stainless-steel surface.

To better describe the dynamics of the droplet after impinging on the flat surface, a coordinate system is defined as shown in Fig. 2. The moment at which a water droplet first impacts the sample surface is named as the impact point. The x-axis is parallel to the sample surface and the y-axis is perpendicular to the sample surface, and it is positioned in the middle of the droplet. Fig. 3 clearly indicates a typical droplet impact and nucleation process on a flat smooth surface. Kinetic energy, surface tension, air drag, liquid viscosity, and surface structure play important roles during the droplet impact process. The surface temperature, droplet size, and surface wettability play important roles during the droplet nucleation process. In general, the water droplet goes to a dynamic phase after impacting the sample surface, and the ice nucleation phase (phase change) occurs after the dynamic phase. The dynamic phase contains: a spreading phase (Fig. 3 b-e); a retraction phase (Fig. 3 f-i); and a relaxation phase which contains many cycles of spreading and retraction processes. The dynamic phase lasted 334 ms before moving into an ice nucleation phase.

The impact process of a water droplet ( $D = 2.82 \text{ mm}$ ) on the smooth sample surface at the temperature of  $-10^\circ\text{C}$  and impact speed at 0.77 m/s is shown in Fig. 3. After hitting the sample surface, a lamella was formed from the base of the water droplet, and then a ring was formed. Most of the volume of the droplet stayed in the outside ring instead of inside the lamella (Fig. 3 b-e). At the end of the spreading phase, the water droplet reached its maximum contact diameter which is 5.31 mm (Fig. 3 e). The total spreading process lasted for 8 ms. The retraction phase started right after the spreading phase (Fig. 3 f-i). During the retraction phase, the water droplet started to recoil from the outside ring to the inside lamella. After the relaxation phase which contained a number of cycles of spreading and retraction phases, the droplet became steady and

reached its equilibrium state for about 334 ms. The ice nucleation phase started after the dynamic phase, and the water droplet took about 12.9 s to freeze. The droplet freezing process initiated at the liquid-solid interface (Fig. 3 i), and it propagated to the top of the droplet (Fig. 3 k). A small tip was formed on the top of the droplet at the end of the ice nucleation phase (Fig. 3 l).

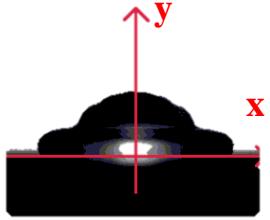

Fig. 2 Coordinate system of droplet impact and movement

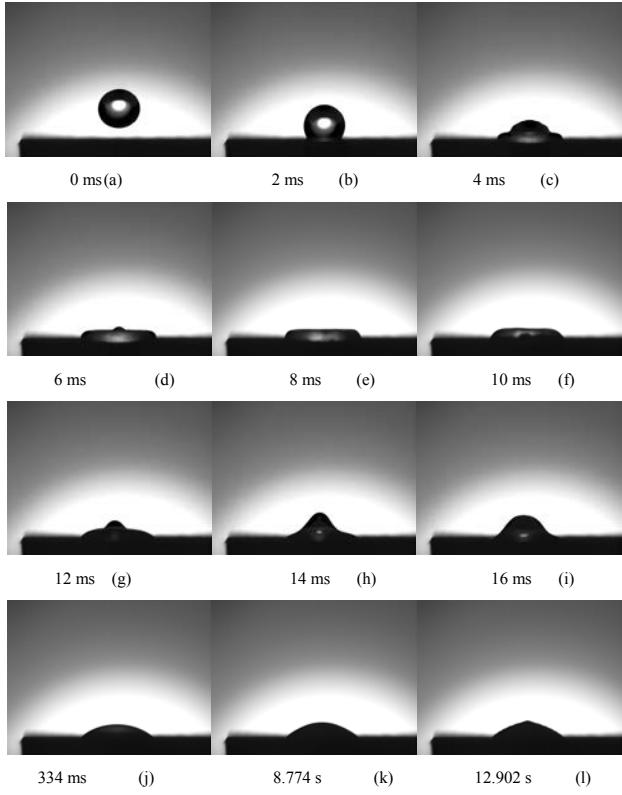

Fig. 3 Images of water droplet impact on a flat smooth surface ( $D_0=2.82$  mm,  $T_s=-10^\circ\text{C}$ ,  $v_0=0.77$  m/s, and  $T_d=5^\circ\text{C}$ )

The impact process of a water droplet ( $D=2.82$  mm) on a varied channel textured surface [20] with Aculon coating at temperature of  $-10^\circ\text{C}$  is shown in Fig. 4. It was very similar to the smooth surface case with a lamella outside of the droplet formed right after impact, and then a ring formed. This means a large proportion of the droplet stays in the outside ring instead of the inside lamella (Fig. 4 d). The first spreading process lasted about 6 ms, and the maximum spreading diameter was 4.28 mm (Fig. 4 b-d). The retraction process started at 8 ms (Fig. 4 e). Since the coated varied channel textured surface is hydrophobic, the height of the droplet is larger than a smooth

surface during the retraction process (Fig. 4 e-h). The dynamic phase lasted about 532 ms. Then the ice nucleation process is initiated and lasts for about 21.3 s (Fig. 4 i-m). The droplet freezing process initiated at the liquid-solid interface (Fig. 4 i), and it propagated to the top of the droplet (Fig. 4 j-l). A small tip was formed on the top of the droplet at the end of the ice nucleation phase (Fig. 4 m). Compared with the total icing time on the smooth surface, the total icing time on this very hydrophobic surface is much longer under the same conditions.

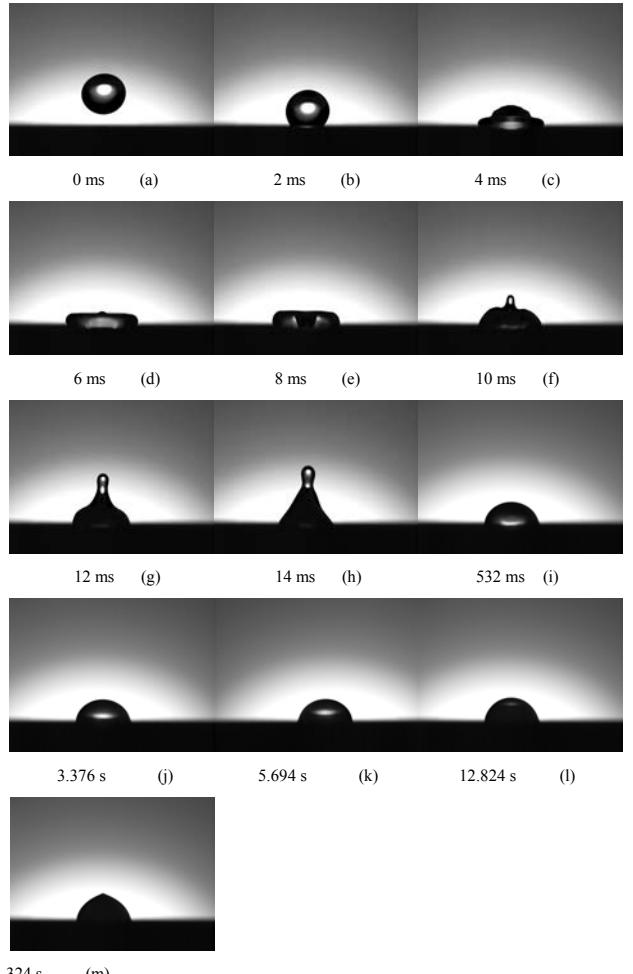

Fig. 4: Images of water droplet impact on a flat coated varied channel surface ( $D_0=2.82$  mm,  $T_s=-10^\circ\text{C}$ ,  $v_0=0.77$  m/s, and  $T_d=5^\circ\text{C}$ )

The droplet nucleation experiment is performed with varying droplet impact speed, droplet diameter, sample surface temperature, and surface wettability. The experiments are performed to find out the relationship between different factors and droplet overall icing times. Five runs of experiments are conducted at each experimental condition. The following figures show the experimental result and analysis.

Fig. 5 indicates how the droplet icing time varies with respect to static contact angle and temperature. As the static contact angle increases, the icing time increases. The icing time decreases with decreasing temperature. Since the water droplet spreads less, oscillates longer, and partially sits on the hydrophobic surface with a low wettability, the contact area at

solid-liquid interface is much smaller than a hydrophilic surface. The surface energy at the solid-liquid interface is lower when the contact angle is small, so the ice formation initiates earlier on a smooth surface than a hydrophobic surface. The total icing time is much longer on a hydrophobic surface due to a smaller solid-liquid contact area which means a smaller heat transfer rate.

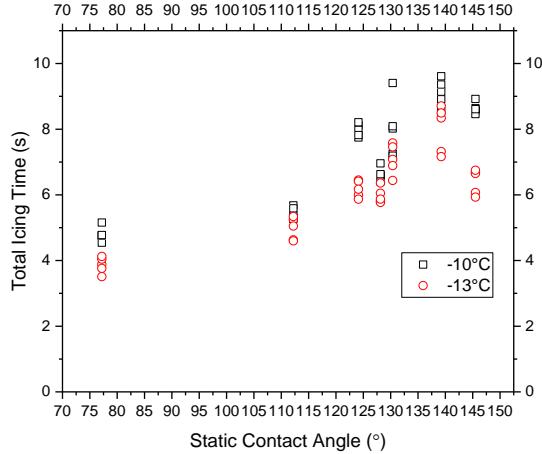

Fig. 5 Droplet icing time vs. Static contact angle at impact speed = 0.77 m/s when the surface temperature is -10 °C and -13 °C.

Fig. 6 shows how the water droplet total icing time changes with respect to static contact angle at impact velocity of 0.77 m/s, 0.99 m/s, and 1.17 m/s. From the figure, the total icing time decreases as the impact velocity increases. Since the impact velocity increases, the droplet spreads faster and the maximum contact area increases due to higher initial kinetic energy. Since the contact area and time during the dynamic phase increase while increasing the impact velocity, the heat transfer rate from droplet to the surface increases. The droplet may also penetrate into micro-grooves on the hydrophobic surface while increasing the impact velocity. In that case, the droplet penetration would also increase the heat transfer rate from droplet to the surface.

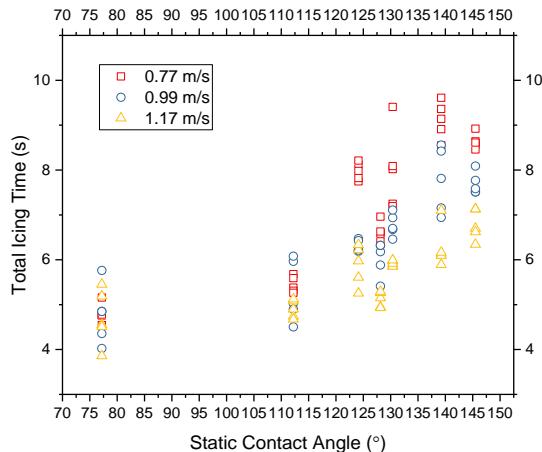

Fig. 6 Droplet icing time vs. Static contact angle at -10 °C when the impact speed is 0.77 m/s, 0.99 m/s, and 1.17 m/s.

Fig. 7 shows the relationship between the total icing time and droplet diameter which are 1.80 mm, 2.82 mm, and 4.11 mm. When increasing the droplet diameter and surface hydrophobicity, the droplet icing time increases. Since the volume of the droplet increases when increasing the diameter, more time and overall heat transfer are needed to fully freeze the droplet.

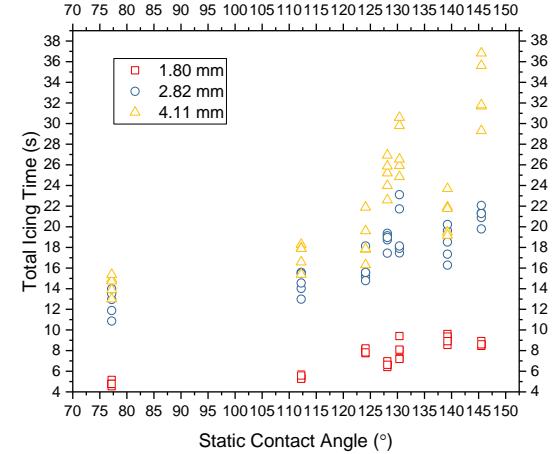

Fig. 7: Droplet icing time vs. static contact angle at -10 °C when the droplet diameter is 1.80 mm, 2.82 mm, and 4.11 mm.

#### IV. CONCLUSION

This paper investigated the effects of surface wettability, droplet impact speed, surface temperature, and droplet diameter on the total icing time on surfaces. The experimental results demonstrated that when the surface wettability decreases, the total icing time increases. Since the water droplet spreads less, oscillates longer, and partially sits on surfaces with low wettability, the contact area at the solid-liquid interface is much smaller which means a lower heat transfer rate. The total icing time decreases with decreasing temperature, increasing impact velocity or decreasing droplet diameter. The water droplet spreads more and oscillates longer with increasing droplet size because the larger droplet contains more kinetic energy. Since the contact area and time during the dynamic phase increase while increasing the impact velocity, the heat transfer rate from droplet to the surface increases. So increasing droplet diameter, decreasing droplet impact speed, or increasing surface hydrophobicity can decrease or delay the droplet icing time.

**Abstract** - Nanoparticle-enhanced tailing-paraffin composite phase change material (NCPCM) is fabricated by spontaneous melt infiltration. Industrial waste-iron tailing is used as raw material to prepare ceramic porous carrier with a foam-gel casting method. By adjusting the fabrication parameters, optimal NCPCM properties are obtained with paraffin content of 70%~88% and thermal conductivity of 0.351~0.490 W/(m·K), which is nearly 200% the thermal conductivity of paraffin wax. After 25 melting/solidification cycles, the nanoparticles remain well dispersion with overall stability in the composite phase change material, and the thermal conductivity slightly decreased from 0.349 to 0.317 W/m·K. With multiple melting and solidification cycles, a low weight loss of 2.3~7.8 wt.% is demonstrated. The strength of ceramic frame is found to have a direct effect on the weight loss. Compared with existing nanoparticle-enhanced phase change material, the new NCPCM shows significantly improved thermal conductivity and better nanoparticle stability due to its ability to prevent nanoparticles from disposition.

## I. INTRODUCTION

Energy storage plays an important role in meeting the growing global energy demand. Phase change materials (PCMs), with high storage density and isothermal process in phase change process, are often applied in latent heat energy storage systems where energy is stored in the form of latent heat during melting and recovered during solidification of the PCMs [1].

Paraffin wax is a reliable option for PCM in various engineering applications, such as storage of solar thermal energy, industrial waste heat recovery and insulation building material [2]. But the low thermal conductivity of paraffin causes low heat transfer rate during charging and discharging cycles [3]. Therefore, efforts have been made to enhance the rate of melting/freezing by utilizing different methods. An effective method of improving the melting/freezing rate is to add highly thermal conductive nanoparticles inside the PCM.

This nanoparticle-enhanced phase change material (NePCM) has been studied in a shell-and-tube thermal energy storage system [4]. Khodadadi and Hosseini-zadeh [5] observed that NePCM exhibits higher heat release rate when compared to the conventional PCM partly due to the simultaneous increase of the thermal conductivity and reduction of the latent heat. Although nanoparticles can improve the thermal conductivity of the PCM, the stability issue presents a major challenge. It's very difficult to achieve long term uniform dispersion of nanoparticles in paraffin wax since nanoparticle sedimentation is almost unavoidable [1].

Another heat transfer enhancing technique involves composite phase materials (CPCM) incorporating porous ceramics. This technique can efficiently improve the thermal conductivity and maintain original shape of the PCM even when the wax is melted. Several authors reported the thermal enhancement of CPCMs. Zhao et al.[6] performed an experimental investigation to characterize the phase change processes (both melting and solidification) of paraffin wax inside copper metal foam. The porous materials, through capillary and surface tension forces, keep the PCM in stable shape at liquid phase [7]. Qian, et al. [8] fabricated shape-stabilized composite phase change material (ss-CPCM) based on SiO<sub>2</sub> materials. SiO<sub>2</sub> acts as the carrier matrix to provide structural strength and prevent the leakage of melted PCM. Their results show that the use of porous medium enhances the melting/solidification process faster than pure PCM without a porous medium.

NCPCM is a new way that combines the advantages of NePCM and CPCM. Although the transport processes of nanofluids in a porous medium have been studied in recent years, the fabricating technology and thermal properties of NCPCM were barely reported. The key point is that the ceramic must have micron-sized pores and high porosity, good wettability and chemical stability with NePCM. Iron ore tailings (IOT) have been generated in steel production as an industrial waste all over the world, which caused economic, environmental and health-related problems [9]. Using IOT as a carrier to fabricate NCPCM is an efficient method for improving thermal properties, keeping the shape of melted paraffin, reducing industrial pollution and drastically

decreasing the manufacturing cost. This paper presents the preparation and analyzes the thermal conductivity of NCPCM.

## II. MATERIALS AND PROCEDURE OF PREPARATION

### A. Preparation of Tailing Porous Ceramic Media

Tailing was obtained from iron mines of Miyun area in Beijing. Tailing porous ceramics were fabricated by a foam-gel casting method. First, iron tailing slurries with a solid loading of 45 wt.% were prepared by mixing ball-milling IOT powders, deionized water, Acrylamide, N,N'-Methylenebisacrylamide and ammonium polyacrylate for 15h. After that, Sodium dodecyl sulfate and lauryl alcohol were added into the slurries, followed by high-speed stirring to acquire foamed slurries. Tetraacetyl ethylenediamine and Ammonium persulfate were slowly added to the foamed slurries and mixed adequately. Then the slurries were poured into molds and gelled in the air for 10 min to get green porous bodies. Finally, the green bodies were dried and sintered at different temperatures of 1070, 1080, 1090, 1100, 1110 and 1120 °C for 7 h.

### B. Preparation of NCPCM

Technical grade paraffin wax with melting temperature 56 °C and graphene nanoplatelets were supplied by Sigma-Aldrich Canada. The porous ceramic and 99g paraffin were heated to 150°C and 90°C, respectively. Then 1g of graphene nanoparticles were added into the melted paraffin and the mixture was stirred for 30 min.

The mixture is under ultrasonic treatment for 5min after stirring to prevent nanoparticles from aggregation. Then, the porous ceramics were put into a beaker full of melted paraffin to make sure that the melted paraffin covers the ceramics. The infiltration process needs 5min. After that, the beaker is let to cool down to 60 °C and the samples are taken out to dry in the air. Figure 1 shows pictures of samples of the porous ceramic, CPCM and NCPCM. Due to the black color of graphene nanoparticles, the color of NCPCM is much darker than the other samples.

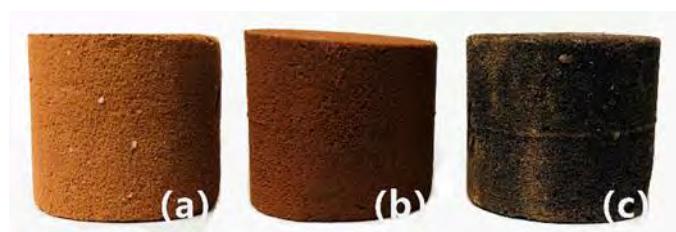

Figure 1. Pictures of porous medium (a), CPCM (b) and NCPCM (c)

## III. PROPERTIES OF POROUS CERAMIC AND NCPCM

### A. Properties of Ceramic and Infiltration Result

The porosity of porous ceramic is a key property to decide NePCM content in NCPCM which is measured by the Archimedes method in distilled water. Compressive strength was measured by a WDW-100E testing machine with a crosshead loading speed of 0.5 mm/min, using cylindrical

specimens with a diameter of 20 mm and a height of 20 mm. Phase composition of the sintered materials was identified by X-ray diffraction (D/MAX-III, Rigaku, Japan). Eight specimens were used to acquire average property. Pore size distribution was analyzed by the mercury intrusion method in an Auto Pore IV 9510 instrument.

Physical properties of the tailing porous ceramics sintered at different conditions are listed in Table 1, and the effects of sintering temperature on the compressive strength are shown in Fig.2. Six samples were tested for each temperature point.

Table 1 PROPERTIES OF THE TAILING POROUS CERAMICS

Sintering temperature (°C)	Bulk density (g/cm³)	Apparent Porosity (%)	Shrinkage (%)
1070	0.39±0.01	88.8±0.1	3.81±0.43
1080	0.38±0.01	87.4±0.4	5.59±0.31
1090	0.36±0.01	87.0±0.8	8.20±1.42
1100	0.29±0.02	85.5±0.1	9.46±0.23
1110	0.48±0.01	82.6±0.2	10.74±0.31
1120	0.76±0.01	71.6±0.4	20.67±0.45

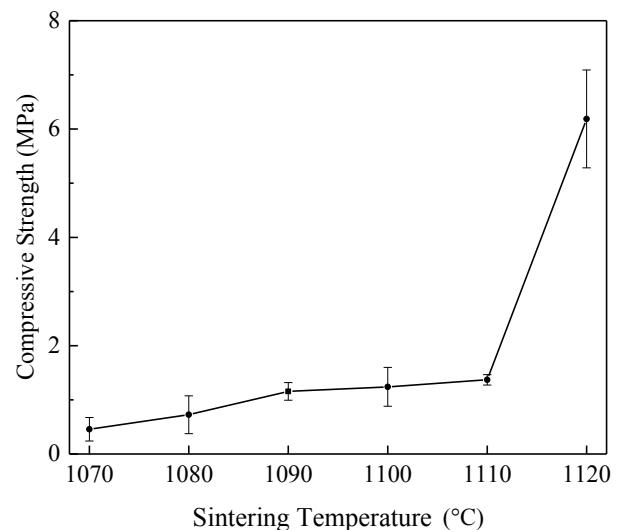

Figure 2. Relationship between sintering temperature and compressive strength

As temperature increased from 1070 to 1120 °C, bulk density and shrinkage of ceramic increased from 0.39 to 0.76 g/cm³ and 3.81 to 20.67 % respectively, and the porosity decreased from 89% to 71%. With the increase of sintering temperature, atomic diffusion kinetic energy increases, which enhances the sintering activity and makes the tailings particles closer. 1110 °C is likely a point where liquid phase is significantly generated, while higher temperatures lead to drastic shrinkage of the samples, resulting in increased porosity of the porous ceramics. Higher porosity of porous ceramics means bigger energy storage density of the NCPCM.

As we can see in Fig 2, with higher sintering temperatures, the compressive strength of porous ceramics increased due to the much stronger interconnection among quartz grains and framework of more glass phase generated in higher

temperature. Based on the Gibson equation, the following relationship between porosity and strength was correlated from the experimental data:

$$\sigma_1 = 129 \times (1 - \Gamma)^{2.53} \quad (1)$$

where  $\Gamma$  is porosity,  $\sigma_1$  is compression strength of porous ceramics.

When sintering temperature reached 1080 °C and held for 3 hours, porosity, bulk density and compression strength were 86.6 %, 0.31 g/cm<sup>3</sup> and 0.75 MPa respectively, which can satisfy the needs of NCPCM.

Figure 3 shows the phase composition of tailing porous ceramics sintered at 1080 °C. The mineralogical composition of the porous samples determined by X-ray Diffraction (XRD) shows main crystalline phases like quartz (SiO<sub>2</sub>), diopside (CaMgSi<sub>2</sub>O<sub>6</sub>), augite (Ca(Mg,Fe,Al)(Si,Al)<sub>2</sub>O<sub>6</sub>). Anorthite (CaAl<sub>2</sub>Si<sub>2</sub>O<sub>8</sub>) and hematite (Fe<sub>2</sub>O<sub>3</sub>) were identified. This phase has good erosion resistance and forms the main mineral framework of the tailing porous ceramics, which are responsible for the physical properties and mechanical strength of porous ceramics.

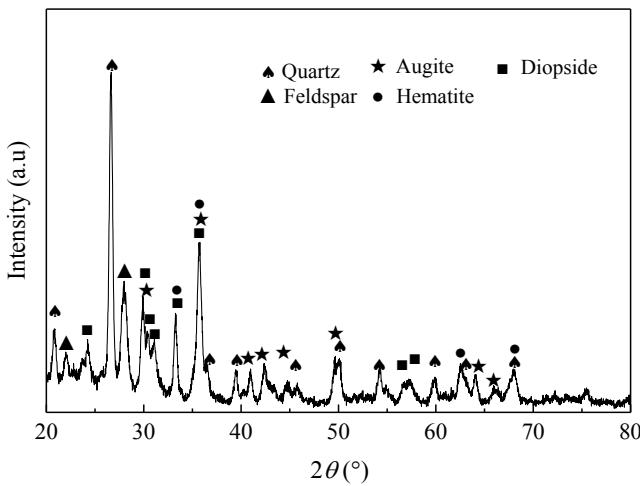

Figure 3. XRD patterns of porous ceramics sintered at 1080 °C

Figure 4 shows the pore size distribution of porous tailing ceramics sintered at 1080 °C for 3 hours. It shows a bimodal distribution of the pore size of the porous tailing ceramic, with a weak peak at about 1.4 μm and a strong peak at 45 μm, while the pore diameter was mainly in the range of 20-80 μm. According to previous work, when the radius of pores is smaller than 100 μm, the capillary force is larger than that from atmospheric pressure, which helps to eliminate air from the samples in the infiltration process. Also, when the pore radius is 3~35 μm, the differential pressure ΔP changes from 6 MPa to 1 MPa, which efficiently prevents the melted paraffin from leaking out of the porous medium.

Table 2 shows filling fractions of the prepared CPCM and NCPCM. The values indicate percentage of pores that are occupied by liquid paraffin (which has a density of 0.74 g/cm<sup>3</sup>) and liquid nanoparticle enhanced paraffin (which has a density of 0.73 g/cm<sup>3</sup> due to the low density of graphene nanoparticles).

As we can see in Table 2, different sintering temperatures lead to different pore sizes of the samples, which causes variation in capillary forces and therefore changes in the infiltration efficient. Compared with the CPCM, adding graphene nanoparticles didn't seem to change the wettability of paraffin on the surface of the ceramics.

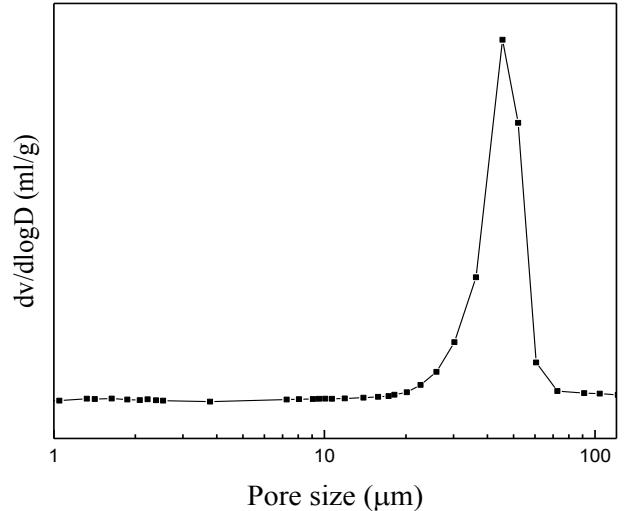

Figure 4. Pore size of sample sintered at 1080 °C

Table 2 INFILTRATION OF CPCM AND NCPCM

Sintering Temperature (°C)	Porosity of Porous Ceramic (%)	Filling Fraction of CPCM (%)	Filling Fraction of NCPCM (%)
1070	89	98.08	99.21
1090	86	98.91	99.08
1110	82	98.13	97.30

### B. Thermal Conductivity

The thermal conductivities of iron ore tailing were measured on 5×5×3 mm<sup>3</sup> machined specimens at room temperature, using the Thermal Transport Option (TTO) of Physical Properties Measurement System (PPMS, Model 6000, Quantum Design, USA). The NCPCMs, i.e., tailing ceramic/NePCM composite materials, were measured with a KD2 Pro Thermal Properties Analyzer (Decagon Devices, USA). The thermal conductivity of the tailing ceramic and the NePCM is 1.41 W/m·K and 0.282 W/m·K, respectively.

Figure 5 shows thermal conductivities of NCPCM, CPCM, NePCM and the base PCM (paraffin wax). With combined advantages of CPCM and NePCM, the new NCPCM shows a significant increase of thermal conductivity to 0.428 W/m·K, as compared to 0.229 W/m·K of the base PCM. It was confirmed that the micron-sized pores can prevent nanoparticles from deposition. Also, the tailing ceramic has higher thermal conductivity than paraffin, which also helps improve the thermal properties.

### C. Multiple Melting Solidification Cycles

Weight loss of samples was tested after 1, 5, 10, 15, 20 and 25 melting / solidification cycles. Figure 6 shows cross-

sectional view of a sample after these cycles. As we can see in Fig. 6, there is no observable color change in the cross-sectional view of the NCPCM, suggesting that the nanoparticles were still well dispersed in the PCM without deposition (otherwise there will be dramatic change of color gradient with dark colored area from nanoparticle deposition). These results demonstrate that the NCPCM technique can effectively prevent the nanoparticles from disposition.

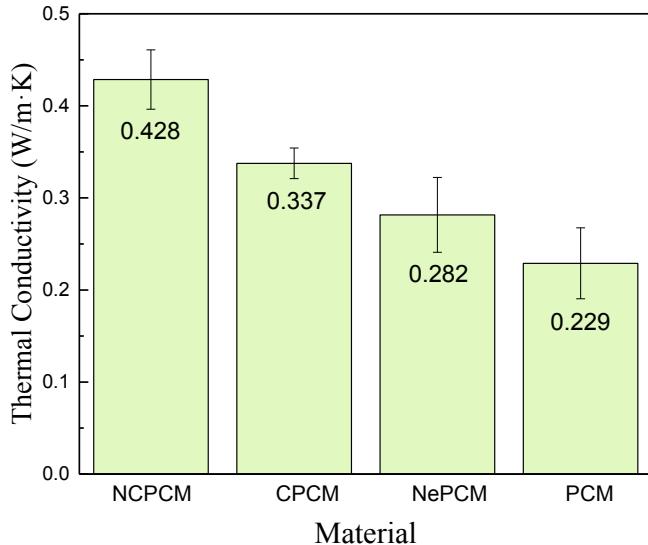

Figure 5. Thermal conductivities of NCPCM, CPCM, NePCM and pure PCM

Figure 6. The section of sample after 1(a), 5(b), 10(c), 15(d), 20(e) and 25(f) times of melting / solidification cycles

Figure 7 shows weight losses of two NCPCM samples after 1, 5, 10, 15, 20 and 25 melting / solidification cycles respectively.

As the number of melting/ solidification cycles increased, the mass of samples slightly decreased. With air fills into the sample after paraffin leaking, the thermal conductivity decreased from 0.349 to 0.317 W/ m·K. This can be explained by evaporation and leak of paraffin. Comparing the two curves in the Figure 7, one can find that the leakage and weight loss are greatly affected by the porosity. As the porosity increases, more and more glass phase forms on internal walls of the ceramics promoting the strength of samples. Stronger wall of the pores can decrease the impact from liquid paraffin in melting and solidification and prevent the paraffin from leaking.

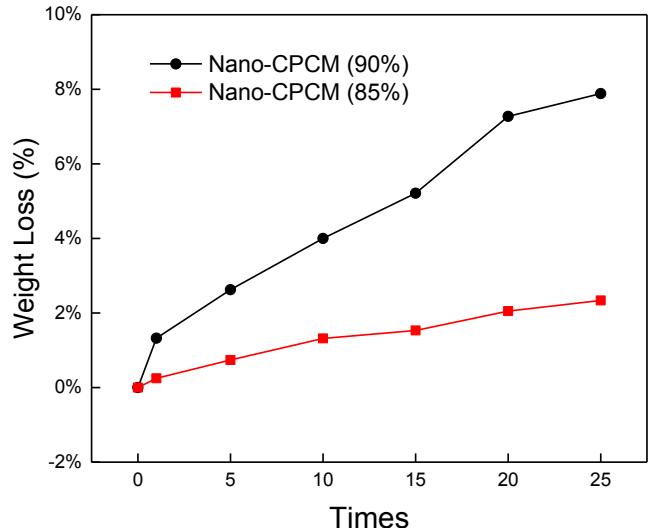

Figure 7. NCPCM Sample material weight loss with 90% and 85% porosity after multiple melting / solidification cycles

#### IV. CONCLUSIONS

Nanoparticle enhanced tailing-paraffin composite phase change material (NCPCM) was successfully prepared using iron ore tailing, graphene nanoparticles and paraffin as raw materials with a foam-gel casting method and spontaneous infiltration technique. With higher sintering temperature, the porosity of ceramic decreased from 89% to 71% and the bond between particles become stronger as well. It was found that paraffin dispersed with graphene nanoparticles has good wettability with the tailing ceramic. It efficiently prevents leaking of the melted paraffin out from the porous medium. NCPCM significantly increases the thermal conductivity of PCM from 0.229 W/m·K to 0.428 W/ m·K. In addition, the porosity of the ceramic porous media has a significant effect on weight loss which was only 2.3wt.% when porosity is smaller than 85%. NCPCM with tailing porous ceramic demonstrates good mechanical integrity, with significantly improved and controllable thermal properties.

**Abstract**—Phase Change Materials (PCMs) have been widely used in Latent Heat Thermal Energy Storage Systems (LHTES) to store and release thermal energy. However, PCMs suffer from their low thermal conductivities, which leads to longer melting (charging) or solidification (discharging) time. Dispersing highly conductive nanoparticles into PCM is one of the methods to improve the thermal conductivity of the PCM. In this paper, we have experimentally and numerically investigated the effect of dispersing Copper Oxide nanoparticles into RT-35 filled a vertical cylindrical Thermal Energy Storage (TES) system. The TES system is consisted of two vertical cylindrical enclosures, which are attached to a thick acrylic plate. One of the enclosures is filled with pure PCM and the other one is filled with nano-PCM. The setup is insulated from the bottom and isothermally heated from its sides by using a constant temperature bath. To study more about the thermal and velocity fields, melting fraction and stored energy, a numerical simulation is conducted by using COMSOL Multiphysics software. It is concluded that although adding nanoparticles to PCM improves the melting rate, it is lowering the amount of energy stored inside the TES system.

**Keywords:** Thermal energy storage (TES); Latent heat; Phase change material (PCM); nano- PCM

## *I. INTRODUCTION*

The increase in the amount of greenhouse gasses especially Carbon dioxide caused by burning fossil fuels has caused a serious environmental concern known as global warming. On the other hand, the increase in the worldwide population and industrial units have forced energy suppliers to search for alternate energy sources ( i.e. renewable energy) and or use of energy efficiently. Thermal Energy Storage (TES) systems have developed with the aim of storing thermal energy effectively and release that energy in the demand time. TES systems are divided into three main groups including: (i) Sensible Heat TES system, (ii) Latent Heat TES system and,

(iii) Thermo-Chemical TES system. However, among these three groups, LHTES system is more attractive. LHTES systems use PCMs to store or release thermal energy which offers two main advantages: (i) higher capacity of storing energy (i.e. 5-14 times higher than sensible heat TES) and (ii) smoother temperature fluctuations during the operation [1,2]. A wide variety of PCMs are available with different melting temperatures ( $T_m$ ) which have been used for both cooling and heating purposes. Paraffin waxes, hydrated salts and organic compounds (e.g. Coconut oil) are the most available types of PCMs. Although PCMs seem to be a proper material for store/release of thermal energy, they suffer from a low thermal conductivity. This disadvantage leads to longer melting/solidification time, which affect the performance of the LHTES system [3]. Several methods have been proposed to enhance the thermal conductivity of PCMs such as (i) dispersing highly conductive nanoparticles into the PCM, which is the main purpose of this study, (ii) inserting metal fins, and (iii) the use of conductive porous medium [4]. Different weight fractions/volume fractions of nanoparticles can be dispersed in to the PCM to increasing its thermal conductivity. However, in practical, sedimentation is an issue caused by using high weight/volume fractions of nanoparticles [5,6]. Different configuration of PCM container such as rectangular, cylindrical (both horizontal/vertical), and spherical can be used. Cylindrical can be installed both vertically and horizontally according to a specific application/ occupied space [7].

In this paper, the main aim of study is to investigate the melting process of a nano-PCM filled in a vertical cylindrical enclosure. By surveying the literature, it can be found that a considerable number of researchers have studied the use of vertical cylindrical enclosures filled with nano-PCM. Wu et al. [8] performed a numerical study on the melting process of Paraffin enhanced with Copper nanoparticles filled in a cylindrical enclosure which was heated from the bottom. It was found that the melting rate was 13.1 % improved by using 1wt.

% of nanoparticles. Sciacovelli et al. [9] numerically studied the melting of paraffinic PCM with copper nanoparticles. In their investigation, the nano-PCM was isothermally heated by placing an inner tube at the center of cylindrical enclosure. It was reported that by using 4% volume fraction of nanoparticles, the melting time was decreased by 15%. Das et al. [10] numerically studied the melting process of n-eicosane enhanced with carbon allotropes. The enclosure was isothermally heated placing an inner pipe at the center. It was concluded that by using 1 % volume fraction of single-walled carbon nanotubes, the melting time melting time was decreased by 15%. The melting time was decreased up to 25% with the use of 1% volume fraction of graphene. An experimental study on melting process of 1-dodecanol enhanced with carbon nanotubes was performed by Zeng et al. [11]. In their experiment, the cylindrical enclosure was insulated from the surroundings and heated from the bottom. It is reported that by dispersing the carbon nanotubes, melting rate was degraded due to the increase of viscosity and decrease in the natural convection. Fan et al. [12] experimentally investigated the effect of adding Graphene nanoplatelets in to tetradecanol on the melting rate. The cylindrical enclosure was isothermally heated from the bottom. It was reported that by using 3 wt.% of nanoparticles at the temperature of 55 °C, a 8% decrease in the melting time is observed.

According to the literature, the melting process of a nano-PCM inside a vertical cylindrical enclosure, insulated from the bottom, and isothermally heated from the sides has not been extensively investigated. In this work, an experimental and numerical investigation are performed to study the effect of adding Copper oxide nanoparticles into RT-35 with the melting temperature ( $T_m$ ) in a range of 34 °C- 36 °C. To do so, an experimental setup is built to visualize and compare the melting process of pure PCM and nano-PCM. Moreover, a COMSOL simulation is developed to compare the energy stored in PCM and nano-PCM.

## II. EXPERIMENTAL INVESTIGATION

### A. Experimental setup

The primary objective of the experimental work is to visualize and compare the melting process of PCM and nano-PCM. The experimental setup is consisted of two transparent acrylic pipe with the inner diameter of 4.4 cm, a transparent water bath equipped with temperature regulator, a circulation pump, and a digital camera to capture the melting pattern periodically. Two cylindrical acrylic pipes are vertically attached to a thick plastic plate (thickness= 3.5 cm) with the center-to-center distance of 13 cm. The cylindrical pipes are thermally insulated from the bottom and to avoid any pressure at the top of PCM/nano-PCM, it is kept open from the top. A schematic of the experimental setup is shown in Fig.1.

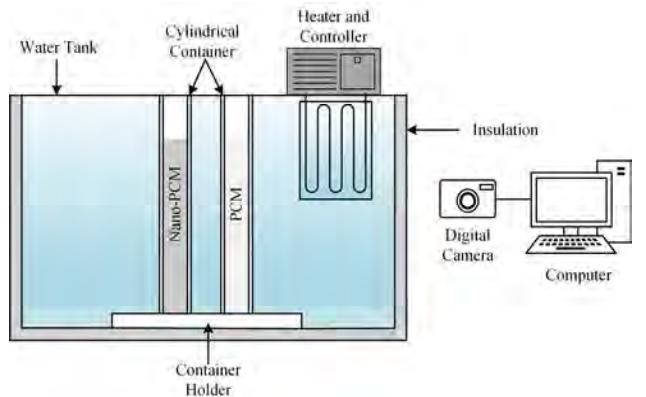

Fig.1. A schematic of the experimental setup

### B. Nano-PCM preparation

One of the main challenges associated with the use of nano-PCM is the sedimentation of nanoparticles at the bottom of enclosure after several cycles of operation. Therefore, preparation of the nano-PCM is an important step for the experimental work. At the first step, the required amount of RT-35 and Copper oxide nanoparticles to have a 0.2 wt.% nano-PCM was weighed by a precise balance. It should be mentioned that dispersing Copper oxide nanoparticles into RT-35 results to a dark black fluid. Thus, to have a clear melting visualization, low amount of nanoparticles is used. Then, the mixture was heated up to 60 °C and stirred by using a magnetic stirrer for 24 hours. To ensure the homogeneity of mixture and release the trapped air inside the nano-PCM, an ultrasound sonicator was used for two hours. At the next step, the nano-PCM was kept in a bath with the temperature of 45 °C for three hours (more than the time required for melting experiment) to see the amount of sedimentation. After ensuring the homogeneity of mixture, the nano-PCM was solidified gradually at the room temperature (i.e.,  $T_0 = 23$  °C). Solidification at the temperatures close to the  $T_m$  requires a longer time, however, it provides the advantages of having less trapped air inside the nano-PCM and avoiding the sub-cooling effect. Table.1 shows the thermophysical properties of RT-35 and Copper Oxide nanoparticles.

Table 1. Properties of RT-35 and CuO nanoparticles

Property	RT-35 [13]	Copper oxide[14]
$\beta$ (1/K)	$6 \times 10^{-4}$	$85 \times 10^{-7}$
$h_{sf}$ (kJ/kg)	170	—
$k$ (W/m K)	0.2	18
$\mu$ (Pa.s)	0.023	—
$c_p$ (kJ/kg K)	2	0.54
$\rho$ (kg/m <sup>3</sup> )	815	6500

### C. Experimental procedure

Several steps were taken to start the experiment. First, a predetermined amount of molten Pure PCM and nano-PCM was poured in cylindrical pipes at the same height ( $H = 8.3$  cm) representing Rayleigh number of  $10^7$ . Then, the PCM/nano-PCM were gradually solidified by keeping the setup at the room temperature. Next, the temperature of the constant bath was set to  $45^\circ\text{C}$ . To ensure the accuracy of the thermal regulator, a T-type OMEGA thermocouple was placed inside the bath and monitored the temperature. The Cylindrical TES system enclosures were suddenly placed inside the bath to initiate the melting process. A digital camera was used to record the melting pattern periodically (i.e. every five minutes) during melting process.

## III. NUMERICAL INVESTIGATION

### A. Numerical model

To study the effect of dispersing nanoparticles to pure PCM on the thermal fields, melting fraction and energy stored, a numerical model with the same geometry as the experimental setup was developed by using COMSOL Multiphysics. The model is insulated from the bottom, isothermally heated from its sides, and filled with PCM/nano-PCM at the height of  $H$ . The liquid phase of PCM/nano-PCM is assumed as a Newtonian incompressible fluid. A 2-D view of the numerical model is shown below.

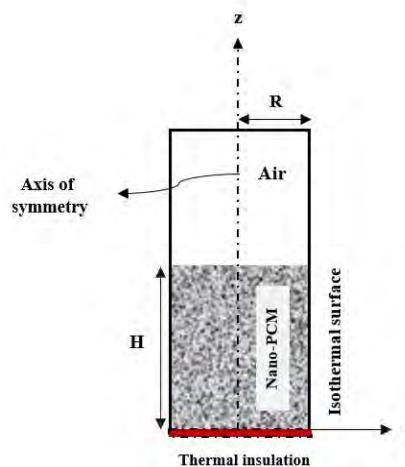

Fig. 2. A 2-D view of the numerical model

The governing equations representing the conservation of mass, momentum and transferred energy are presented below [15]:

$$\text{Continuity equation : } \frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

where  $u$  and  $w$  are the components of velocity in  $r$ -direction and  $z$ - direction, respectively.

Energy equation:

$$\frac{\partial T}{\partial t} + u \frac{\partial T}{\partial r} + w \frac{\partial T}{\partial z} = \frac{k}{\rho C_p} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial T}{\partial r} \right) + \frac{\partial^2 T}{\partial z^2} \right] \quad (2)$$

where  $t$ ,  $K$ ,  $\rho$  and  $C_p$  represent time, thermal conductivity, density and specific heat at constant pressure, respectively.

Momentum (z-direction):

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial r} + w \frac{\partial w}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial z} + \frac{\mu}{\rho} \left( \frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} + \frac{\partial^2 w}{\partial z^2} \right) + g\beta(T - T_m) \quad (3)$$

Momentum(r-direction):

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial r} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial r} + \frac{\mu}{\rho} \left( \frac{\partial^2 u}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} - \frac{u}{r^2} + \frac{\partial^2 u}{\partial z^2} \right) \quad (4)$$

where  $\mu$ ,  $g$ ,  $\beta$  and  $T$  represent viscosity, gravitational acceleration and coefficient of thermal expansion and temperature, respectively. The amount of stored energy is one of the main parameters for designing a LTES system which can be determined by Eq. 5 [16].

$$E = \int_0^t \dot{Q}(t) dt \quad (5)$$

In this equation,  $\dot{Q}(t)$  is the transferred heat during the melting process which can be determined by Eq.6.

$$\dot{Q}(t) = (\pi d) \int_0^H \left( -k \frac{\partial T}{\partial r} \right) dz + (2\pi) \int_0^R \left( -k \frac{\partial T}{\partial z} \right) rdr \quad (6)$$

Where  $d$  and  $k$  are the inner diameter of the circular pipe and thermal conductivity of the nano-PCM respectively.

Dispersion of nanoparticles to PCM results to new properties such as density, viscosity, thermal conductivity, and heat capacity. The thermophysical property relationships for the nano-PCM can be found in [17]. Moreover, as the change in the phase of the nano-PCM occurs within a transition stage, the properties of the nano-PCM are affected by a transition temperature range (i.e.  $T = T_m - \Delta T$ , and  $T = T_m + \Delta T$ ). The thermophysical properties of the nano-PCM at the transition

stage can be found in [18]. In addition, a Gaussian function is used to approximate the heat capacity during the phase change process [19].

### B. Grid size and time step independency test

To test the mesh size and time intervals independency, simulations were carried out in different steps. First, the melting fraction was calculated by using three different mesh sizes including (i) 6965 elements, (ii) 15062 elements and (iii) 33905 elements. The result of this test is shown in Fig. 3.

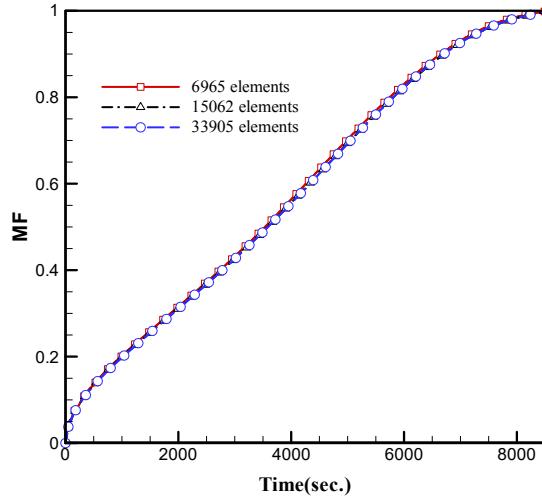

Fig. 3. Grid size independency test

As it can be seen from Fig. 3, the values of melting fraction for different meshes are almost identical. Hence, to obtain the proper accuracy and less simulation time, the mesh quality with 15062 elements was selected. At the next step, the time step independency is examined. In this test, melting fraction was calculated by using three different simulations with different time steps. Table 2 shows the different time steps used in these series of tests.

Table 2. Time intervals used to examine the time step independency

Time zone (s)	Time step (s)		
	Test 1	Test 2	Test 3
0 to 10	0.01	0.1	0.005
10 to 100	0.1	1	0.05
100 to 10000	10	100	5

Fig.4 presents the result of these tests. As it can been seen, there is a slight difference in the values of melting fraction resulted by these three time steps. Therefore, to have both accuracy and less simulation time, the simulations were carried out by using the time interval in Test 2.

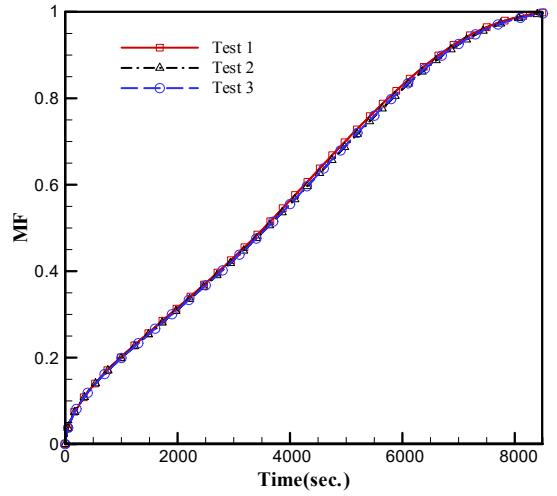

Fig. 4. Time step independency test

### C. Validation with experimental work

Figure 5 presents a melting visualization comparison between numerical results and experimental work for 0.2 wt.% of nano-PCM. To do so, some selected results obtained from numerical and experimental are compared. In general, a good agreement is achieved. However, there are some discrepancies in melting pattern, which may be due to the two main factors. First, the air trapped inside the nano-PCM in the experimental work was seen to cause a non-uniform melting at the times that trapped air was released. The other major factor is neglecting of the thermal resistance of the acrylic pipe in the numerical model. As a result, more heat could be transferred between hot wall and the nano-PCM during numerical simulation.

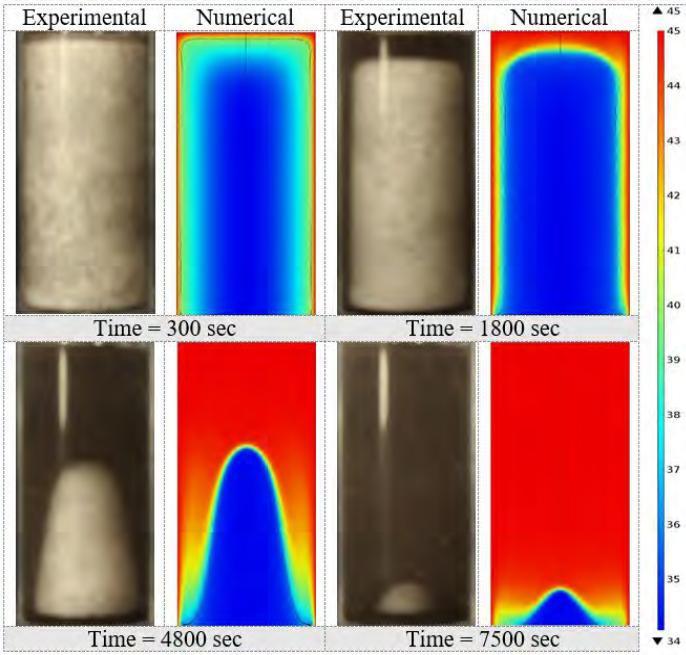

Fig. 5. Validation of numerical model with experimental work

#### IV. RESULTS AND DISCUSSION

##### A. Melting pattern visualization

In this section a comparison of melting pattern between pure PCM and Nano-PCM is presented. Some selected results are presented in figure 6. After a few minutes of initiating the experiment, a thin layer of molten PCM/nano-PCM appeared which lead to a solid-liquid interface. At the early stages of melting process (up to 300 s), conduction was the dominant mode of heat transfer since the solid-liquid interface is parallel to the lateral walls. As time furthered, the buoyancy force started to dominate the viscous force and natural convection started to establish. This phenomenon can be clearly observed from the remaining shape of the solid PCM/nano-PCM. At the later stages of melting process (i.e. after 3600s), convection became the dominant mode of heat transfer which resulted to a dome shape solid PCM/nano-PCM. As it can be seen from the figure 6, an improvement in the melting rate is observed by using 0.2 wt. % nano-PCM. To assist the discussion, the melting fractions for both PCM and nano-PCM at different times was calculated from the digital photos by using a software called Grafula. Calculation of melting fraction from digital image was also used in other published works in the literature such as [20].

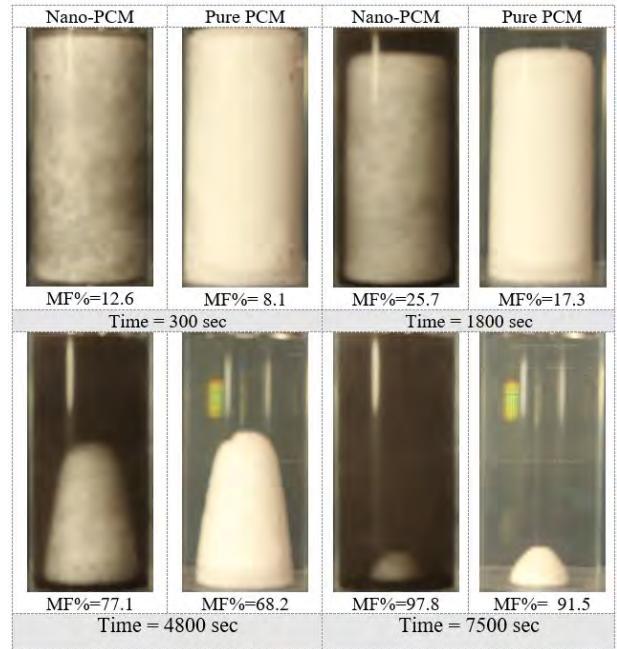

Fig. 6. Visualization of melting pattern for nano-PCM and pure PCM

##### B. Energy Stored

Figure 7 presents the stored energy during the melting process for both the nano-PCM and the pure PCM cases. At the beginning of melting process, the temperature difference between hot lateral walls of the circular enclosure and cold PCM/nano-PCM is more than the later stages of melting process. As a result, the slope of energy stored is higher at the early stages (i.e. up to 600s) than other times. From this point onward, the rate of energy-stored decreases until it reaches to zero by reaching to the thermal equilibrium. The amount of energy stored during the melting process mainly depends on the specific heat capacity and the latent heat capacity of nano-PCM/PCM. As it can be seen from the thermophysical relations of the nano-PCM presented in [21], adding nanoparticles to the PCM at the liquid phase increases the heat capacity, while, it decreases the latent heat capacity of the PCM. Therefore, it is expected to have a lower amount of energy stored in the nano-PCM which will be further degraded by adding higher weight/volume fractions of nano-particles. The amount of this decrease in the energy stored is not significant in this work due to the use of low weight fractions of nanoparticles in the experimental work. However, this phenomenon is more apparent in Groulx's numerical study [19].

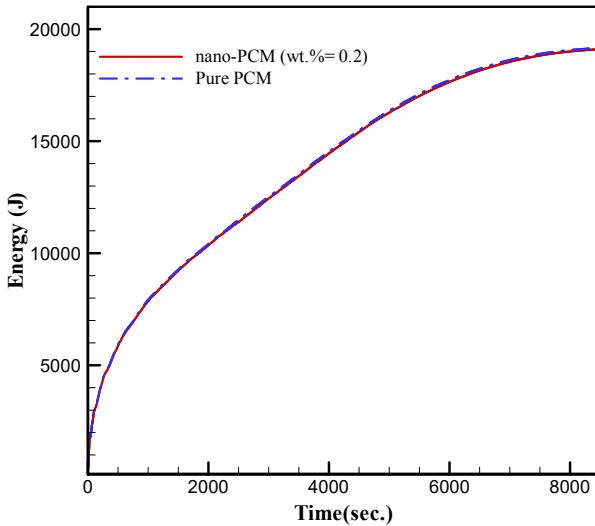

Fig.7. Stored energy

## V. CONCLUSION

A numerical and experimental study were conducted to investigate the effect of dispersing copper oxide nanoparticles into the RT-35 as the base PCM on the melting rate and energy stored. The followings can be concluded from the results obtained from this work:

a) Dispersion of the Copper oxide nanoparticles in to the RT-35 increased the melting rate due to enhancing the thermal conductivity of base PCM. From the numerical simulations, it can be found that this improvement increases by using higher weight/volume fractions of the nanoparticles. However, it is worth mentioning that in practical, dispersion of high weight/volume fractions of nanoparticles results to the sedimentation issue.

b) The rate of energy stored is seen to be high at the beginning of melting process due to the high temperature gradient. This stored energy rate degraded to zero at the end of melting process due to the thermal equilibrium. In addition, nano-PCM showed a lower amount of energy stored.

c) Finally, as both melting time (charging) and the total energy stored are important for an optimal design of a LHTES system, it is recommended to maintain a balance between improvement in the thermal conductivity and decrease in the energy stored if use of nano-PCM is required.

**Abstract**— In this paper, ice accretion on a wind turbine blade with a NACA 63415 airfoil is investigated with experimental techniques. Several different angles of attack, from 0° to 90°, and wind velocities, 3 m/s, 4 m/s and 5 m/s are studied. Tests are conducted in a climatic wind chamber with a fan and two spray nozzles. The largest quantity of ice accumulation on the blade was 7.2 kg, at an angle of attack of 90°. The results of this paper provide valuable new experimental data for ice accretion on wind turbine blades.

**Keywords**-Wind turbines; ice accretion; wind tunnel

## I. INTRODUCTION

In northern locations, ice is a significant obstacle for efficient operation of wind turbines. From measurements by Natural Resource's Canada, ice accretion can occur up to 20% of the time, between November and April [1]. Several problems for wind power are caused by ice accretion, including reduced power output due to disrupted aerodynamics, overload due to delayed stall, and increased fatigue of components due to imbalance of the ice load [2]. Ice accretion on a wind turbine occurs when super cooled liquid water droplets in fog, clouds or rain collide with a turbine and freeze on the surface.

To predict the annual power production for a wind turbine in northern locations, the wind and ice conditions must be considered [3]. Power output losses were estimated from 17% to 30% for wind turbine operating in locations that are affected by ice accumulation [4-6]. Ice accumulation changes with variations of the atmospheric temperature and water droplet size [2]. Better predictive techniques and experimental data are needed to predict ice accretion on wind turbine blades [7]. The external conditions at a cold climate site have several effects on wind turbine behaviour and on the efficiency of a wind farm.

Ice accumulation on a wind turbine blade causes distortion to the blades profile, which can impede the aerodynamic efficiency of an airfoil. The distortion frequently does not depend on the amount of ice accretion but on the location that accrues it; a small amount of ice accretion on the leading edge of a blade can significantly impair the aerodynamic performance. Additionally, ice accretion can cause wind turbine vibration, which can increase fatigue loads and cause structural failure [8].

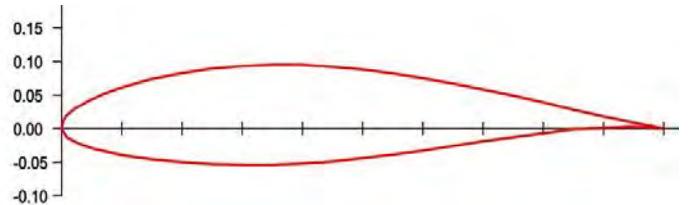

Figure 1. NACA 415-63 blade airfoil (NASA, 2014).

During icing conditions, a wind turbine is often shut-down to prevent damage caused by the ice accumulation. In this paper, experiments are conducted on a non-rotating wind turbine blade (NACA 415-63 airfoil (Fig. 1)). This research will focus on two important aspects of ice accumulation on non-rotating wind turbine blades, including (i) the quantity and (ii) location of ice accumulation.

## II. EXPERIMENTAL METHODOLOGY

In this section, details of the experimental setup used to study ice accretion on non-rotating wind turbine blades is presented. As illustrated in Fig. 2, a wind turbine blade of 0.93 m length, with a chord length of 19 cm at the root to 8.3 cm at the tip is manufactured for the experiments. The blade is made by carbon fiber. During the experiments, the thickness and chord of the blade are measured at four points (Tip, Mid1, Mid2, Root) six times (each 30 min). A digital caliper is used to measure the thickness of ice and a digital scale to measure the mass of ice.

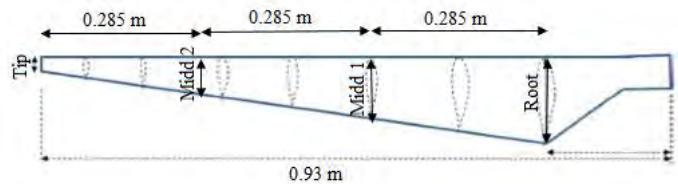

Figure 2. Schematic of wind turbine blade.

Figure 3. Schematic of experimental setup.

The experiments are conducted in a cold chamber with dimensions of 7.6 m, 4.6 m, and 4.6 m. The cold chamber is climatically controlled to allow sub-zero temperatures (-10 °C in this paper). As illustrated in Fig. 3, two FullJet spray nozzles are placed between the fan and the wind turbine blade. The wind velocity ( $V$ ) is maintained at 3.5 m/s, 4 m/s and 5 m/s. The positions of the blade and spray nozzle from the fan are (1.5 m, 0.502 m, 0.835 m) and (0.833 m, 0.485 m, 0.321 m), respectively. All coordinates are taken from the bottom left edge of the front side of the fan.

### III. RESULTS AND DISCUSSION

In this section, new experimental results on wind turbine blade icing are presented. As presented in Table 1, 7 different experiments are conducted with different wind velocities and angle of attacks ( $\alpha$ ). Wind velocities from 3.5 m/s to 5 m/s are investigated for a 45° angle of attack and angle of attacks from 0° to 90° are investigated for a wind velocity of 5 m/s. In all tests, the wind turbine blade has a horizontal angular position (Fig. 4). The liquid water content (LWC) is 0.6 and the mean volume diameter of the spray is 50  $\mu\text{m}$ . All experiments are conducted for 3 hours.

Table 1. Parameters of experiments

Velocity (m/s)	Angle of attack (°)
5	0°
5	30°
5	45°
5	60°
5	90°
4	45°
3.5	45°

As illustrated in Fig. 4, the thickness of ice on the wind turbine blade is measured every 30 minutes during the 3-hour test. Two different measurements (chord and width) are taken at four location of the blade span (Fig. 2). The chord length is measured before the tests, at each location, and then it is measured again with ice accumulation. The difference in the two measurements represents the thickness of ice on the

leading and trailing edge (chord thickness of ice), which is plotted in Fig. 4a. As presented in Fig. 4, the majority of ice on the chord is at the leading edge. This is noteworthy as ice buildup on the leading edge can cause significant deterioration of aerodynamic performance [9]. The width ice thickness, represents the thickness of ice perpendicular to the chord and is plotted in Figure 4b. The results plotted in Figure 4 are for a wind velocity of 5 m/s and an angle of attack of 45°. The transient results of other tests follow similar trends.

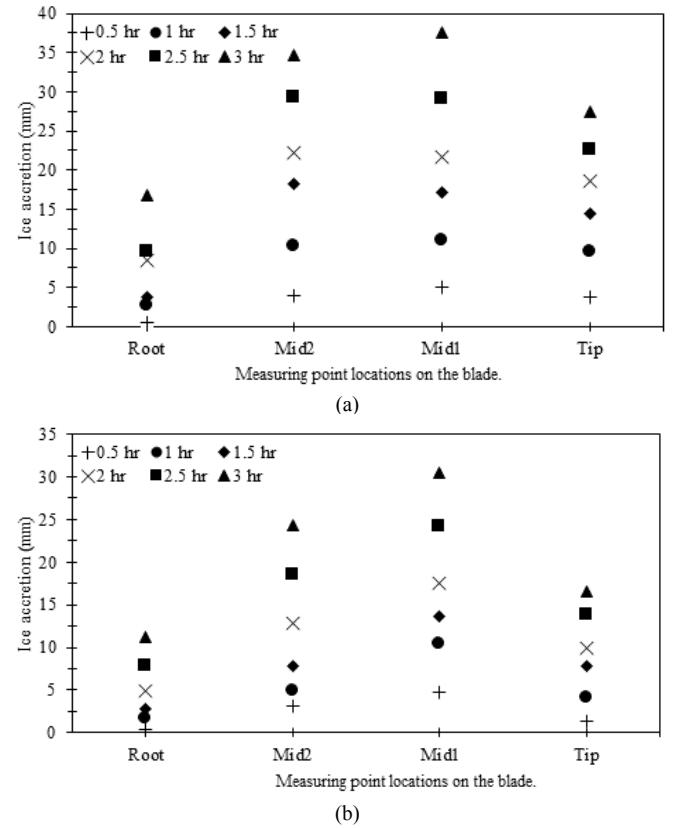

Figure 5. Transient ice accretion for  $V = 5 \text{ m/s}$  and  $\alpha = 45^\circ$  on the (a) chord and (b) width of a wind turbine blade.

As illustrated in Fig. 5, significant ice accretes on the leading edge of the wind turbine blade. Comparing Figs. 4 and 5a, over 30 mm ice thickness is accreted on the leading edge, in the middle section. The root has the smallest thickness of ice, which is approximately half as thick as in the middle of the blade. The blade's tip also has significant leading edge ice accumulation, which is more than 25 mm thick.

Figure 5. Ice accretion on a wind turbine blade at  $V = 5 \text{ m/s}$  and  $\alpha = 45^\circ$  after 3 hours of icing conditions.

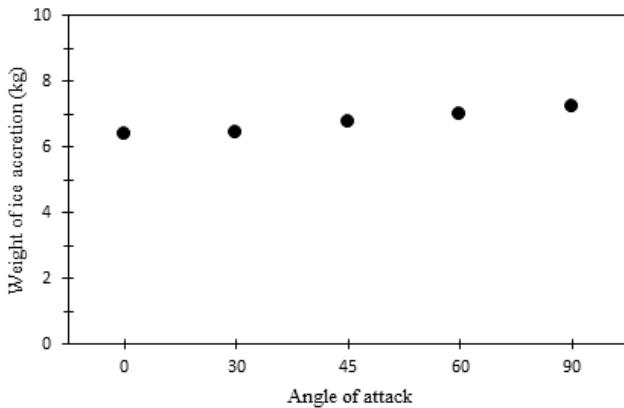

Figure 6. Weight of ice accreted on a wind turbine positioned at different angle of attacks for a wind velocity of 5 m/s.

As illustrated in Figure 6, the total quantity of ice that accretes on a non-rotating wind turbine blade is affected by the blade's angle of attack. At an angle of attack of  $0^\circ$ , the total ice accumulation is approximately 6.5 kg, which increases to 7.2 kg at an angle of attack of  $90^\circ$ . The results of Fig. 6 suggest that angle of attack of a non-rotating wind turbine blade can affect the quantity of ice accretion. For conditions that are causing ice accretion, the position of the blade can be altered to help reduce the quantity of accumulated ice on the blade which can help reduce the amount of time the turbine is unable to be operated. However, when the angle of attack is low, the quantity of ice accumulation on the leading edge is higher than for a blade at  $90^\circ$ , despite more total ice accumulating on a blade at  $90^\circ$ .

In Figure 7, the quantity of ice accretion on the wind turbine blade for different wind velocities are presented. The increase in ice accretion is nearly linear with respect to wind speed. In the conditions of these experiments, the ice accretion quantity increased from approximately 3.45 kg at 3.5 m/s to 4.92 kg at 5 m/s.

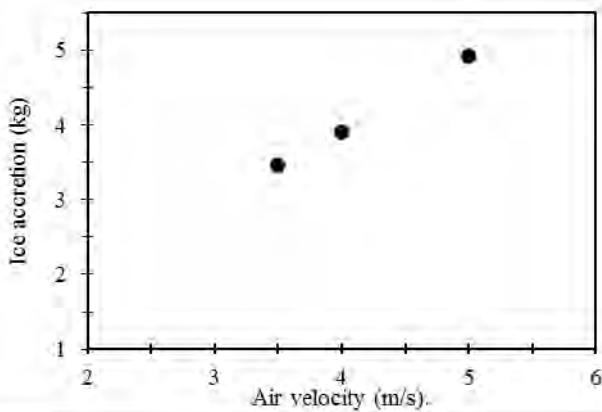

Figure 6. Weight of ice accreted on a wind turbine positioned at an angle of attack of  $45^\circ$  in different wind velocities.

#### IV. CONCLUSIONS

This paper studied the accumulation of ice on a wind turbine blade. The study was conducted for five different angles of attack ( $0^\circ$  to  $90^\circ$ ) and three speeds of wind (3.5 m/s, 4 m/s and 5 m/s). The temperature was maintained at  $-10^\circ\text{C}$  with a LWC of  $0.6 \text{ g/m}^3$ . The largest accumulation of ice was at 5 m/s, with the blade at  $45^\circ$ . More ice accretion occurred for higher angles of attack, however, more ice accumulated on the leading edge at lower angles of attack. The results also indicated a linear relationship between ice accumulation and wind velocity. The results of this paper provide new experimental data and insights for ice accretion on a wind turbine blade that has twist and varied chord length along the blade span.

**Abstract**— Solidification of water in closed piping systems is a common phenomenon in both the industrial and residential sectors. In some cases, the resulting damage may be both costly and dangerous and thus warrants attention. Therefore, further study of the cooling and freezing behavior of stagnant water within closed pipes seems to be necessary. In this regard, several experiments were performed to investigate the freezing behavior of water in pipes. The inelastic deformation, work hardening, and fracture of the pipes that were caused by volume expansion due to the freezing of the water were also studied. Two conventional steel pipe materials, namely ASTM A333-6 and ASTM A106-B, were used in the freezing tests. The fracture surfaces of the pipes were analyzed by using both macroscale and microscale images of the surfaces. Fractography analysis of the fractured regions was also performed by using a scanning electron microscope. It was found that the damage caused during freezing to the A106-B pipe was considerably more than that in the A333-6 pipe. The results confirm that A333-6 should be used instead of A106-B in pressure equipment, such as pipes, that are exposed to low temperatures.

**Keywords** - Fracture analysis; ice accumulation; pipe bursting; pressure build-up; pressure vessel

## I. INTRODUCTION

Failure of pressure equipment due to solidification of entrapped water in closed systems exposed to temperatures below freezing is very widespread and costly in both the industrial and residential sectors. According to the Insurance Information Institute (I.I.I.) [1], frozen pipes are one of the main problems that occur during winters and the financial losses because of ice, freezing, and related issues averaged \$1.2 billion annually in the United States alone over the last 20 years.

The failure of pipes in commercial and residential heating, ventilating, and air-conditioning (HVAC) systems in which pipes are located in low-temperature environments, is also common. The most conventional pipe materials that are used in HVAC systems are steel, copper, and chlorinated polyvinyl

chloride (CPVC) [2]. In this regard, further study of freezing behavior of water within these pipes and the failure of such piping systems has been necessary. Gordon [3] conducted a series of experiments to study the freezing behavior of water within closed pipes and the bursting of pipes used for residential applications. Smith, *et al.* [4] performed freezing experiments with copper and steel pipes. In this study, it was shown that the ice front did not reach the rupture site and failure of the pipe occurred at a location in which water was entrapped. Edwards, *et al.* [5] studied bursting of three different plastic pipe materials. Given the noticeable inelastic deformation of the plastic pipes that could accommodate the expansion of freezing liquid, it was concluded that longer pipe lengths were required for the plastic pipes compared to the metallic pipes to cause over-pressurization and bursting.

Mathematical simulation of the cooling and freezing of water in pipes has been the subject of substantial research investigations [6 - 9]. In this regard, Sugawara, *et al.* [6] and Oiwake, *et al.* [7] performed both experimental and numerical studies to evaluate the internal pressure changes during the solidification of water. Sullivan and McDonald [8] developed a one-dimensional transient heat conduction mathematical model to estimate the cooling and freezing times of water within copper and polyvinyl chloride (PVC) pipes of various inner diameters. McDonald, *et al.* [9] compared the results obtained from experimental data with estimates from the mathematical model and concluded that the separation of variables method for a finite length-scale heat conduction problem is an acceptable method for use in developing a predictive model for the total cooling and freezing times of water in small diameter pipes.

The study of the current paper investigated the freezing behavior and the resulting failure in two conventional grades of carbon steel pipes. The objectives of this study were to: (1) investigate different stages of freezing in the closed pipes, (2) analyze the inelastic deformation and the resulting work hardening of the pipe materials, and (3) analyze the fracture surfaces to determine the fracture mechanism and failure mode for each rupture case.

## II. METHODOLOGY

Two 254-mm (10-inch) long, 51-mm (2-inch) diameter carbon steel pipes were used in the freezing experiments. The steel pipes were of two different materials namely ASTM A333-6 and ASTM A106-B. However, the wall thickness of both of the pipes was the same. Schedule 40 pipes, which are widely used in industry, were selected for the tests. The pipes were chosen to study the effects of pipe material on the resulting failure.

Each pipe assembly included a 254-mm (10-inch) long pipe with two A420 WPL6 butt-welded end caps, each including a 19-mm ( $\frac{3}{4}$ -inch) Class 3000 A350 LF2 threadolet. Welding consisted of a typical SMAW P1-P1 procedure using E6010 for the root and E7018 for the cap. The total length of the assembly that consisted of the pipe, the two end caps, and the two threadolets was approximately 381 mm (15 inches). A pipe assembly, which is related to a Schedule 40 ASTM A333 Grade 6 pipe, is shown in Fig. 1.

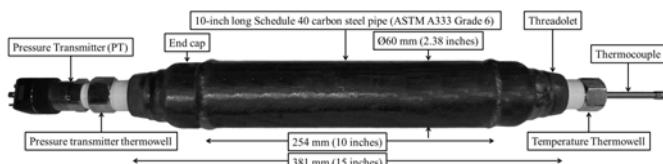

Figure 1. Pipe assembly, complete with the installed thermowells, thermocouple, and pressure transmitter

A thermowell (TW15, WIKA Instruments, Edmonton, AB, Canada) was installed into the threadolets at each end of the pipe. The thermowells were used for positioning the type T thermocouple (TC40, WIKA Instruments, Edmonton, AB, Canada) and the pressure transmitter (PT) (S-20, Klingenberg, Germany). The tip of the thermowell used for the PT was drilled through to enable pressure to be measured. A balloon filled with antifreeze was installed on the tip of the PT thermowell to ensure that no ice would form inside the pressure sensing pathway and to ensure that the peak pressure in the pipe, which occurs in the liquid phase, would be measured.

Temperature and pressure data were collected at regular time intervals from the thermocouples and the pressure transmitter by using two data acquisition systems. One data acquisition system (SCXI-1600, National Instruments, Austin, TX, USA) was used to measure the ambient and water/ice temperatures and a second data acquisition system (cDAQ-9171, National Instruments, Austin, TX, USA) was utilized to collect and record pressure measurements. The NI MAX software was used to collect all the measurement readings. The rate at which data was collected from all the mentioned devices was one data point per second (1 Hz).

In order to assess the freezing behavior of water inside the closed pipes, several freezing tests were performed in an 18.2 m<sup>3</sup> (640 ft<sup>3</sup>) cold room freezer (Foster Refrigerator USA, Kinderhook, NY, USA) that was equipped with a temperature controller. The experiments were all conducted with pipes that were oriented horizontally and under the same environmental ambient conditions. The pipes were placed in the cold room in advance of conducting the tests so that both the ambient and the water inside the pipe were at steady state. Care was taken to

start all the tests at approximately the same temperature (27°C). The cold room set-point temperature was -25°C and the tests were stopped when the water inside the pipe reached -15°C.

All of the experiments involved leaving a small predetermined percentage of air space inside the pipe, rather than filling it completely with water. The reason for having air in the system was twofold. First, the first solidification plateau and ice cooling can only be seen when some air is entrapped in the closed system. Second, some air in the system prevents the pipe from yielding excessively and allows the pipe to be used for more freezing tests and, therefore, work hardening of the pipe material can be better observed and assessed. As a result, the amount of entrapped air in the pipe assemblies was set to a constant value of 5 vol.% for all the tests so that the work hardening behavior of the pipe materials was studied without introducing the effect of variation in the air content.

Considering the volume expansion of the pipes due to inelastic deformation, the volume of the pipe assemblies was measured after each test. Then, the pipe assemblies were refilled with water so that the increase in the volume of the pipe assembly was filled with water and the volume percent of air could be maintained constant in all the freezing tests.

Eventually, after conducting repeated freezing tests, the piping assemblies failed. The fracture surfaces were cleaned in order to study the microscopic features of the fracture surfaces. The sectioned samples of the pipes were placed in an ultrasonic cleaner (Haver USC 200, HAVER & BOECKER, Oelde, NRW, Germany) and cleaned with corrosion inhibited detergent solution (Citranox, Alconox, NY, USA) for 30 minutes to ensure that the oxide scale and deposits were removed from the fracture faces. The microstructure of the fracture surfaces was then examined by using a scanning electron microscope (Zeiss Sigma 300 VP-FE, Carl Zeiss Canada Ltd., Toronto, ON, Canada).

## III. RESULTS AND DISCUSSION

### A. Freezing Behavior

The temperature and pressure traces of water/ice for the first freezing test that was conducted on ASTM A333 Grade 6, hereafter referred to as A333-6, Schedule 40 steel pipe in which 5 vol.% of air was entrapped in the pipe are shown in Fig. 2. The graph includes five stages, namely water cooling, the first solidification plateau, cooling of the mix of water and ice, the second solidification plateau, and the solid ice cooling. The first stage, which was related to the liquid cooling, began when the fans in the cold room started cycling (dropping the temperature in the room) and finished after a short supercooling period. The nucleation and growth of plate-like solid crystals known as dendritic ice occur at this stage and during the supercooling [10]. The length of the first solidification plateau in the second stage indicates the time needed for some of the liquid water in the pipe assembly to solidify so that a mixture of water and ice fills the entire volume of the pipe assembly. As the solidification proceeded through this stage, the annular ice formed inward and the dendritic ice was engulfed by solid ice [11]. At this point, solidification of water was paused due to the pressure increase.

At the end of the first solidification plateau, all the water had not been transformed into solid ice and some water was still entrapped in the middle of the pipe assembly.

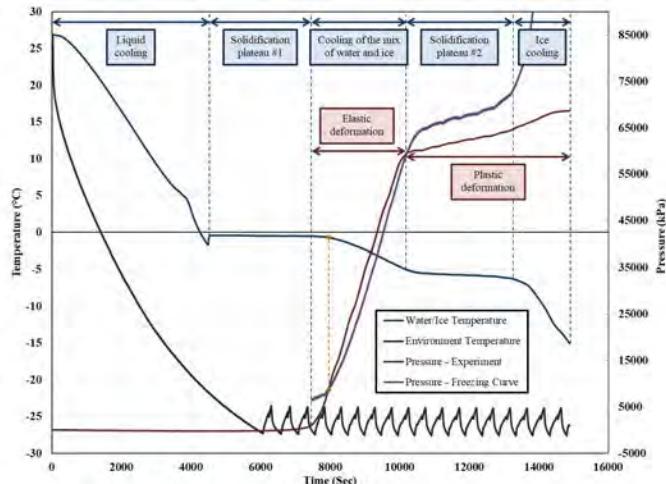

Figure 2. Curves of temperature and pressure versus time for water/ice in A333-6 Schedule 40 low carbon steel pipe

In the third stage and during the elastic deformation of the pipe, the pressure of water within the pipe increased sharply. As shown in Fig. 2, at the beginning of this stage, the average rate at which the water temperature decreased in this period was very low (order of  $-0.02^{\circ}\text{C}/\text{min}$ ) because the pressure of the water was lower than the pressure that was calculated from the non-linear freezing relation for the hexagonal ice, which is given by Eq. (1) [12] as

$$P_f = 6.11657 \times 10^{-4} - 414.5 \times \left[ \left( \frac{T_f}{273.16} \right)^{8.38} - 1 \right]. \quad (1)$$

The values of pressure obtained from Eq. (1) were based on the transient temperature of the freezing water inside the pipe (see Fig. 2).

Further transformation of the water into ice caused an increase in the pressure of the freezing water such that the experimentally determined transient pressure curve intersected and crossed the transient pressure curve that was obtained from the non-linear freezing relation, which was representative of the magnitude of pressure that was required to maintain the freezing water in its liquid form. This point and its analogous point on the water temperature trace have been connected to each other with a dashed line (see Fig. 2) in order to highlight the interaction between water pressure and temperature. After this point, the high rate of increase in the pressure of the water caused a decrease in the rate of solidification of the rest of the pressurized water due to a continuous depression of the freezing point. Therefore, the heat loss in this period was mainly sensible as observed from the decrease in temperature of the ice-water mixture and consequently, the average rate of decrease of the water temperature changed noticeably from  $-0.02^{\circ}\text{C}/\text{min}$  before 7,960 seconds after the start of the

experiment to  $-0.12^{\circ}\text{C}/\text{min}$  after 7,960 seconds after the start of the experiment.

Once the carbon steel pipe entered the plastic deformation region, the pressure increased with time at a lower rate than that which occurred earlier in the elastic deformation region. As a result of further cooling of the freezing water when the pipe material was deforming plastically, the pressure on the water was not sufficiently high to maintain the freezing liquid in its liquid form and, therefore, the remaining water started transforming to solid ice. The average pressure that was obtained from the experiment during this period (solidification plateau #2) was 5.2 MPa lower than the average pressure that was obtained from the freezing curve for the given temperatures (see Fig. 2). The transformation of water to ice, when the temperature trace plateaued again, was clearly observed at the time when the pipe material started deforming plastically.

The magnitude of freezing point depression correlates with the pressure of the freezing water, which itself is a function of the yield strength of the pipe and the pipe wall thickness according to the von Mises yield criterion and thick-walled pressure vessel theory relations, respectively. The yield strength of the pipe is not a constant value and varies due to work hardening from one test to another.

At the end of the second plateau, all the water in the pipe had been transformed into hexagonal ice. In the last stage, further cooling resulted only in temperature decrease of the solid ice. The increasing deviation of theoretical pressure values from the experimental values in this stage was likely due to a lack of pressurized water in the closed pipe. Therefore, comparison of pressure values between the non-linear freezing relation and the experiment is not valid in this stage.

#### B. Inelastic Deformation and Work Hardening

The inelastic deformation of the pipes that occurred during each freezing test was determined by measuring the diameter of the pipes by using a Pi-tape. The outer diameter of the pipes was measured before each test and after the failure of each pipe in the last test. The transverse strain values were calculated by comparing the current diameter of the pipe with its actual original value. As expected, the highest strains occurred near the middle of the pipe where the reinforcing effects of the circumferential welds had the lowest impact.

It was found that the maximum strain values that A106-B and A333-6 steel pipes could accommodate before rupture was 13.3% and 11.3%, respectively. It should be noted that the minimum transverse elongation required before failure according to the standard respecting ASTM A106 Grade B steel, hereafter referred to as A106-B, is 16.5% [13]. Therefore, the material did not meet the criteria under the frozen pipe tests. However, the requirement of the minimum transverse elongation at failure for A333-6 steel is 11.4% [14], which is very close to the strain value at which the pipe failed.

The number of loading/unloading cycles had a profound impact on the pressure values that were required to promote plastic deformation of the pipe material in each freezing test. The work hardening of both A106-B and A333-6 Schedule 40

steel pipes, which was caused by generation and movement of dislocations within the pipe material, can be observed clearly in Figs. 3 and 4, respectively.

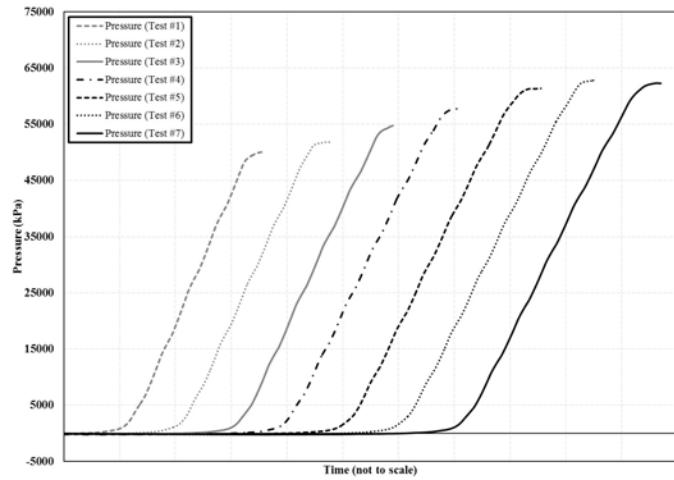

Figure 3. Effect of freezing/thawing cycles on yield pressure of A106-B Schedule 40 low carbon steel pipe

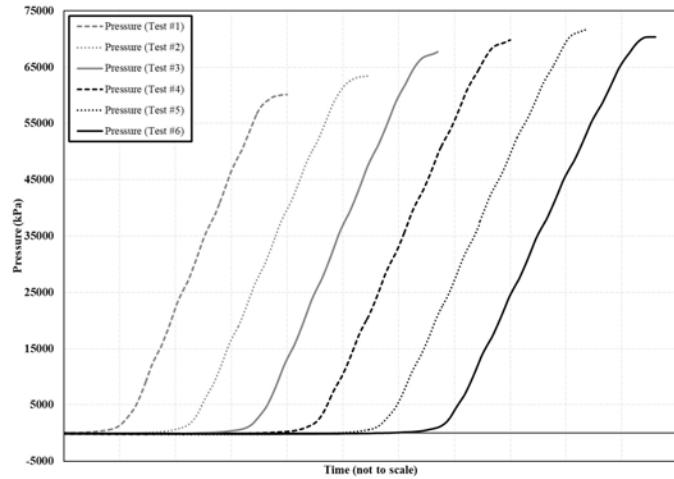

Figure 4. Effect of freezing/thawing cycles on yield pressure of A333-6 Schedule 40 low carbon steel pipe

A comparison of the peak pressures in the elastic region between the first and the last tests for both pipes shows approximately 23% and 17% increase in the pressure at which the pipe material started to deform plastically for A106-B and A333-6 Schedule 40 steel pipes, respectively (see Figs. 3 and 4). Therefore, the number of freezing/thawing (loading/unloading) cycles and the resulting work hardening of the pipe material had an impact on the increase of the peak pressures in the elastic region and, consequently, further depression of the freezing point of the remaining water in the closed system during the second solidification plateau according to Eq. (1).

A comparison of the temperature and pressure data of the first and the last tests that were performed with A333-6 steel pipe is shown in Fig. 5. The increase in the yield pressure and

the decrease in the temperature at which temperature curve plateaued again can be clearly observed in Fig. 5.

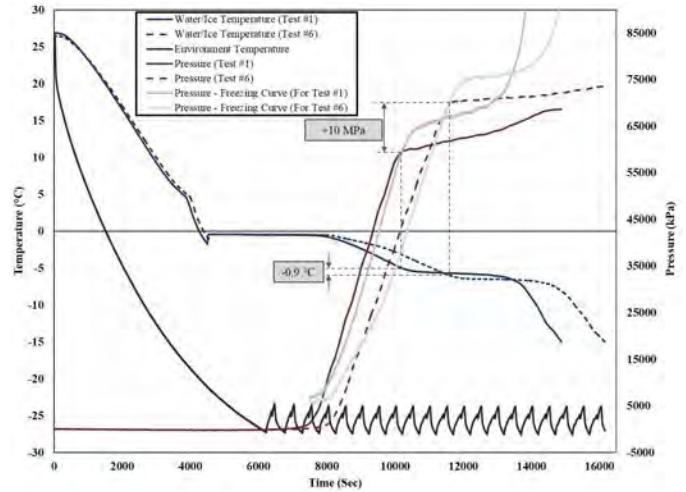

Figure 5. Effect of loading/unloading cycles on further depression of the freezing point at the beginning of the second solidification plateau

The relatively lower rate of temperature decrease in Test #6 compared to that of Test #1 at the beginning of the third stage (cooling of the mix of water and ice) was an indirect consequence of non-uniform bulging of the pipe assembly during the previous freezing tests, which resulted in the increase of the volume of the closed pipe from 649 ml to 718 ml. Therefore, more ice was required to be formed to compensate for the 10.6% increase in the volume of the pipe assembly and caused an increase in the water pressure to that which was required according to the freezing curve.

### C. Pipe rupture

Failure of the pipes occurred after conducting several tests. The pattern of failure that is shown in Fig. 6 is very common in pipe rupture cases. As expected, both pipe assemblies fractured along the axial direction, which was perpendicular to the direction of the applied hoop stress where the maximum principal stress for the case of the cylindrical pressure vessel was located. Considering the geometry of the pipe assembly with thermowell installed, the center of the pipe is the part that froze last. It was the expansion of the ice plugs in the axial direction and the low compressibility of the entrapped water that caused freeze-induced pipe failure [4].

The gap at the failure site of the A333-6 steel pipe was remarkably narrower and shorter than that of the A106-B steel pipe. It is believed that the longer axial crack for the A106-B pipe compared to that of the A333-6 pipe was due to the decrease in the amount of energy that was absorbed by the pipe material during propagation of the crack, which was due to the lower toughness of A106-B material at low temperatures. While not dramatically obvious in these specific tests due to the low amount of stored energy released at failure, the improved toughness properties of A333-6 is expected to be much more relevant and evident in actual field conditions where large amounts of stored energy is released at failure. The higher toughness of A333-6 provides better resistance to a brittle

fracture developing following a ductile overload. The dependency of the absorption energy in Charpy impact tests on temperature for an A106-B pipe can be found in literature [15].

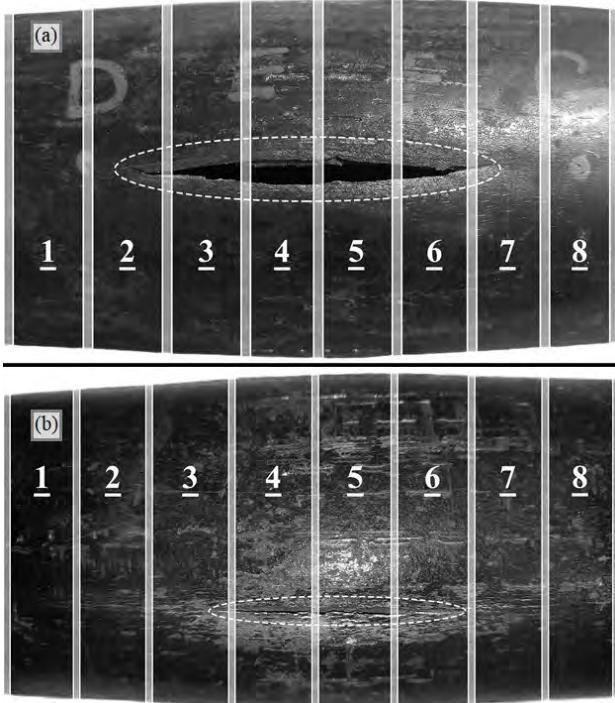

Figure 6. Failure of (a) A106-B and (b) A333-6 Schedule 40 low carbon steel pipe due to internal over-pressurization

The pipes were cut open after failure so that the fracture surfaces could be better observed. Eight rings, each one centimeter wide, were cut from the middle section of the pipe to study the fracture at different locations. The exact locations from which these eight rings were cut are shown in Fig. 6.

#### D. Fracture Analysis

In order to study the macroscopic features of the fracture surfaces, images of the sides of the fractured regions were taken, which can be seen in Figs. 7 and 8. The geometry and appearance of the fractured regions are the characteristics that may be used to determine the fracture mechanism and the failure mode of the pipe material. Both slant fracture and double-slant fracture features, which are typical of planes-stress loading conditions in ductile materials [16] and are common failure modes in pressure vessel and in the piping industry [17], can be observed in cross-sectional views of the sectioned rings from the fractured portions.

These types of fractures, which are common in tubes with low wall thicknesses due to their minimum through-the-thickness stresses, are known to be ductile in nature [16]. It is well known that the tearing process is initiated by local thinning. The localization of two shear bands oriented at 45° angles occurs inside the necked region [18 - 19]. The resulting slant failure and the necked regions can be observed in Figs. 7 and 8, in the middle and in front of the axial cracks, respectively.

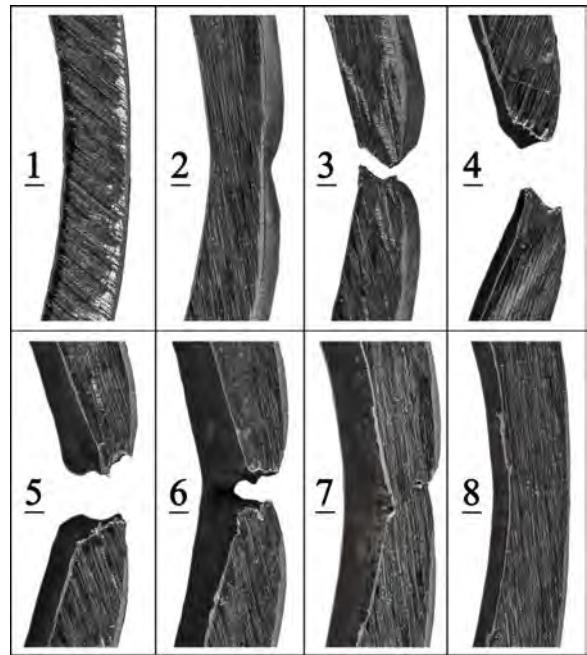

Figure 7. Cross-sectional views of the rings sectioned from A106-B Schedule 40 low carbon steel pipe

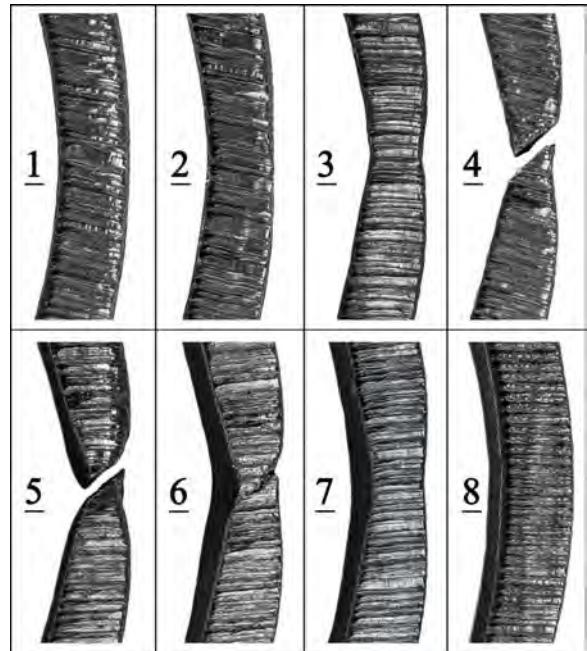

Figure 8. Cross-sectional views of the rings sectioned from A333-6 Schedule 40 low carbon steel pipe

#### E. Fractography

The higher-magnification fractographs show that the mode of failure was ductile tearing from void coalescence induced microcracks, which is characteristic of ductile fracture. This can be observed from coalescence of adjacent microvoids in the axial direction (see Fig. 9). The dull and fibrous surfaces of the fracture that contained many dimples are indicative of dimpled rupture fracture.

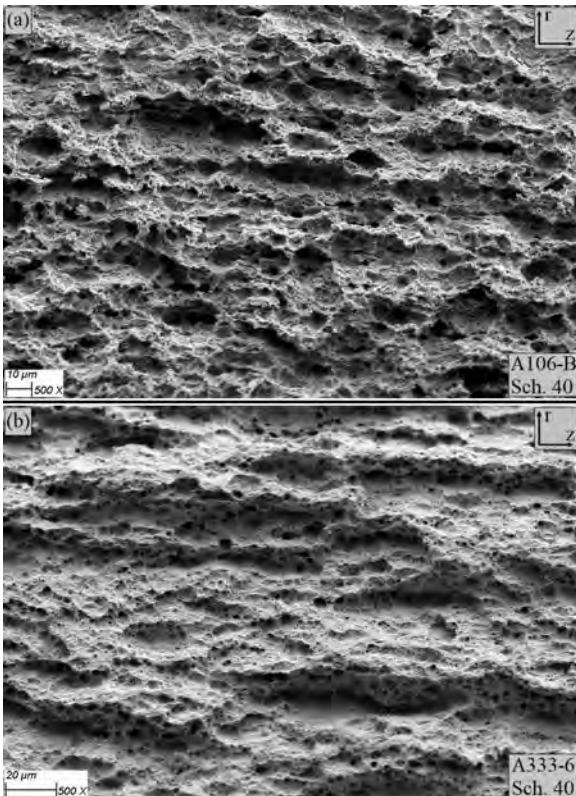

Figure 9. Micrograph of the fracture faces of (a) A106-B and (b) A333-6 Schedule 40 low carbon steel pipe (500X magnification)

#### IV. CONCLUSION

Several freezing tests were performed on two steel pipe assemblies with the same dimensions, but with two different steel materials. By comparing the data, the following conclusions can be drawn.

- The freezing point depression of the water depended on the fluid pressure, which itself was a function of pipe material yield strength and wall thickness.
- The amount of work hardening mainly depended on the number of freezing/thawing cycles that the closed pipes had experienced. After performing several freezing tests, the pressure at which both A106-B and A333-6 steel pipes started deforming plastically was increased 23% and 17%, respectively.
- Work hardening of the material caused depression of freezing point in the second solidification plateau. It was found that an increase in the yield pressure of A333-6 steel pipe material on the order of 10 MPa (1,450 psi) resulted in a 0.9°C decrease in the temperature at which the remaining entrapped water started to freeze to solid ice.
- Failure and bursting of the pipes occurred after several loading/unloading (freeze/thaw) cycles. Double-slant and slant fracture appearances were observed in the macroscopic examination of the cross-sectional views of the sectioned rings.

- Higher-magnification views of the fracture surfaces of both pipes confirmed dimpled rupture fracture, which was indicative of ductile fracture. It was observed that the axial cracks were formed by coalescence of adjacent microvoids in the axial direction.
- As expected, the resulting damage in A333-6 pipe was less noticeable than that in A106-B pipe due to decreased toughness of the A106-B material at low temperatures.

**Abstract**—A modified three-layer model for solid-liquid flow in horizontal pipes is developed, which overcomes the limitations of many previous models. The steady-state model predicts the pressure loss, critical velocity, concentration profile in the heterogeneous layer, mean heterogeneous layer and moving bed layer velocities, and bed layer heights for each set of parameters. We propose a new correlation for the turbulent solids diffusivity. This and the steady state model predictions show a good agreement with experimentally measured results in literature: for concentration profile in the heterogeneous layer and pressure loss, over a wide range of conditions [1]. In turbulent flow, the pressure loss vs mean velocity curve shows a characteristic minimum just before the critical velocity is attained.

**Index Terms**—three-layer model, solids transport, critical velocity, solids diffusivity, pressure gradient

## I. INTRODUCTION

The flow of solid-liquid mixtures in the form of slurry occurs in a wide range of situations, e.g. river bed erosion and sedimentation, ocean-bed avalanches, transport of mined particulate, etc.. Pipe flows of water-sand slurry are commonly encountered in many applications such as mined slurry transport, hole cleaning, hydraulic fracturing and gravel packing in oil & gas wells. There are numerous studies of the fundamental sub-processes of solids phase transport (erosion, dispersion, sedimentation, deposition, shear-migration) appearing over the past 20-30 years, and dating back to the 1950s.

Many different two-layer multi-phase hydraulics models have appeared in the slurry transport literature, e.g. the two-layer model of Shook and Bartosik [2], and many others, where a heterogeneous layer, and a sliding/stationary bed layer is predicted. Doron and Barnea [3] first introduced a three-layer slurry transport model. They identified the flow patterns of slurries flowing in horizontal pipes as the flow rate increases: (a) flow with a three-layer configuration, i.e. a stationary bed layer at the bottom, a sliding bed layer in the

middle, and a heterogeneous layer at the top; (b) flow with a sliding bed and heterogeneous layer; (c) fully-suspended flow.

Transitions between the different observed flow regimes have historically formed one major axis of the research work on slurry transport. These are typically represented as transition velocities, one of the most important being the *deposition*, *suspension* or *critical* velocity: defining the onset of a bed at the bottom of the pipe. There are many correlations and models for predicting the deposition velocity in literature, e.g. that of Oroskar and Turian [4]. The empirical correlations and theoretical predictions are in qualitative agreement and what is interesting about the methodology in [4] is that it is based on modeling the physical balance between turbulent eddies suspending the particles and buoyancy driven settling.

Other critical velocity predictions in literature are based on a frictional pressure drop prediction, e.g. see [3]. Prediction of frictional pressure gradient is of key importance for industrial applications and has attracted many researchers since 1950's. For example, Turian and Yuan [5] developed correlations based on over 2800 data points, for the frictional pressure in each of the four different flow regimes. This is probably the most comprehensive empirical correlation developed to date.

Particle turbulent diffusivity prediction plays an important role in modeling the slurry flow and predicting the concentration distribution in the pipe. We mention here the work of Walton [6] who proposed a correlation to predict the mean particle diffusivity which consists of three empirical parameters, Based on which he derived an equation for the critical particle velocity. However, the correlation does not account for the dependence of the mean particle diffusivity on the solids concentration.

In the present paper we present a new three-layer model which is based on Doron and Barnea's concept [3], with the main change in defining the solids diffusivity. This affects the prediction of the concentration distribution in the hetero-

geneous layer and with this the critical velocity. A number of the stress and force closure models in the bed layer were changed and the heterogeneous layer Reynolds number for fine particles was modified. Validation against experimental data is presented in [1]. In §II we outline the model development and assumptions, and in §III, we bring an example of reference outputs from the proposed model.

## II. MODEL DEVELOPMENT

In this study we outline a steady state three-layer model used to predict the transport of solids in horizontal wells, typically sand-water flows. These flows arise in many well operations and the model is developed to overcome limitations of existing three- and two-layer models. Conservation of mass equations for the two phases and momentum balance in each layer are combined in the model. A convection-diffusion equation models the solids distribution profile and average concentration in the heterogeneous suspension layer, above the bed. These 5 equations plus the imposed flow rate are solved iteratively to predict pressure drop, individual layer heights, mean layer velocities and solids distribution. Additional closure expressions are used to describe other effects.

### A. Dimensional analysis

Steady state slurry flow along the pipe depends on many parameters such as the pipe diameter,  $\hat{D}$ , the liquid phase density,  $\hat{\rho}_l$ , the solids phase density,  $\hat{\rho}_s$ , the liquid phase viscosity,  $\hat{\mu}_l$ , the particle diameter in the solids phase,  $\hat{d}_p$ , Gravitational acceleration,  $\hat{g}$ , the flow rate of the slurry,  $\hat{Q}$ , measured positive in the downwards direction along the pipe, and the fraction of the flow rate due to the solids phase,  $q$ , (or alternatively, the mean volumetric concentration of solids in pipe cross section, say  $C_v$ ). The last two mentioned parameters are dimensionless, but others are dimensional.<sup>1</sup> Thus, the base flow is described by four dimensionless groups, plus the solids phase flux fraction,  $q$ , (or  $C_v$ ). There are various equivalent choices for the four dimensionless groups, but we will adopt two geometric groups, which are the scaled diameter ratio,  $\delta = \hat{d}_p/\hat{D}$ , and the density ratio,  $s = \hat{\rho}_s/\hat{\rho}_l$ , and two others, the Froude number ( $Fr$ ) and Reynolds number ( $Re$ ):

$$Re = \frac{\hat{\rho}_l \hat{D} \hat{U}_s}{\hat{\mu}_l}, \quad (1a)$$

$$Fr = \frac{\hat{U}_s^2}{\hat{g} \hat{D} (s - 1)}, \quad (1b)$$

where  $\hat{U}_s = 4\hat{Q}/(\pi \hat{D}^2)$ . Other choices could have included a Richardson or Bagnold number.

The base set of five parameters ( $Re, s, Fr, \delta, q$ ) is clearly not sufficient to fully describe all phenomena one is likely to encounter in a pipe flow. Characterising the particle distribution via a single parameter is considered as a simplification, apart from a size distribution particle shape can have significant effects and as soon bed formation and motion

<sup>1</sup>Throughout this paper we write all dimensional quantities with a  $\hat{\cdot}$  symbol and dimensionless parameters without.

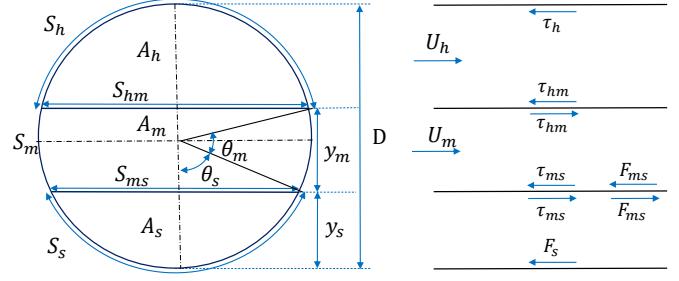

Fig. 1. Schematic of the proposed three-layer model, including geometrical parameters, moving and static bed layers positions, and stresses and forces on each layer

is considered other mechanical and geometric parameters become important, e.g. friction coefficient, maximal packing fraction, etc.

In order to render the model dimensionless we scale all lengths with  $\hat{D}$ , areas with  $0.25\pi\hat{D}^2$ , velocities with  $\hat{U}_s$ . The stresses are scaled with  $0.5\hat{\rho}_l\hat{U}_s^2$ , forces are scaled with  $0.5\hat{\rho}_l\hat{U}_s^2\hat{D}$  and the pressure gradient is scaled as follows:

$$\frac{\partial \hat{p}}{\partial \hat{z}} = [\hat{\rho}_l(1 - C_m) + \hat{\rho}_s C_m]\hat{g} + \frac{2\hat{\rho}_l\hat{U}_s^2}{\pi\hat{D}} \frac{\partial p}{\partial z}, \quad (2)$$

where  $0.25\hat{D}^2C_v = \hat{A}_h C_h + \hat{A}_m C_{max}$ , i.e.  $C_v$  is the mean spatial solids concentration.

### B. Three-layer steady state model equations

According to the flow parameters, the pipe cross-section may contain moving and/or stationary beds at the bottom of the pipe, of heights  $\hat{y}_m$  and  $\hat{y}_s$  respectively, see Fig. 1. Above the bed the flow is assumed to consist of a heterogeneous slurry, in which the concentration (volume fraction) of solids varies with height  $\hat{y}_h$ . Within the bed the concentration is assumed to be at the maximal packing fraction,  $C = C_{max}$ . The heterogeneous layer moves in the axial direction with mean speed  $\hat{U}_h$  and the moving bed layer moves with mean speed  $\hat{U}_m$ .

Conservation of the total mass flow rate is represented by

$$\hat{Q} = 0.25\pi\hat{D}^2\hat{U}_s = \hat{A}_h\hat{U}_h + \hat{A}_m\hat{U}_m, \quad (3)$$

and mass conservation of the solid and liquid phases is governed by:

$$\hat{Q}q = C_h \hat{A}_h \hat{U}_h + C_{max} \hat{A}_m \hat{U}_m, \quad (4)$$

$$\hat{Q}(1 - q) = (1 - C_h) \hat{A}_h \hat{U}_h + (1 - C_{max}) \hat{A}_m \hat{U}_m, \quad (5)$$

where  $C_h$  is the mean solids concentration of the heterogeneous layer and the areas  $\hat{A}_h$  and  $\hat{A}_m$  are heterogeneous and moving bed cross section areas respectively. Evidently, one of Eqs. (3 - 5) is redundant.

We select Cartesian coordinates such that  $\hat{z}$  denotes axial distance along the pipe in the downwards direction,  $\hat{y}$  measure distance perpendicularly upwards from the base of the pipe,

viewed in a cross-section, and the  $\hat{x}$  direction is orthogonal, within the plane of the cross-section. The axial momentum balance in heterogeneous and moving bed layers are:

$$\hat{A}_h \frac{\partial \hat{p}}{\partial \hat{z}} = -\hat{S}_h \hat{\tau}_{hw} - \hat{S}_{hm} \hat{\tau}_{hm}, \quad (6)$$

$$\hat{A}_m \frac{\partial \hat{p}}{\partial \hat{z}} = -\hat{F}_{mw} - \hat{F}_{ms} - \hat{S}_{ms} \hat{\tau}_{ms} - \hat{S}_m \hat{\tau}_{mw} + \hat{S}_{hm} \hat{\tau}_{hm}, \quad (7)$$

where the perimeters  $\hat{S}_h$  and  $\hat{S}_m$  are illustrated in Fig. 1. The axial pressure gradient is denoted  $\frac{\partial \hat{p}}{\partial \hat{z}}$ . The mean shear stresses along  $\hat{S}_{hw}$  and  $\hat{S}_{mw}$  are denoted  $\hat{\tau}_{hw}$  and  $\hat{\tau}_{mw}$ , respectively.  $\hat{F}_{ms}$  is the dry friction force acting at the interface between the moving bed and stationary bed,  $\hat{\tau}_{ms}$  is the hydrodynamic shear stress acting on the interface.  $\hat{F}_{mw}$  is the dry friction force acting at the surface of contact of the moving bed with the pipe wall,  $\hat{S}_{mw}$ , and  $\hat{\tau}_{mw}$  is the hydrodynamic shear stress acting on the pipe wall. Closure models for the stresses and forces are described in §II-D.

To obtain the velocity of the moving bed layer, which is a key feature of the three-layer model, we use the method suggested by [3], in which a moment balance equation is written on a solid particle in the lowermost stratum of the moving bed layer, which is at the verge of rolling (for more details, see [3]). Evaluating the moments exerted about the particle, just about to move, we get:

$$\hat{U}_m = \sqrt{\frac{0.779(\hat{\rho}_s - \hat{\rho}_l)\hat{g}\hat{d}_p[C_{max}\frac{\hat{y}_m}{\hat{d}_p} + (1 - C_{max})]}{\hat{\rho}_l C_D}}. \quad (8)$$

Within the heterogeneous layer, the solids distribution  $C(\hat{y})$  is governed by a balance between sedimentation and turbulent resuspension:

$$0 = \frac{\partial}{\partial \hat{y}} \left[ \hat{v}_p C + \hat{\epsilon}_p \frac{\partial C}{\partial \hat{y}} \right], \quad (9)$$

where  $\hat{v}_p$  is the sedimentation velocity and  $\hat{\epsilon}_p$  is the turbulent particle diffusivity. At the interface between bed and heterogeneous layer we have  $C = C_{max}$ , and at the top of the heterogeneous layer there is no flux of particles, so that:

$$\hat{v}_p C + \hat{\epsilon}_p \frac{\partial C}{\partial \hat{y}} = 0. \quad (10)$$

### C. Concentration distribution in the heterogeneous layer

On scaling  $\hat{y}$  with  $\hat{D}$ , and on integrating (9), the solids distribution within the heterogeneous layer ( $y_b, 1]$  satisfies the following initial value problem:

$$\frac{\partial C}{\partial y} + \frac{\hat{v}_p \hat{D}}{\hat{\epsilon}_p} C = 0, \quad (y_b, 1], \quad C(y_b) = C_0. \quad (11)$$

In the case that there is a bed, ( $y_b > 0$ ), then the initial condition is given by  $C_0 = C_{max}$ . The differential equation

(11) is solved to give  $C(y)$  and the area-averaged value of  $C(y)$  is then computed as follows:

$$\bar{C}(y_b) = \frac{\int_{y_b}^1 C(y) \sqrt{1 - (2y - 1)^2} dy}{\int_{y_b}^1 \sqrt{1 - (2y - 1)^2} dy}, \quad (12)$$

We note that the value of  $\bar{C}$  depends also on the initial condition  $C_0$ , used in (11), and on any other dimensionless parameters in (11). Thus, we write  $\bar{C} = \bar{C}(y_b, C_0)$  and the height of the heterogeneous layer is determined from the equation:

$$\bar{C}(y_b, C_0 = C_{max}) = C_h. \quad (13)$$

In the case that there is no bed, ( $y_b = 0$ ), then the initial condition is unknown but the average concentration must still equal  $C_h$ . Thus,  $C(y)$  satisfies (11) and the initial condition is found from

$$\bar{C}(y_b = 0, C_0) = C_h. \quad (14)$$

Evidently, the solution of (11) depends on the closure laws used for the sedimentation velocity,  $\hat{v}_p$ , and for the turbulent particle diffusivity,  $\hat{\epsilon}_p$ .

1) *Sedimentation velocity,  $\hat{v}_p$ :* The sedimentation velocity is assumed to depend on the particle concentration according to Richardson and Zaki's hindered settling law [7]:

$$\hat{v}_p = \hat{v}_{p0}(1 - C)^n, \quad (15)$$

where  $\hat{v}_{p0}$  is the settling velocity of a single particle and  $n$  depends upon the particle Reynolds number,  $Re_p$ . The settling velocity of a single particle could be obtained by a force balance between the gravitational and drag forces:

$$\hat{v}_{p0} = \sqrt{\frac{4\hat{g}(s - 1)\hat{d}_p \sin \beta}{3C_D(Re_p)}}, \quad (16)$$

where  $C_D(Re_p)$  is the drag coefficient:

$$C_D(Re_p) = \begin{cases} \frac{24}{Re_p} & Re_p < 1.4 \\ \frac{A_{CD}}{Re_p^{0.625}} & 1.4 \leq Re_p \leq 500 \\ \frac{A_{CD}}{500^{0.625}} & 500 < Re_p \end{cases} \quad (17)$$

where  $A_{CD} = 24/1.4^{0.375}$ , and

$$Re_p = \frac{\hat{\rho}_l \hat{v}_{p0} \hat{d}_p}{\hat{\mu}_l}. \quad (18)$$

Using the groups  $Re$ ,  $Fr$ , and  $\delta$ , we can solve explicitly for  $\hat{v}_{p0}$ , from which  $Re_p$  is determined.

For very low particle Reynolds numbers, the exponent  $n$  only depends on the diameter ratio  $\delta$ , whereas in the intermediate range of Reynolds number it depends on both  $\delta$  and Reynolds number, and lastly, for high Reynolds numbers it is a constant. These closure expressions can be found in [7]. It is also worth mentioning that the range of  $Re_p > 500$  is unlikely to be attained. The values of  $n$  are between 2.39

for inertia dominated settling and 4.65 for viscous dominated settling, and also it is a strong function of  $Re_p$  specially when  $0.2 \leq Re_p < 500$ , while it is a weak function of  $\delta$ .

2) *Turbulent particle diffusivity,  $\hat{\epsilon}_p$ :* For obtaining the solids diffusivity, we have adopted and modified Eskins model [8], which is based on an expression for the turbulent diffusivity in isotropic turbulence and is characterized by two empirical parameters that have been identified from the experimental data for solids concentration distribution available in the literature. Eskins model only covers a small range of diameter ratio ( $\delta = 3.636e^{-4}$  to  $9.320e^{-3}$ ), and also used the pressure drop model of Turian and Yuan [5] to obtain the pressure drop and the Fanning friction factor along the pipe. Here we have modified the solid diffusivity model taking into account a wider range of diameter ratio including much coarser ones, using the pressure drop obtained by the present model. The modified solids diffusivity correlation is validated against the experimental data for solids concentration distribution and critical velocity in the literature; see [1]. The modified solid diffusivity correlation is as follows.

$$\hat{\epsilon}_p = \alpha \delta^\zeta \left( \frac{\bar{\rho}_h}{\hat{\rho}_h} \frac{dp}{dx} \right)^{\frac{2}{3}} \left( 1 + \frac{\tau_s}{T_l} \right) \hat{D} \hat{U}_s, \quad (19)$$

where  $\bar{\rho}_h$  is the mean slurry density in the heterogeneous layer,  $\hat{\rho}_h$  is the slurry density which is a function of the local concentration,  $\tau_s$  is the particle relaxation time, and  $T_l$  is the Lagrangian time scale for the pipe flow. This model was fitted against the experimental concentration data using least square method and we obtained  $\alpha = 0.81$ , and  $\zeta$  was found to be dependent on the diameter ratio as

$$\zeta = -333.3\delta^2 + 26.37\delta + 1.355. \quad (20)$$

The particle relaxation time can be calculated as

$$\tau_s = \tau_{st} \frac{24}{Re_p C_D} \quad (21)$$

where  $\tau_{st}$  is the Stokesian particle residence time in the flow.

#### D. Closure equations for stresses and forces

In the following subsections we define the various closures we have used for the stresses and forces in each layer. For friction factors we use the Fanning friction factor as opposed to the Darcy-Weisbach friction factor, i.e. the relation between a wall stress  $\hat{\tau}_w$  and the friction factor  $f$  is

$$\hat{\tau}_w = 0.5f\hat{\rho}\hat{U}^2,$$

and typically  $f = 16/Re$  in laminar flow. Explicit friction factor formulas will be defined in the following subsections for each layer.

1) *Heterogeneous layer:* The wall shear stress in the heterogeneous layer is defined by

$$\hat{\tau}_{hw} = 0.5[\hat{\rho}_s C_h + \hat{\rho}_l(1 - C_h)]\hat{U}_h|\hat{U}_h|f(Re_h, 0), \quad (22)$$

where  $Re_h$  is the heterogeneous layer Reynolds number and  $f_{CW}$  is the friction factor, based on the Colebrook-White relation for turbulent flows, as described below.

We base the heterogeneous layer Reynolds number  $Re_h$  on the hydraulic diameter of the layer, on  $\hat{U}_h$ , on the mean density of the slurry and on an effective viscosity. Typically these flows are fully turbulent and the viscosity to use depends therefore on how viscous stresses are conveyed to the wall. In the case that the particles are larger than the viscous sub-layer in the flow, then the fluid effective viscosity is simply  $\hat{\mu}_l$ . In the case that the particle size is comparable to the thickness of the viscous sub-layer, we treat the slurry as a pseudo-fluid, with effective viscosity:

$$\hat{\mu}_s = \hat{\mu}_l[1.0 + 2.5C_h + 10C_h^2 + 0.0019e^{20C_h}], \quad (23)$$

see [9]. Eq. (23) is an extension of the Einstein-Thomas relation to higher concentrations and sand particles.

To estimate the size of the viscous sublayer  $\hat{d}_v$  we use the estimate

$$\hat{d}_v \approx 10 \frac{\hat{D}_h}{Re_h \sqrt{0.5f(Re_h, 0)}}$$

(i.e. the viscous layer is approximately  $10y^+$  in turbulent duct flows). Here  $\hat{D}_h$  is the hydraulic diameter of the heterogeneous layer and  $f$  is the friction factor.

If the particle diameter  $\hat{d}_p$  satisfies  $\hat{d}_p < \hat{d}_v$  we assume (23) to be valid:  $\hat{\mu}_h = \hat{\mu}_s$ . If the particle diameter is significantly larger than  $\hat{d}_v$ , say  $\hat{d}_p > 10\hat{d}_v$ , we assume that  $\hat{\mu}_h = \hat{\mu}_l$ . For intermediate values of  $\hat{d}_p/\hat{d}_v$  we interpolate between the above values. Finally,  $Re_h$  could be obtained using the effective viscosity in the heterogeneous layer,  $\hat{\mu}_h$ . We note that the viscosity ratio  $\hat{\mu}_h/\hat{\mu}_l$  and  $Re_h$  depend on the 6 parameters ( $Re, C_h, s, \delta, y_b, u_h$ ).

The friction factor formula we use is based on the Colebrook-White equation for turbulent flow. The Colebrook-White expression is:

$$\sqrt{1/f} = -2 \log \left( \frac{2.51}{Re \sqrt{f} + \frac{\epsilon_r}{3.71}} \right),$$

which gives a Darcy-Weisbach friction factor  $f(Re, \epsilon_r)$ .

2) *Interfacial stresses:* The interfacial stresses are defined in essentially the same as the heterogeneous layer stresses, except that the velocity differences are used, and a roughness is assumed at each interface to determine the corresponding friction factors.

We assume that the "interface" between the heterogeneous and moving bed layers is rough, with the roughness  $\epsilon_r = \min\{1, \delta/d_h\}$  where  $d_h$  is the dimensionless hydraulic diameter of the heterogeneous layer. We also assume the "surface" between heterogeneous layer and bed to be "rough", with roughness  $\epsilon_r = \min\{1, \delta/d_h\}$ . The interfacial stress is then defined as follows:

$$\begin{aligned} \hat{\tau}_{hm} &= 0.5[\hat{\rho}_s C_h + \hat{\rho}_l(1 - C_h)](\hat{U}_h - \hat{U}_m) \\ &\times |\hat{U}_h - \hat{U}_m|f(Re_h, \min\{1, \delta/d_h\}). \end{aligned} \quad (24)$$

Similarly, for the interface between the moving and stationary bed layers, we assume the roughness  $\epsilon_r = \min\{1, \delta/d_m\}$ , and accordingly, we define the dimensional interface stress as follows.

$$\begin{aligned}\hat{\tau}_{ms} &= 0.5[\hat{\rho}_s C_{max} + \hat{\rho}_l(1 - C_{max})]\hat{U}_m |\hat{U}_m| \\ &\times f(Re_h, \min\{1, \delta/d_m\}),\end{aligned}\quad (25)$$

where  $d_m$  is the dimensionless hydraulic diameter of the moving bed layer. In addition to the defined interfacial stresses in (26), we should consider the solid particle contribution to the friction force on the interface  $S_{ms}$  due to the effect of the submerged weight of the particles in the moving bed layer. In the heterogeneous layer, it is assumed that the weight of the particles is entirely supported by turbulent suspension. In contrast, the submerged weight of the particles in the moving bed layer is supported by the wall and also the interface  $S_{ms}$ . The resulting dry friction force at the interface which is transmitted to the wall as a Coulomb friction term is defined as

$$\hat{F}_{ms} = \eta(\hat{\rho}_s - \hat{\rho}_l)gC_{max}\hat{y}_m S_{ms}^{\wedge}. \quad (26)$$

*3) moving bed layer:* Our treatment of the moving bed layer wall shear stress is similar to that of the heterogeneous layer, which is defined as

$$\begin{aligned}\hat{\tau}_{mw} &= 0.5[\hat{\rho}_s C_{max} + \hat{\rho}_l(1 - C_{max})]\hat{U}_m |\hat{U}_m| \\ &\times f(Re_m, 0).\end{aligned}\quad (27)$$

Where  $Re_m$  is the moving bed layer Reynolds number which could be determined as follows.

$$Re_m = Re d_m |u_m| (1 + (s - 1)C_{max}). \quad (28)$$

As was discussed in §II-D2 the submerged weight of the solid phase is partially transmitted through the bed to the wall as a Coulomb friction term. Thus, the dimensional term of the dry friction force at the wall is defined as follows.

$$\begin{aligned}\hat{F}_{mw} &= 2\eta(\hat{\rho}_s - \hat{\rho}_l)gC_{max}\left(\frac{D}{2}\right)^2 \\ &\times \left\{ [2\frac{(\hat{y}_s + \hat{y}_m)}{D} - 1]\theta_m + \cos(\theta_m + \theta_s) - \cos\theta_s \right\}.\end{aligned}\quad (29)$$

*4) Static bed layer, and transition to two-layer solution:* The existence of a static bed is determined based on the momentum balance equation on the static bed layer. It should be checked whether the sum of driving forces on the static bed layer exceeds the maximal available resistance force on this layer. The driving forces on the static layer are pressure gradient, and the shear at the interface between the moving and static bed layers. The maximal available resistance is the dry friction force acting on the periphery of the static bed which is defined as follows.

$$\begin{aligned}\hat{F}_{mw} &= 2\eta_s(\hat{\rho}_s - \hat{\rho}_l)gC_{max}\left(\frac{D}{2}\right)^2 \\ &\times \left[ \left( \frac{2\hat{y}_s}{\hat{D}} - 1 \right) \left( \theta_s + \frac{\pi}{2} \right) + \cos\theta_s \right].\end{aligned}\quad (30)$$

where  $\eta_s$  is the dry static friction coefficient. if

$$\hat{A}_s \frac{\partial \hat{p}}{\partial \hat{z}} + \hat{F}_{ms} + \hat{S}_{ms}\hat{\tau}_{ms} \leq \hat{F}_{sw}, \quad (31)$$

is satisfied, the static bed layer does not move, and it is indeed "static"; Otherwise, the static bed layer moves and we get a transition from three-layer model solution to the two-layer model solution, where we assume that there is one bed layer in the pipe which is moving. For solving the two-layer problem, we adopt the similar procedure to the three-layer problem. The only difference between the two problems is that in the two-layer model, five equations are numerically handled to get the five unknowns  $\hat{U}_h, \hat{U}_m, \hat{y}_m, C_h, \frac{\partial \hat{p}}{\partial \hat{z}}$ , whereas for three-layer model we deal with six equations to get six unknowns (aforementioned unknowns plus  $\hat{y}_s$ ).

### III. RESULT AND DISCUSSION

An example of reference outputs from the proposed model is given in Figs. 2(a-f). We present results for  $C_v = 0.2, 0.25, 0.3, 0.35$ , over a wide range of mean superficial velocities, for the horizontal pipe diameter of  $D = 0.1m$ . For each example we present the solids phase flux fraction, frictional pressure drop, heterogeneous and moving bed layers velocities, and moving and static bed layers heights. Note that all of the outputs in Figs. 2(a-f) are dimensionless except for the pressure drop result (Fig. 2(f)). As mentioned before, the velocities are scaled with slurry mean superficial velocity  $\hat{U}_s$ , and the lengths are scaled with the pipe diameter  $D$ .

Eq. 11 suggests that the concentration distribution, and the bed height in the pipe depend on the competition between the sedimentation velocity and solid turbulent diffusivity. At low mean superficial velocities, the turbulent eddies are not strong enough to suspend the solid phase; As a result ,a considerable portion of the pipe is covered with bed layers, and we get low mean delivered solids concentration (Figs. 2(a), 2(c), and 2(e)). Also, the height of the static bed is larger than the moving bed (Figs. 2(c) and 2(e)). As a result, the mean heterogeneous layer velocity is at its maximum at low flow rates to satisfy the continuity equation (Fig. 2(b)).

As the mean superficial velocity increases, the turbulent eddies get more capable of suspending the solids; Thus, the mean delivered solids concentration increases as could be observed in Fig. 2(a). Furthermore, the height of moving bed increases as the height of static bed drops(Figs. 2(c) and 2(e)). The total bed height also decreases with increasing the flow rate. From Eq. (8) it is obvious that the mean moving bed velocity  $\hat{U}_m$  monotonically increases with the moving bed height as long as we get a three-layer configuration with a static bed, although Fig. 2(d) could be misleading as it shows the dimensionless mean moving bed velocity  $u_m$  decreases with the flow rate increases.

As the flow rate increases, we reach a point where there is no static bed layer, and the pipe consists of the heterogeneous and the moving bed layers. As was discussed in §II-D4, this is the transition from the three-layer to two-layer model solution, where the mean velocity and the height of the moving bed

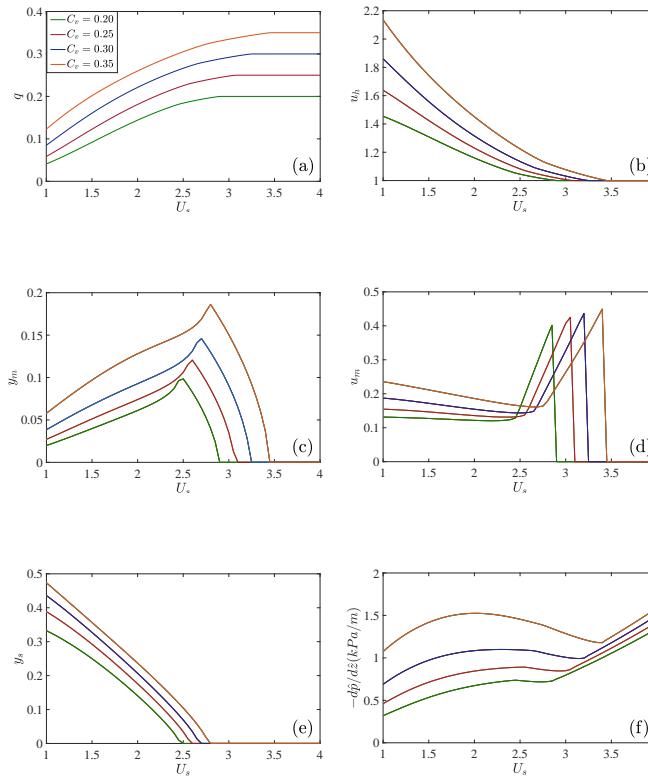

Fig. 2. Example solutions from the proposed steady state three-layer model problem at various  $C_v$ , as a function of  $\hat{U}_s$ , for a sand-water mixture flowing in a horizontal pipe of diameter  $\hat{D} = 0.1\text{m}$ . Fixed parameters are  $C_{max} = 0.55$ ,  $\hat{\rho}_s = 2650\text{kg/m}^3$ ,  $\hat{\rho}_l = 1000\text{kg/m}^3$ ,  $\hat{\mu}_l = 9 \times 10^{-4}\text{Pa.s}$ ,  $\hat{d}_p = 7 \times 10^{-4}\text{m}$ ,  $\eta = 0.5$ , and  $\eta_s = 0.7$ .

layer reach their maximum values. As we further increase the flow rate, the height of moving bed decreases until we reach the deposition velocity where there is no sedimentation bed, and we get a single heterogeneous layer across the pipe, and evidently, the mean delivered solids concentration is equal to the mean spatial solids concentration (Fig. 2(a)). As can be observed in Fig. 2(f), the pressure gradient reaches its minimum value at the deposition velocity. Furthermore, the deposition velocity increases with  $C_v$ . These findings are consistent with the published results of most of the researchers in the field, e.g. [2], [5].

Fig. 3 shows a colormap of solids concentration in the  $(\hat{U}_s, y)$  plane for a constant value of  $C_v = 0.3$ . At low flow rates, the bottom of the pipe is at maximum packing concentration  $C_{max}$  which indicates the existence of the sedimentation bed. Also, we observe that the concentration gradient is very large in the heterogeneous layer at low flow rates. As  $\hat{U}_s$  increases, the total bed height decreases as was discussed before, and the concentration gradient drops as well. At very high velocities, the solids turbulent diffusivity becomes dominant and we get a pseudo-homogeneous slurry flow in the pipe.

#### IV. CONCLUSIONS

A modified three-layer model for solid-liquid flow in horizontal pipes has been developed which predicts the pressure loss, critical velocity, concentration profile in the heterogeneous layer, mean heterogeneous layer and moving bed layer velocities, and bed layer heights for each set of parameters. We have also proposed a new correlation for the turbulent solids diffusivity based on concentration profile and critical velocity comparison against the experimental data available in the literature. The pressure loss vs mean velocity curve shows a characteristic minimum just before the critical velocity is attained, in agreement with published research.

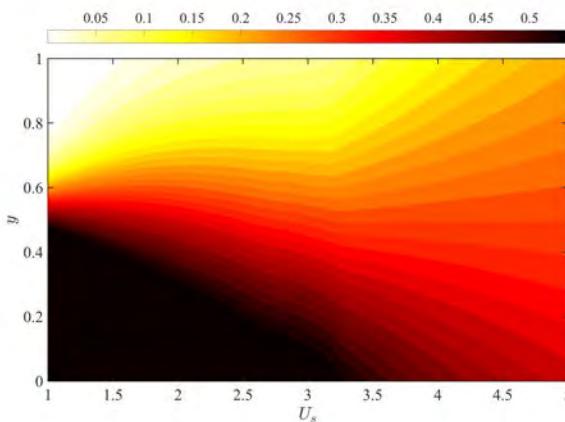

Fig. 3. colormap of concentration in  $(\hat{U}_s, y)$  plane for  $C_v = 0.3$ . Fixed parameters are  $C_{max} = 0.55$ ,  $\hat{\rho}_s = 2650\text{kg/m}^3$ ,  $\hat{\rho}_l = 1000\text{kg/m}^3$ ,  $\hat{\mu}_l = 9 \times 10^{-4}\text{Pa.s}$ ,  $\hat{d}_p = 7 \times 10^{-4}\text{m}$ ,  $\eta = 0.5$ , and  $\eta_s = 0.7$ .

# **Adsorbent-Adsorbate Pairs for Solar Thermal Energy Storage in Residential Heating Applications: A Comparative Study**

Kapil Narwal, R. Kempers, P. G. O'Brien

Lassonde School of Engineering  
York University  
Toronto, Canada

[mr.k.narwal@gmail.com](mailto:mr.k.narwal@gmail.com), [kempers@yorku.ca](mailto:kempers@yorku.ca), [paul.obrien@lassonde.yorku.ca](mailto:paul.obrien@lassonde.yorku.ca)

**Abstract**— This paper investigates the feasibility of using different adsorbent-adsorbate pairs in a thermal energy storage cycle to store solar energy for residential heating applications in Canada. Silica gel, activated carbon, activated aluminum, zeolite-4A, zeolite-5A and zeolite-13X adsorbents paired with methanol and water adsorbates are considered. Calculations are made to determine the volume, mass and cost of the adsorbent-adsorbate pair required to heat a house with four occupants. Zeolite 4A-water and zeolite 13X-water pairs are found to be the most economic (with an actual cost of 285 CAD and 374 CAD, respectively) and efficient (maximum heat of adsorption) adsorbent-adsorbate pairs with the minimum mass required, (290 kg and 226 kg, respectively) to meet the spatial heating requirements of the house.

**Keywords-** Adsorption, adsorption pairs, thermal energy storage

## I. INTRODUCTION

Policy changes incentivizing sustainable energy technologies have provided new opportunities for renewable sources of energy such as solar, wind, tidal and others. Investments in solar energy, which is abundantly available, has increased exponentially in recent years. However, solar energy is intermittent and should be coupled with energy storage technologies to reach its full potential. For example, one promising technology for utilizing solar energy in a Canadian climate is to store it in a thermal battery so it can be used at night to reduce building heating loads. As solar thermal energy storage costs are considerable, various technologies are being explored to optimize its capacity, operating temperature, and overall performance. Heat energy is stored at different temperatures depending on its intended application. Low temperature heat is useful for domestic air-conditioning applications whereas high temperature heat is extremely useful in industry. Furthermore, heat energy can be stored in various forms: sensible heat (solids, liquids, solid-liquid), latent heat

(solid-solid, solid-liquid), chemical heat (reacting solids or liquids, gaseous compounds) and the heat of adsorption or absorption (physisorption, chemisorption, heat of solutions). Sensible heat storage technologies utilize high heat capacity materials, whereas latent heat energy storage technologies absorb/release heat when a material undergoes a phase change from solid to liquid or liquid to gas and vice-versa. On the other hand, chemical heat energy storage technologies utilize reversible thermo-chemical reactions (Rainer et al. 2012) to absorb and release heat. Sorption-based thermal storage technologies can be broadly categorized as absorption and adsorption processes, depending on whether the adsorbate atoms or molecules are dissolved in, or adhered to, the surface of the adsorbent. Advantages of sorption-based thermal energy storage technologies are their minimal costs, and matured performance in heat pumping and solar refrigeration. In this article, adsorption-based thermal energy storage materials are investigated for their potential to store solar energy during the day to provide heat at night in a typical Canadian residential home.

## II. LITERATURE REVIEW

Studies have been conducted to understand thermal energy storage technologies such as electric thermal storage heaters, salt hydrate technology, molten salt technologies and solar energy storage. (Bataineh and Taamneh 2016) conducted a feasibility analysis of both adsorption and absorption systems and concluded that extended adsorption and desorption times, poor exhibitions, and low coefficient of performance (COP) are hindering the widespread commercialization of these technologies. (Papadopoulos et al. 2003) reviewed existing solar energy based sorptive refrigeration technologies for applications in both residential and commercial spaces, and discussed the necessity of implementing energy policies to accelerate the flourishing of solar refrigeration technologies. (Cabeza et al. 2017) presented an exhaustive review on adsorption and absorption technologies in refrigeration and thermal heat storage and discussed research progression

towards developing efficient working pairs with better storage capacities and optimal energy output. (Aliane et al. 2016) studied various solar energy technologies developed for adsorptive cooling. A comparative study of various experimental systems has been done to study the operative behaviors of individual components and whole systems. It was concluded that these technologies can potentially be extended to meet global energy demands by implementing some modest improvements. Further, (Alobaid et al. 2017) reviewed solar absorption cooling systems which were fifty percent more energy efficient than vapor compression based cooling systems. The COP and thermal collector efficiency of the solar-based systems are found to vary from 0.1-0.91 and 0.06-0.64, respectively. It was also noted that solar collector costs comprise a significant portion of the entire system. (Zeyghami et al. 2015) discussed various concepts, designs, and experimental set-ups for thermomechanical solar adsorption systems while discussing performance enhancement approaches. (Goyal et al. 2016) presented the fundamentals of solar energy utilization in adsorption systems and provided a thorough discussion about technological and economic aspects, recognizing that poor heat and mass transfer performances, low COP, and higher costs are the major roadblocks preventing the development of competitive products in this technological field. It has also been observed that hybrid systems, which combine solar adsorption heating and cooling, enhance the system performances significantly. (Askalany et al. 2013) compared various adsorption cooling systems and presented a comparison based on adsorbent-refrigerant pairs on the basis of COP, specific cooling power, driving and evaporation temperatures. It has been observed that the systems employing silica gel-water and chloride composites-water pairs have the highest COP, while those employing zeolite-water pairs have the lowest COP. The lowest evaporation temperatures were found in a system that used metal hydride-water pairs and the lowest driving temperatures were observed for the case of silica-gel-methanol and chloride composites-methanol pairs, whereas the highest driving temperatures are found in zeolite-water pairs.

### III. ADSORPTION

Adsorption involves the adhesion of adsorbate molecules on the adsorbent surface. The adsorbent is usually a porous material with a high surface area. Adsorbate molecules form a thin film on the surface of the adsorbent either by physisorption or chemisorption. Adsorption is referred to as physisorption if the adsorbate molecules are attached on the adsorbent surface by Vander Waals forces, and chemisorption if the adsorbate molecules are chemically attached at the adsorbent surface. Thermal heat storage, therefore, is a physico-chemical phenomenon between the adsorbate and adsorbent molecules while condensation and evaporation facilitate the charging and release of adsorbate molecule onto and from the adsorbent, respectively.

### IV. THERMAL ENERGY STORAGE CYCLE

The thermal energy storage cycle for the application of residential heating in Canada, shown in Figure 1, comprises two main processes: desorption and adsorption.

**Desorption process:** During the day the solar irradiance provides the heat of adsorption required to drive the evaporation of adsorbate molecules from the adsorber. The average daily solar insolation available from November through March in Toronto, Canada is 7.8 MJ/m<sup>2</sup> (October-9.3 MJ/m<sup>2</sup>, November-5.1 MJ/m<sup>2</sup>, December-4.3 MJ/m<sup>2</sup>, January-5.7 MJ/m<sup>2</sup>, February-9.2 MJ/m<sup>2</sup> and March-13.2 MJ/m<sup>2</sup>) [26]. Assuming the average size of a residential building with four occupants is 200 m<sup>2</sup> [27] the net solar radiance available during these cold climatic conditions is 1.56 GJ per day.

**Adsorption process:** During the night adsorbate molecules that have evaporated from the condenser/evaporator are adsorbed by the adsorbent, and the heat of vaporization is released to function as a heat supply for residential heating. The reaction that occurs during the desorption and adsorption processes can be written as follows:

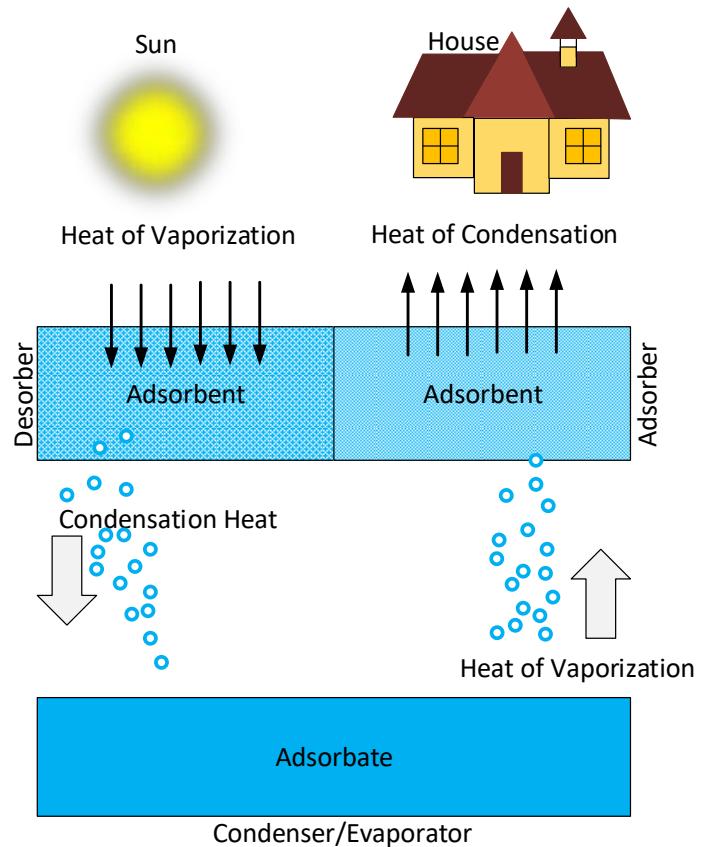

Fig 1. Schematic diagram showing the desorption (left) and adsorption (right) processes in the thermal energy adsorption cycle.

## V. ADSORPTION PAIRS

The adsorbate and adsorbent form an essential component of the thermal energy storage cycle and various factors play a decisive role in selecting the right pair including the maximum adsorption capacity, heat of adsorption, energy capacity, specific heat of adsorbent, adsorbent density, critical pressure and critical temperature. The maximum adsorption capacity is the maximum amount of adsorbate an adsorbent can adsorb. The heat of adsorption is the heat released during the adsorption process, and can be determined by estimating the heat released in a calorimeter experiment or by adsorption isotherms. The energy capacity is the maximum energy an adsorbent can absorb or release. The specific heat of adsorbent is the heat required to raise the temperature of the adsorbent by one degree under constant pressure. At the critical temperature and critical pressure, the density of the adsorbate liquid and vapor is equal.

While many different adsorbates are available for various applications, the most commonly used are water, ammonia, methanol and ethanol. The latent heat of evaporation of water (2258 kJ/kg) is very high compared to that of ammonia (1368 kJ/kg), methanol (1100 kJ/kg) and ethanol (1100 kJ/kg). Thus, water is typically preferred, although other adsorbates can be used to produce sub-zero temperatures. Activated carbons, zeolites, silica gels, metal-organic frameworks, and potassium hydroxide (KOH) are widely used adsorbents as they have a highly porous structure, which increases the adsorption capacity of the system. (Aristov 2007) presented selective water sorbents based on halides, sulphates and nitrates of alkaline and alkaline earth metals possessing an intermediate behavior between solid adsorbents, salt hydrates, and liquid absorbents. Also, an estimation was made on the thermodynamic equilibrium of these materials with water vapors. These sorbents are found to possess a better COP than silica gel-water and zeolite-water based systems. (Aristov 2013) reviewed existing literature on metalaluminophosphates, metal-organic frameworks, ordered porous solids, and porous carbons and composite frameworks. (Gordeeva and Aristov 2012) surveyed composite salts inside porous matrix (CSPM) sorbents. (Bhargav et al. 2017) studied the methanol-activated carbon fiber adsorption pair, and the adsorption capacity and desorption temperature were investigated under isobaric conditions using the Dubinin–Astakhov equation. (Brancato et al. 2015) tested various activated carbon fibers and composites of LiBr on silica gel adsorbents along with ethanol as a refrigerant. A thermo-physical analysis including nitrogen physisorption, specific heat and thermo-gravimetric equilibrium has been performed, and the Dubinin–Astakhov equation has been used to fit the equilibrium data. Furthermore, the thermodynamic performance was estimated by calculating the COP. (Erto et al. 2010) studied trichloroethylene adsorbates precipitated from water-based solutions on a set of 12 different activated carbon adsorbents. Results indicated that the adsorption capacity increases with an increase in Brunauer-Emmett-Teller (BET) surface area, micropore volume, and the percentage of carbon in the

adsorbent. Further, the presence of sodium and tetrachloroethylene also increased the absorption capacity. (Meng and Park 2010) improved the CO<sub>2</sub> adsorption capacity by inserting KOH in graphite nanofibers to increase its porosity under heat treatment at 700-1000°C. The heat treatment temperature had a significant effect on the adsorption capacity and texture of graphite nanofibers, and a positive effect on surface area, total pore volume and micropore volume. (Saha et al. 2011) studied the adsorption of an ethanol-MIL101Cr pair theoretically and experimentally within a 0.1-0.9 bar pressure range and a 30-70°C temperature range. One kg of MIL-101 Cr is found to adsorb up to 1.1 kg of ethanol at 30°C. The Tóth equation has been used to fit experimental data with the goal of enhancing the adsorption capacity in the adsorption cooling cycle employing activated carbon fibers (ACF) as adsorbents. (Saha et al. 2015) studied various adsorbent-refrigerant pairs at a temperature of 77.3K. ACF (A-20), owing to its large surface area, MIL-101Cr was found to have 0.797 kg/kg ethanol adsorption capacity. (Uddin et al. 2014) studied the highly porous Maxsorb III, H<sub>2</sub> and KOH-H<sub>2</sub> surface treated Maxsorb III adsorbents for ethanol adsorption at 30-70°C and evaporation temperatures of 65°C experimentally. The Dubinin-Radushkevich and Dubinin-Astakhov adsorption isotherm models have been used to obtain adsorption isotherms. Adsorption cycle performance studies were conducted using activated carbon-ethanol adsorption pairs. H<sub>2</sub> surface treated Maxsorb III exhibits a COP of 0.51 with a specific cooling effect of 374 kJ/kg at evaporation, heat source, and heat sink temperatures of -5°C, 100°C and 30°C, respectively. (Zeng et al. 2017) studied the ammonia adsorption on four different kinds of activated carbons at 30°C. MSC30 is found to possess a very high adsorption capacity for ammonia. A modified Dubinin-Astakhov equation has been used for isothermal studies. (Dawoud et al. 2007) experimentally studied an adsorption system using a zeolite 13X-water adsorption pair. It was observed that an increase in the flow rates of the adsorber and desorber increase the heat discharge, while higher temperatures occurred at lower flow rates. A radiation shield is found to be effective in minimizing radiation losses during the adsorption process. (Ansari et al. 2014) prepared nano-NaX zeolite using a hydrothermal process. The size and crystallinity of the NaX zeolites is found to increase up to 44 nm and 96%, respectively, as the reaction time was increased from 1h to 4h and the reaction temperature increased from 90°C to 110°C. (Tatler and Erdem-Şenatalar 2004) evaluated the effective diffusion coefficient of water in zeolite-4A coatings. It is observed that the evaluated results qualify the thermogravimetric analysis (TGA) and effective medium theory (EMT) based experimental results from the literature. (Solmuş et al. 2011) developed a zeolite-water pair based adsorption cooling system and investigated its performance at various evaporator temperatures. The COP of the system was about 0.25 at adsorption, desorption, and condenser temperatures of 45°C, 150°C, and 30°C, respectively, for evaporative temperatures ranging from 10°C to 22.5°C. The mean volumetric specific cooling power density and the mean

mass specific cooling power density were found to be 4.8 kW/m<sup>3</sup> and 6.4 W/kg, respectively. (Solmuş et al. 2010) used the Dubinin-Astakhov equation to determine a maximum adsorption capacity of 0.12 kg<sub>w</sub>/kg<sub>ad</sub> for a natural zeolite. Furthermore, the isosteric heat was calculated and a correlation between adsorption and desorption processes was established.

## VI. DISCUSSION

Herein, different adsorbate-adsorbent pairs are investigated for their ability to store solar energy during the day to provide heating for a typical residential home in Canada. The average size of a residence with four occupants is around 200 m<sup>2</sup> [26]

with the overall energy requirements of 130 GJ yearly, or 0.36 GJ daily, by Statistics Canada [27], and it is assumed that 63% of this energy is used for spatial heating [28]. Thus, it is assumed that 0.23 GJ is required for spatial heating, which is much less than the average solar irradiance (1.6 GJ) estimated to be incident on a residential home in Toronto over the months from November to March (Table III).

Different adsorbate-adsorbent pairs comprising seven adsorbents (charcoal, silica gel, activated alumina, zeolite-4A, -5A, -13X, and activated carbon) with water and methanol as

TABLE I. THERMOCHEMICAL PROPERTIES OF ADSORBENT-ADSORBATE PAIRS (RAINER ET AL. 2012)

Material	Adsorbate	Max. adsorbate capacity	Heat of adsorption (average)	Adsorbent specific heat	Net heat of adsorption	Net Heat of adsorption per unit volume of adsorbent	Volume of Adsorbent required for residential heating	Net adsorbent required	Amount of Adsorbate required	Total mass of system

properties of adsorbate-adsorbent pairs are listed in Table I. The adsorbate capacity (figure 3) for the adsorbents considered herein varies from 0.16-0.37 kg<sub>w</sub>/kg<sub>adsorbent</sub>, with the silica gel-water having the maximum followed by active-carbon at 0.32 kg<sub>w</sub>/kg<sub>adsorbent</sub> and zeolite-13X at 0.3 kg<sub>w</sub>/kg<sub>adsorbent</sub> whereas the heat of adsorption (figure 4) of zeolite is the largest with a value of 1400-4410 kJ/kg<sub>w</sub>. Here the zeolite 4A-water and zeolite 13X-water pairs show high potential with energy capacities of 970 and 1320 kJ/kg<sub>adsorbent</sub>, respectively, which is the largest amongst all pairs considered. Thermodynamic properties viz. molecular weight, critical temperature, critical pressure, density and specific heat of some selective adsorbates for adsorption based cooling and heating are given in Table II. Further, Table I shows the net heat of adsorption (figure 8) per mass of adsorbent is the largest for zeolite 4A-water and zeolite 13X-

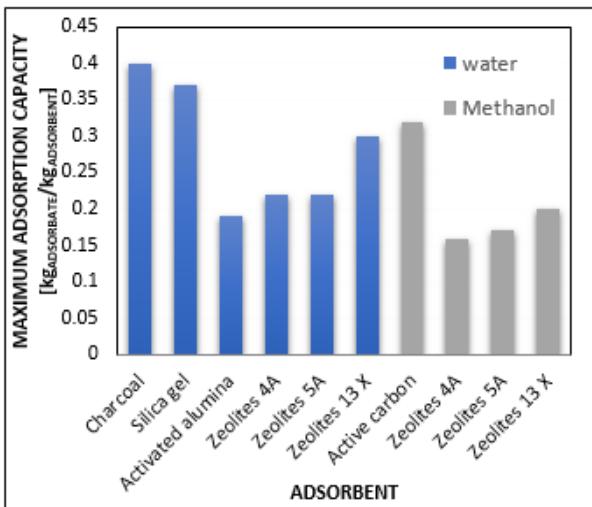

Fig 2. Maximum adsorption capacity of various adsorbents

TABLE III. AVERAGE ENERGY REQUIREMENTS OF A HOUSE OF FOUR IN CANADA [SOURCE: STATISTICS CANADA]

For a house of 4 occupants with an area 206.4 m <sup>2</sup>	GJ
Average energy requirement yearly	130
Average energy requirement per Day	0.36
Average energy requirement for spatial heating per Day	0.23
Average solar energy available per day in Toronto (November-March)	1.56

water with values of 970 and 1323 kJ/kg<sub>adsorbent</sub>, respectively. The total volume of adsorbent required to provide heating for a residential building with four occupants in Canada using a zeolite 4A-water pair is 0.30 m<sup>3</sup>, while the volume would be 0.29 m<sup>3</sup> if a zeolite 13X-water pair were to be used. If a zeolite

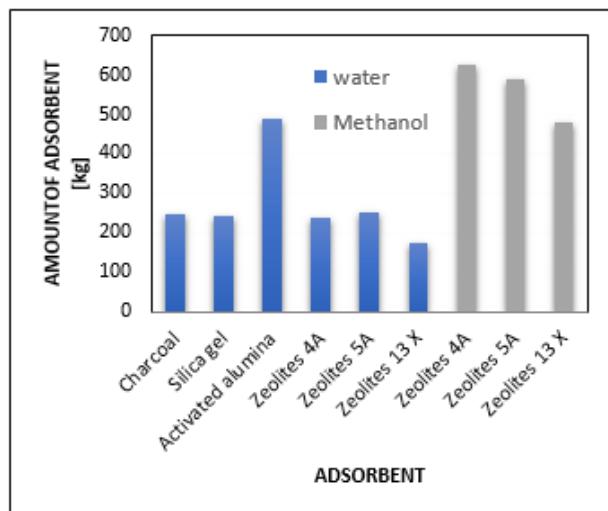

Fig 4. Amount of adsorbents needed to meet the energy requirements for a house with four occupants in Canada

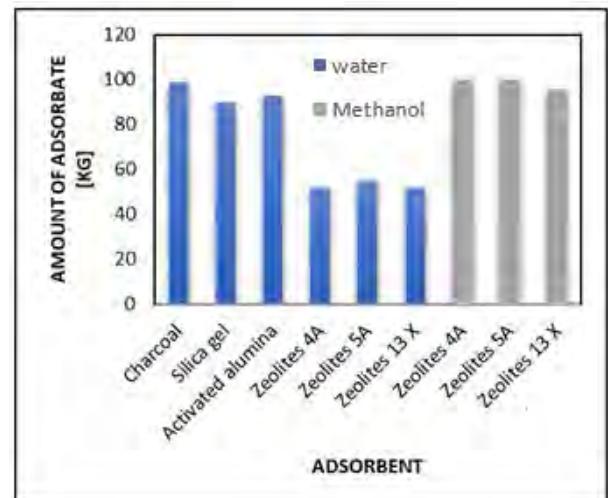

Fig 5. Amount of adsorbate needed to meet the energy requirements for a house with four occupants in Canada

5A-methanol pair were used as the adsorbent/adsorbate then the required volume would increase significantly to 0.87 m<sup>3</sup>. Also, zeolite 4A-water and zeolite 13X-water pairs have the minimum mass of adsorbent (figure 5) and adsorbate (figure 6) required. The total mass of the adsorption system including both adsorbent and adsorbate needed to meet the energy requirement of the house under consideration for zeolite 4A-water and zeolite 13X-water is 290 kg and 226 kg, respectively. Now, if the adsorbent-absorbent pair is situated inside flat rectangular panels that are 1.7 m long, 1 m wide and 3 cm thick, it would take only 6 panels of zeolite 4A-water and 6 panels of zeolite 13X-water pairs to meet the spatial heating requirements. The total cost of the adsorbents in discussion is shown in Figure 9 and the cost of zeolite 4A and zeolite 13X adsorbents required to meet the energy for the house under consideration is 285 CAD and 375 CAD,

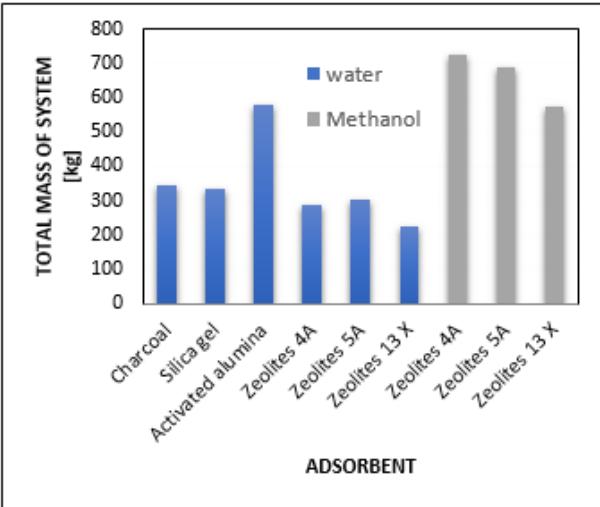

Fig 6. Total mass of the system (adsorbent and adsorbate) needed to meet the energy requirements for a house with four occupants in Canada

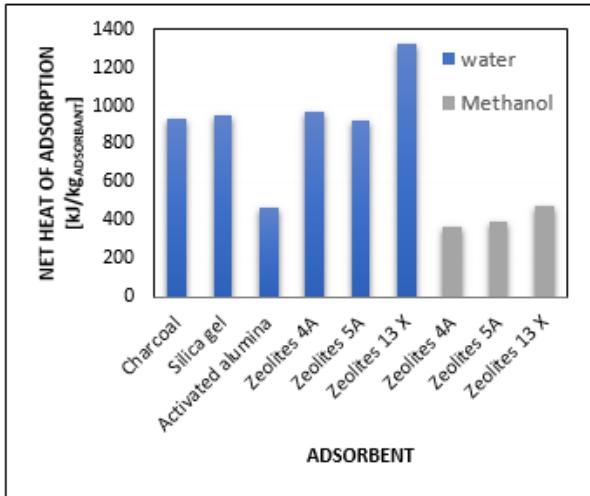

Fig 7. Net Heat of adsorption of various adsorbents

In comparison, an average of about 6.2 m<sup>3</sup> [29] of natural gas per day is required to meet the spatial heating requirements for the residence under consideration, and the daily cost of using natural gas for spatial heating would be about 0.6 CAD. Further, assuming a carbon tax of 1 CAD per GJ [31] of energy produced, this cost would rise from 0.6 CAD to 0.85 CAD daily (~19 CAD monthly). Thus, the owner of the residence under consideration would be able to save ~155 CAD on their natural gas heating bill over the colder seasons of the year by using adsorptive technology to heat their home. Perhaps more importantly, considering CO<sub>2</sub> emissions, 1 GJ of energy generation from natural gas emits approximately 56 kg of CO<sub>2</sub> [30]. For the residence with four occupants and a daily energy requirement of 0.23 GJ, ~13 kg of CO<sub>2</sub> is emitted daily to provide for heating. Thus, about 2.4 tonnes of CO<sub>2</sub> emissions could potentially be prevented by heating a typical

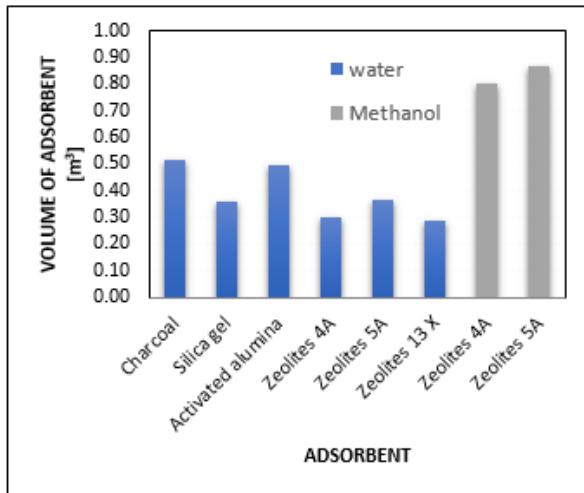

Fig 8. Volume of adsorbents needed to meet the energy requirements for a house with four occupants in Canada

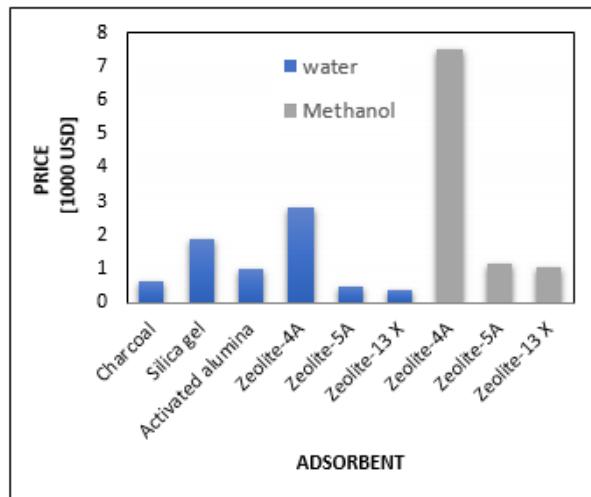

Fig 9. Costs of various adsorbents

Canadian residence using a thermal energy storage cycle based on adsorbate-adsorbent pairs instead of using natural gas. As CO<sub>2</sub> emissions per capita in Ontario are ~15 tonnes, further research and development of sorption-based thermal energy storage cycles that store solar energy for residential heating applications is warranted.

## VII. CONCLUSION

Various adsorbent-adsorbate pairs have been investigated as the working pair in a thermal energy adsorption cycle that provides the energy required to heat a residence with four occupants in Canada. Amongst all pairs considered, the zeolite 4A-water and zeolite 13X-water pairs have the maximum heat of adsorption and the minimum mass (290 kg and 226 kg, respectively) required to meet the heating demands. The net volume of zeolite 4A and zeolite 13X required to meet the spatial heating requirements of the residence is 0.29 m<sup>2</sup> and

0.30 m<sup>2</sup>, respectively. The cost of zeolite 4A and zeolite 13X adsorbents for meeting the heating energy requirements of the residence is 285 CAD and 374 CAD, respectively. Thus, zeolite 4A-water and zeolite 13X-water pairs can potentially be used in a thermal energy adsorption cycle that stores solar energy so it can be used to provide heating for a residential home in Canada and further research in this area is warranted.

**Abstract**— The present experimental research investigates transient thermal performance of a PCM-based thermal management system for cooling electronics components. The proposed system consists of a heatsink that is submerged into Rubitherm (RT-18) for melting experiments. The heat sink has a total length of 10cm, a width of 5cm and a height of 13cm. The heat sink contains 4 vertical copper heat pipes and 34 horizontal aluminum fins. The proposed system is insulated from all sides except the front wall for periodic visualization pictures, and it is exposed to a constant heat flux boundary condition from the top with a 1-inch<sup>2</sup> Omega heat flux heater with a wattage density of 10 W/in<sup>2</sup> at 100V. The PCM is heated from 0°C to about 51°C. The visualization results as well as the temperature distribution are discussed. Primarily, the results show that the melting process of the PCM manages the temperature of the heatsink and the base at which the heater is attached due to the high heat storage capacity of the PCM.

**Keywords** *latent heat thermal energy storage system; PCM, electronics thermal management; rectangular cavity; experimental measurement.*

## I. INTRODUCTION

Sensible heat Thermal Energy Storage (TES) systems are not as efficient as latent heat TES systems for extensive thermal discharge or high climate temperatures [1]. There are many advantages of incorporating PCM in TES systems. PCM-based TES systems can store energy for various periods of time (e.g., from minutes to seasons), which diversifies its applicability and scalability. PCM-based TES systems are used in many applications such as solar engineering, building energy consumption, greenhouse thermal control, food protection, occupant thermal comfort systems, and aircrafts thermal management. Latent heat storage is an efficient way of storing thermal energy for most applications since it can store high amount of energy at nearly constant temperature. Thus, PCM-based TES technologies have been used in electronics and electrical applications for thermal management. Electrical and electronics applications produce a massive amount of heat that minimizes the operation duration and the efficiency of the overall system. PCMs can maintain the optimal operation temperature limits of such delicate systems. However, such

applications require PCMs with high thermal conductivity for more responsive thermal management. Unfortunately, PCMs have low thermal conductivities. In the literature, various methods have been utilized to increase the thermal conductivities of PCMs.

In automobile industry, for instance, a significant amount of carbon dioxide (CO<sub>2</sub>) and other greenhouse gas emissions are produced by traditional transportation vehicles (by means of fossil fuel combustion process). Therefore, researchers have been investigating on how to overcome the major limitations and to grow the potential of electric vehicles in the automobile market. The electric energy storage system (electric battery) is a substantial component of an electric vehicle. Electric batteries necessitate an appropriate thermal management for more effective operation and longer life span at different operation conditions. The common key challenges with these electrical batteries are the small range of their optimal operational temperature, the intensive undesired power consumption associated with their excessive heat generation, the practicality in different climate conditions. Luckily, PCM-based thermal management technology addresses all these issues.

For instance, an improvement of 50% of an electric battery life span was accomplished for a small electric vehicle by combining TES technology and wax as a PCM with an electric scooter bike [2]. The wax was incorporated with graphite to enhance the thermal conductivity of the wax by up to 70 Wm-1K-1. This graphite-wax-based-TES system significantly increased the maximum driving distance of the small electric vehicle from 30Km to 55Km [2]. Moreover, Wang et al. performed an experimental study on electric automobiles battery safety and thermal management using heat pipes. Two battery cells producing 2.5-40W of heat have been built and tested by a thermal camera at off-normal conditions. It was found that incorporating heat pipes helped to maintain the temperature below 40°C when the battery generates a maximum of 10W/cell; when the battery cell generates 20–40 W/cell (uncommon thermal abuse), the proposed system could decrease the temperature of the battery to 70°C [3].

Heat generation in a great deal of engineering applications is nonuniform with time. This unstable behavior of heat generation is associated with undesired spikes of temperature

increase [4]. The sudden increase of temperature could damage or decrease the efficiency of the electrical circuits. Thermal management systems that absorb the undesired heat by means of sensible and latent heat can maintain a nearly constant desired temperature. Number of researchers have investigated the improvements of thermal management performance considering many thermal enhancement methods. Hosseini zadeh et al. [5] conducted a numerical and experimental study on the performance of PCM incorporated with different configurations of fins for thermal management applications. This study considers different number, height, and thickness of fins at different power intensity. The outcomes show that the higher the number of fins and the higher the height of fins, the higher the overall thermal performance. However, increasing the fins thickness does not increase the overall thermal performance as significantly. Furthermore, Peleg et al. [6] conducted a numerical study to optimize the geometry, quantity the number of internal fins, and to optimize the amount of PCM for thermal management of electronics. The results show that at fewer fins, the temperature range increases, which decreases the PCM quantity to keep the electronics at operation temperature range. Rajesh, and Balaji [7] carried out an experimental study on the performance of PCM based thermal management storage systems using several numbers of pin fins (0, 33, 27, and 120 pin fins) for two different PCMs (n-eicosane and paraffin wax). The authors also performed an Artificial Neural Network and Genetic Algorithm optimization techniques to extend the operation time of the system to reach the set point and increase the thermal performance. The results show an improvement factor of 24 was achieved by using 72 pin fins combined with n-eicosane. Li-Wu et al. [8] experimentally investigated the thermal performance of heatsink combined with high aspect-ratio carbon nanofillers at different loads. The results show that for heating cases, the use of high aspect-ratio carbon nanofillers is less effective in removing heat due to the weak natural convection to the environment. Thus, the authors have combined carbon nanotubes and graphene nanoplatelets, which increases the thermal recovery due to their high thermal conductivity. Yoram et al. [4] studied a combination of PCM and heat sink experimentally and numerically. The prototype is meant to absorb the undesired heat by the PCM (eicosane  $C_20H_{42}$ ) and to reject the heat to the surroundings by aluminum heat sinks with a fan. A two-dimensional thermal model was developed and analyzed for estimation of thermal field. The experimental and numerical results of the base temperature and PCM melting behavior have some agreement. It was observed that as the heat input increases, the sensible-heat-based accumulation rate increases. Fok et al. [9] targeted cooling gadgets with power input of 3 to 5W using PCM (neicosane) with and without fins. In this experimental study, the considered variables are the device orientation (vertical, horizontal, and 45° incline), power input level (3-5W), number of fins (3, 6 fins), and the usage intensity (light to heavy). The main objective of this study is to investigate the thermal performance of small handheld devices when cooled using PCM with and without fins. It has been

observed that cooling mobile devices using PCM with fins is feasible; however, an optimization on the device is required considering the amount of PCM used and all previously mentioned parameters.

In this experimental study, a PCM-based thermal management system is examined. The thermal management system contains of a heatsink with 34 horizontal aluminum fins integrated with 4 vertical copper heat pipes to increase the thermal conductivity of RT-18 PCM in a rectangular shaped cavity for electrical and electronics applications. The prototype is examined under transient thermal condition on the top side with maximum power input. All other walls of the enclosure are thermally insulated. This study investigates the thermal performance by means of visualization and the temperature distribution of the PCM during melting.

## II. METHODOLOGY

### A. Components Details and Description

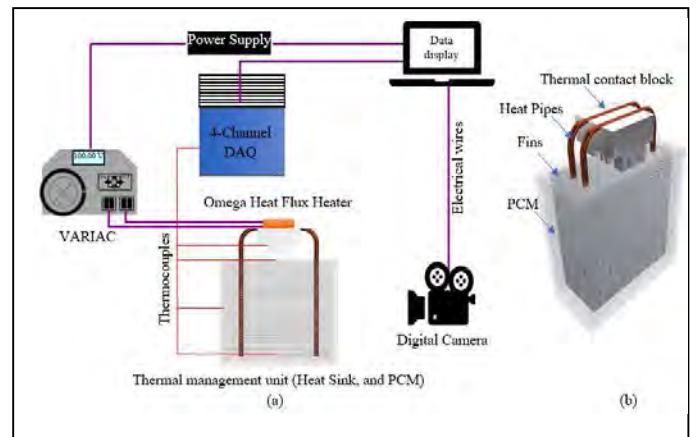

Figure 1: Schematic diagram of the (a) experimental setup and (b) components of thermal management system.

The components of the experimental setup are presented in Figure 1, (a), while Figure 1, (b) shows the components of thermal management system. The main components used in this experiment are: a variac, a DAQ system, an Omega flexible heater, a thermal management unit (heat sink, and PCM), 4 K-type thermocouples, a computer with LabVIEW software installed, and a digital camera. The variac feeds the omega heater with a series of different voltages that vary from 0-100V. 4 thermocouples are instrumented in the thermal management system at four locations (heat source, top fin, bottom fin, and PCM). The thermocouples are measuring the temperature across the heat sink using a DAQ system (NI USB-9162) from National Instruments. The LabVIEW software monitors and saves the thermocouples readings. The Omega heater (SRFG-101/10) is 1-inch<sup>2</sup> with a wattage density of 10 W/in<sup>2</sup>. The maximum operating temperature of the heater is 232°C, and the maximum rated voltage is 115VAC. The heater is in a direct contact with the heatsink from the top base as illustrated in Figure 1, (a). The heat sink has a total length of 10cm, a width of 5cm and a height of

13cm. The heat sink contains four vertical copper heat pipes and 34 horizontal aluminum fins. The heat sink is submerged into a phase change material to assist the heat sink to dissipate heat coming from the electronic component (Omega heater). Therefore, this helps to maintain the operational average temperature for the electronic component. Rubitherm (RT-18) whose melting point ranges from 17-19°C was selected as thermal storage medium. The heat storage capacity of RT-18 is 250 kJ/kg, and the maximum operation temperature is 48°C. The container is made of a clear acrylic with a thickness of 0.24-inch. The outer shell of the container is insulated by 1-inch thick Styrofoam. A high definition Canon camera "EOS Rebel T2i" is used to capture the images periodically during the melting process. The laptop monitor is used to display and save visualization pictures and the thermocouples readings.

### B. Experimental Procedure

The experimental setup of the electronics thermal management system is presented in Figure 2. Initially, the thermal management system is placed in a refrigerator at about (0°C) for 24 hours to ensure a uniform temperature across the PCM at a solid state. Then, the thermal management system is connected to the DAQ system and the heater is connected to the variac power supply. The digital camera starts taking pictures, and the LabVIEW software starts running to take the readings. The variac is turned on immediately at maximum voltage to feed omega heater with (100V). Once the PCM is in a liquid form, the experiment is done.

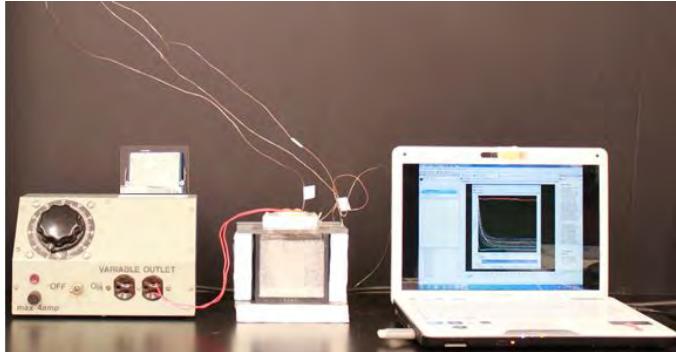

Figure 2: Experimental setup of the electronics thermal management system.

## III. RESULTS AND DISCUSSION

### A. Experimental Temperature Distribution Analysis

Figure 3 presents the experimental temperature profile in the thermal management system at 100V. The initial temperature of the PCM is 0°C. The thermal management system is insulated from all sides except the front wall for visualization. The PCM was heated up to 34.7°C. Four thermocouples are measuring temperatures at four locations in the thermal management system (heat spreader, top fin, bottom fin, and PCM). As can be seen from Figure 3 that once the heater is tuned on, most of the heat is absorbed by the aluminum heat spreader and top fin since they are close the

heat source. It also can be seen from Figure 3 that once the heater is tuned on, the temperature of top fin increases rapidly from 0°C to 18°C by means of sensible heating. Then, the temperature of the top fin remains almost constant at the melting point temperature while the PCM was melting at the top. Once the melting of PCM is done at the top, the temperature of PCM increases due to sensible heating supplied by the heater. Note that temperature of PCM at the top and the heat source remains the same throughout the melting process. Further, it can be observed that the temperature of bottom fin increases less rapidly from 0°C to 15°C by means of sensible heating. The PCM temperature profile follows the same trend to that of the bottom fin. The melting of PCM occurs around 15°C and this is the reason the bottom fin and the PCM temperature remain nearly 15°C during the melting. The temperature of the PCM and the bottom fin increases due to sensible heating once melting of PCM is finished. Due to high thermal energy storage and low thermal conductivity of PCM, the temperature of PCM remains constant around melting point temperature for a longer period compared to bottom fin.

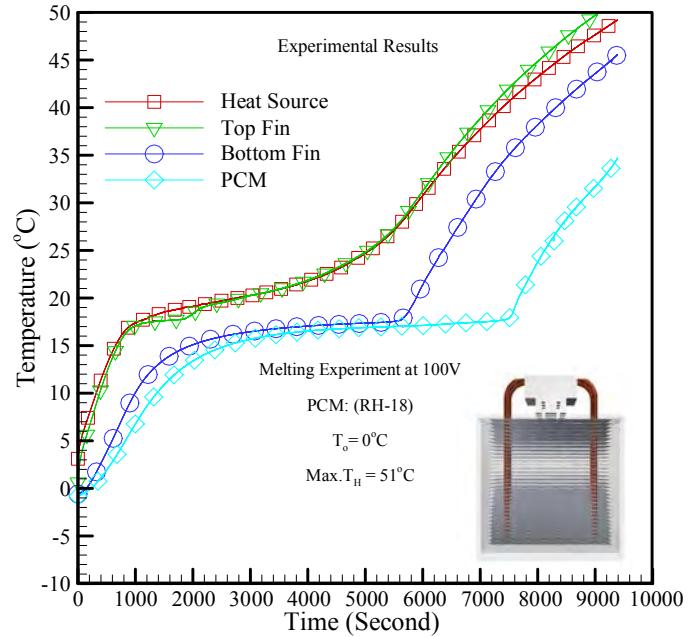

Figure 3: Temperature profile at different locations in the thermal management system at 100V.

### B. Experimental Visualization Results

Since the heater is in direct contact with the top base of heat sink, the heat sink will absorb the heat through the base. Then, the heat will dissipate through the heat pipes and then to the fins. Therefore, the solid PCM starts absorbing the heat across the heatsink by conduction in a sensible form, as shown in Figure 4 (at time=0-16 minutes). The initial sensible heat storage takes about 1000 seconds (16 minutes). This sensible heat transfer keeps going until the PCM temperature reaches 17-19°C causing the PCM to start melting down, as shown in Figure 4 (at time=25 minutes). The melting starts from the right and left sides of the thermal storage system due to the vertical heat pipes that are transferring the heat from the top

base. The melting process (latent heat storage process) takes about 4750 seconds (79 minutes) at nearly constant range of temperature (17-19°C). During the melting process, heat will transfer to the liquid PCM by convection in a latent form until all PCM become liquid. As the temperature increases above 19°C, the heat will transfer by convection in a sensible form to the liquid PCM, as shown in Figure 4 (at time=126 minutes). This entire process helps to maintain the temperature of the attached electronic component at a desired temperature range.

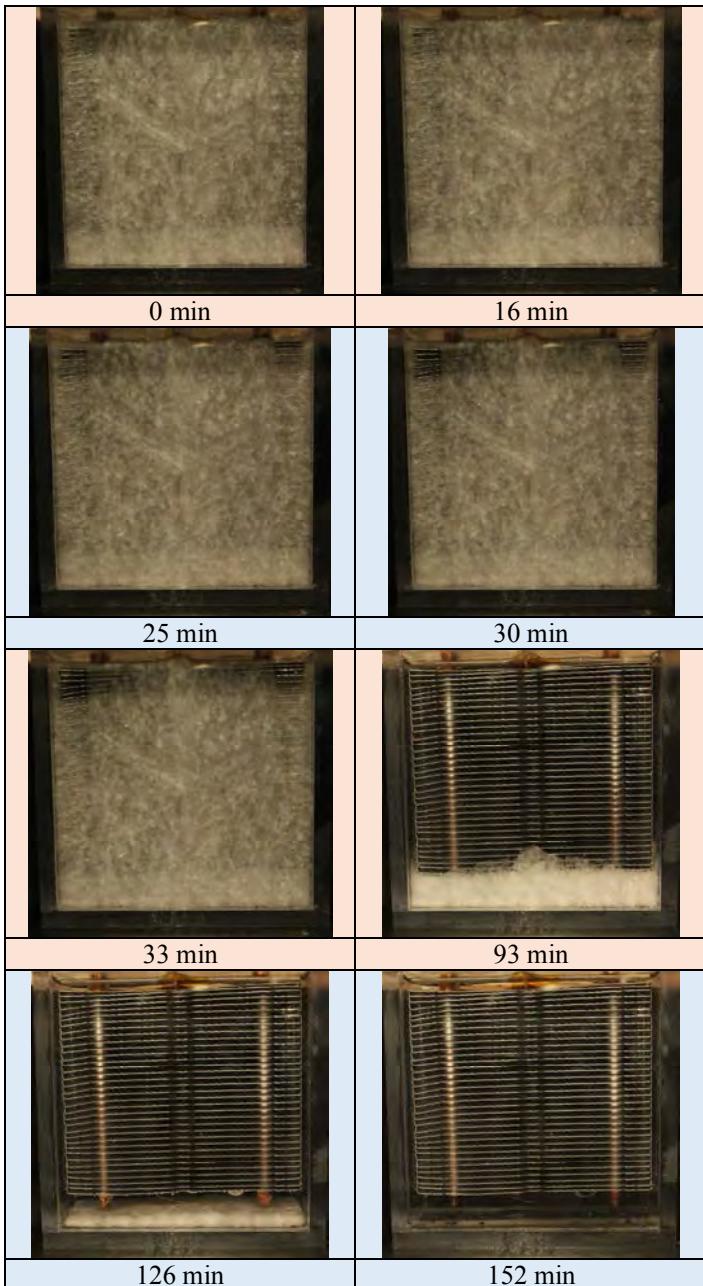

Figure 4: Visualization pictures of the PCM melting process in the thermal management system.

#### IV. CONCLUSION

In this research, an experimental investigation has been carried out to examine the thermal performance of a PCM-based thermal management system for cooling of electrical and electronics components. The thermal management system consists of a heat sink that is submerged into Rubitherm (RT-18) to assist the heat sink to dissipate the heat coming from the electronic component. The heat sink contains 34 horizontal aluminum fins and 4 vertical copper heat pipes. The thermal management system is insulated from all sides except the front wall for capturing periodic visualization pictures; the thermal management system is tested under a transient condition by a 1-inch<sup>2</sup> Omega heat flux heater. The PCM was heated from 0°C to about 51°C. To assess and analyze the performance of the cooling system, the camera records the visualization of the melting process of PCM, while the DAQ system records the temperature profile in different locations of the thermal energy storage system. The visualization results as well as the temperature profile are discussed. Mainly, the results show that the melting process of the PCM manages the temperature of the heat spreader of the heatsink, at which, the heater is attached. This thermal control is associated with the high heat storage capacity of the PCM.

# Investigation of Latent Heat Thermal Energy Storage System for Air-Conditioning Applications

Muath A. Alomair\*, Yazeed A. Alomair,  
School of Engineering, University of Guelph  
Guelph, Ontario, Canada  
\*e-mail: [alomairm@uoguelph.ca](mailto:alomairm@uoguelph.ca)

**Abstract**— Around 40% of the total energy in USA is consumed by buildings, and about \$370 billion US dollar is spent each year to supply this energy and thus reduction in energy consumption is extremely important. One of the most effective and reliable ways to reduce energy consumption is the use of Phase Change Materials (PCMs) in Latent Heat Thermal Energy Storage (LHTES) systems. In this study an experimental setup was constructed to investigate the solidification process of PCM using two different types of heat exchangers: pipe heat exchanger and horizontal finned-pipe heat exchanger. The PCM used in this study is Rubitherm (RT-18) that has a melting point of 18°C, and the heat transfer fluid (HTF) is water. To investigate the performance of pipe heat exchanger versus finned-pipe heat exchanger, two experiments were performed under identical initial, thermal and boundary conditions. The PCM is cooled down from 20°C to 5°C in both heat exchangers. Result of the temperature distribution as a function of time during the solidification process inside the TES system is presented and investigated. Visualization of the solidification process inside the TES system is also presented. Generally, the PCM is solid when its temperature is lower than the melting point, and it is liquid when its temperature is higher. PCM stores thermal energy during melting and releases heat as it solidifies. Both visualization and periodic temperature distribution results showed that as time progresses, the amount of the solid PCM increases in both heat exchangers. At a certain time, finned-pipe heat exchanger has higher amount of the solid PCM than the pipe heat exchanger. Also, the solidification time is reduced significantly when fins are added to the TES system. After 75,000 seconds of solidification, the average PCM temperature of pipe heat exchanger reached to 8.5°C. Whereas, the average PCM temperature of the finned-pipe heat exchanger reached to 8.5°C after 19,000 seconds of solidification. Significant time reduction equivalent to 54,000 seconds is observed when the fins are added to the TES system. Employment of fin is preferred to improve heat transfer rate as the solidification process is enhanced due to the incorporation of fin.

## I. INTRODUCTION

Buildings use approximately 40% of the total energy consumed in USA followed by industry and transportation [1]. Approximately \$370 billion US dollar is spent each year to supply this energy and thus reduction in energy consumption is extremely important [2]. One of the most efficient and reliable ways to reduce energy consumption is the use of PCMs in LHTES system [3]. Solid-liquid PCM have long been adopted as a thermal energy storage medium in LHTES system. Typically, a LHTES system consists of: (a) a PCM, (b) a container and (c) a thermal conductive surface for exchanging heat with the PCM [4, 5], a heat exchanger. In a typical LHTES system, a large amount of thermal energy is absorbed or released by the PCM during its nearly constant temperature phase change processes.

PCMs can be classified into (i) non-organic compounds (e.g., salt hydrate, metals, alloys) and (ii) organic compounds (e.g., wax). Organic PCMs can be further divided into (i) paraffinic PCMs (e.g., wax) and (ii) non-paraffinic PCMs (e.g., fatty acid). Paraffinic PCMs have extensively been used in LHTES system design because of their high latent heat of fusion, wide range of phase change temperatures, and good chemical stability [6]. Another advantage of paraffinic PCMs is that they have unlimited numbers of cycles [7]. However, PCMs have low thermal conductivity which results in reduction of the rate of melting and solidification of the PCMs [3]. Therefore, there are several ways to increase the performance of PCMs, such as using fins [8].

Bechiri and Mansouri [9] analyzed charging and discharging paraffin PCM in a shell and tube heat exchanger analytically. Anisur et al. [10] performed a 2-D analysis on a double wall circular tube heat exchanger with paraffin PCM for air cooling application. Heat Transfer Fluid (HTF) flow, pipes sizes and different radius of the PCM container were investigated analytically. Air was used as HTF, and the

highest co-efficient of performance (COP) of the system was calculated to be 8.79.

Anisur et al. [11] analytically and experimentally studied melting of PCM in a shell and tube heat exchanger for air cooling applications. They used Heptadecane PCM which had a melting point temperature of 22.33°C. The analytical result was validated with the experimental result, and the COP of the system was calculated to be 4.16. Nithyanandam and Pitchumani [12] performed a numerical analysis on charging and discharging of PCM in finned heat pipes for concentrated solar power applications. The authors observed an enhancement of heat transfer by adding vertical fins, the larger the number of fins, the higher the heat transfer. Liu et al. [13] investigated melting characteristics of Paraffin PCM surrounding heat pipes. They found that when the inlet temperature of the heat pipe is increased, the total heat storage capacity and heat storage rates are increased. Also, the total heat storage capacity and heat storage rates are increased with decreasing the initial temperature of heat storage material. Khalifa et al. [14] performed an experimental and numerical study on PCM solidification around tube integrated with vertical fins versus a bare tube for solar thermal power generation application. Their findings illustrated that heat transfer performance was improved 24% compared to a bare tube.

Khalifa et al. [15] performed an experimental investigation on solidification of a high temperature PCM in a finned heat pipe duct. A significant improvement in the heat transfer rate was observed for the finned heat pipe case especially during later times of the solidification process. Li et al. [16] experimentally studied the melting and solidification of PCM in a flat heat exchanger with heat pipes. The system's performance showed a uniform temperature across the heat exchanger and an increase in the heat transfer inside the PCM. Rahimi et al. [8] performed an experimental analysis on melting and solidification of PCM inside a thermal energy storage system using copper pipes and aluminum fins. They found that when the aluminum fins were added to their system, the heat transfer in the PCM was increased. Other studies [17, 18] experimentally investigated melting performance of PCMs by using heat pipes. They studied the performance of their systems with increasing the heat pipe numbers and increasing the power input of the heat pipes. An enhancement of heat transfer was observed with increase in the numbers of heat pipes and input power of heat pipes.

Based on the literature review above, there is a lack of experimental studies that examined the effect of solidification (heat discharging) of PCMs with copper fins. The aim of this study is to compare the performance of a tube heat exchanger and finned-tube heat exchanger experimentally. RT-18 Rubitherm is used as PCM, and water is used as a heat transfer fluid (HTF). To compare the performance, transient temperatures are measured at different locations and visualization of the solidification process is performed. This information will enable us to assess the performance of heat exchanger with fins and help to understand the

fundamental of liquid-solid phase transition and heat transfer during solidification of PCM.

## II. EXPERIMENTAL SETUP AND PROCEDURES

### A. Description of experimental set-up

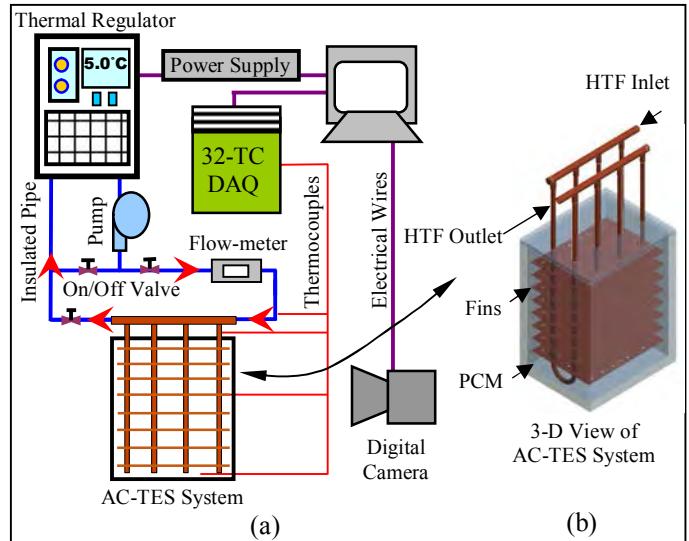

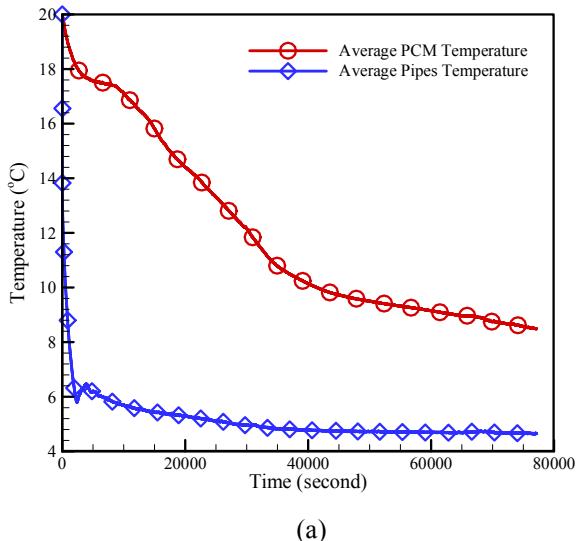

Figure 1: Schematic diagram of the (a) experimental setup and (b) components of thermal energy storage system (TES).

An experimental set-up was designed and built in order to visualize and investigate the solidification process of the PCM in LHTES system. Figure 1(a) shows a schematic diagram of the experimental set-up, and figure 1(b) shows the finned TES system. The experimental set-up in figure 1(a) consists of a (Polystat recirculator, model: 13042-01, supplier: Cole-Parmer) that controls water inlet temperature; a water pump (model: FP1, supplier: Cole Parmer), and a series of valves to regulate water flow rate; a digital flow meter (model: RT-375MI-LPM2, supplier: Blue-White) and the heat storage system. The set-up allows replacing readily the heat exchanger with no changes in the rest of equipment. 32 K-type thermocouples (model: 5TC-TT-K-30-36, supplier: Omega) were installed at different locations inside the TES system and the copper pipes to record temperatures at different times. These measurements were performed to ensure that the PCM was well distributed within all pipes and sheets. Temperatures were recorded as function of time in a computer via the DAQ system (model: NI9213, supplier: National Instruments) using LabView software (version: 15, supplier: National Instruments). A digital camera (model: EOS rebel T5, supplier: Canon) is connected to the computer to capture the images during the experiment periodically. The external surface of the TES system was totally covered with insulation foam to minimize heat losses. For both pipes and finned-pipes heat exchangers, the following temperatures measurements were taken: ambient temperature; water inlet and outlet temperatures of the TES system; water inlet and outlet temperatures for each U-shaped copper pipe; and halfway between water inlet and outlet of each U-shaped copper pipe (at the bottom point). The rest of the 17 thermocouples were distributed evenly through the PCM for

the pipes heat exchanger. To measure the temperature distribution across the copper sheet wall for the finned-pipes heat exchanger, 5 thermocouples were distributed in the middle copper sheet (4 corners and 1 in the center). To measure the temperature distribution across the PCM, 12 thermocouples were evenly distributed in three elevations (4 corners for each elevation). The TES system in figure 1(b) consists of a transparent acrylic container filled with a PCM, copper pipes and copper sheets. The outer surface of the TES system was made of a 30-cm height, 24.5-cm width and 20-cm depth. The thickness of the transparent acrylic wall is 1-cm (supplier: McMaster Carr). The used PCM is Rubitherm (RT-18) (supplier: Rubitherm) that has a solidifying range of 19°C–17°C, heat storage capacity of 250 kJ/kg, and a max operation temperature of 48°C. The volume of PCM was 0.01 m<sup>3</sup>. Four U-shaped vertical copper pipes of a diameter of 0.9525 cm

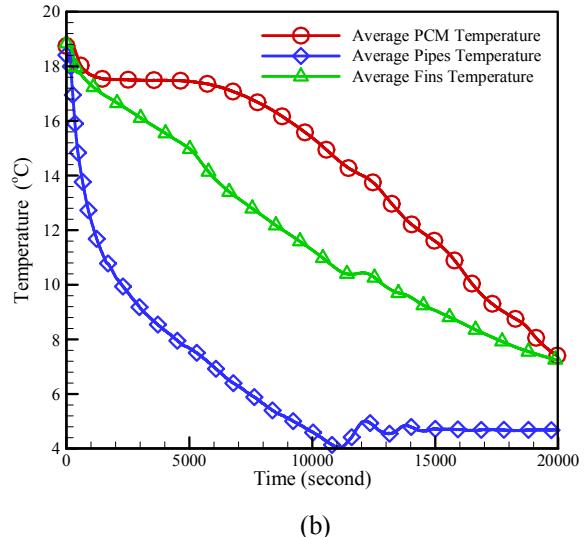

(a)

### III. RESULTS AND DISCUSSION

#### A. Temperature distribution of the solidification process

Figures 2 (a) and (b) present periodic average temperature variation of the pipes, PCM and fins at different locations inside the TES system. The red curve represents the average PCM temperature while the average pipes temperature is presented in the blue curve. For the finned-pipes heat exchanger, the green curve represents the fins temperature. In general, the PCM is liquid when its temperature is higher than the melting point temperature (18°C), and it solidifies when its temperature is lower. Initially, the PCM is liquid, and the temperature of the PCM is 20°C. The solidification process is initiated when cold water at 5°C is bypassed through the copper pipes. The liquid PCM around the tube absorbs thermal

(b)

Figure 2: (a) Temperature distribution (°C) versus time (second) for solidification process inside the pipe heat exchanger and (b) Temperature distribution (°C) versus time (second) for solidification process inside the finned-pipe heat exchanger.

(0.375 inch) were passed through the center of the PCM. Pipes were distributed evenly from each side: 6-cm away from the front and back walls and 1-cm away from right and left side walls. These copper pipes carried water as the heat transfer fluid during the experiment. Eight horizontal copper sheets of 21.5-cm width, 16.5-cm depth, and 1-mm thickness are aligned on the base with 3-cm spacing between them. The fins were soldered to the pipes to minimize the thermal contact resistance between the heat exchanger parts.

#### B. Experimental Procedure

The experiments were conducted in several steps. First, the TES system was filled with RT-18 PCM. Second, the temperature of the PCM was heated up to about 20°C (liquid phase). Third, the water of thermal regulator was cooled down to 5°C and supplied to the TES system through the copper pipes. Meanwhile, the temperatures of the water flow, copper sheets and PCM were recorded at each 10 second. Also, images of the solidification process were captured at each 10-minute interval.

energy from the cold water (HTF) via the tube surface, removes the sensible heat of the PCM and drops the temperature down to the freezing point. The PCM starts solidifying around the tube in the radial direction when the temperature drops below freezing point temperature. The thickness of the solid PCM grows with time around the tube. This solid PCM around the tube then behaves as an insulation material due to its low thermal conductivity compared to the copper tube material and slowed down the solidification process. Heat transfer through the solid PCM is dominated by conduction and as the thickness of the solid PCM increases around the tube, the heat transfer from the tube surface is further reduced. This reduction in heat transfer enhances the solidification time for a bare tube case. Adding horizontal copper fins decreases the thermal resistance during the solidification process and enhances the solidification time. The average PCM temperature of pipe heat exchanger results shown in figure 2 (a) reached to 8.5°C after 75,000 seconds of cooling. The results of the finned-pipe heat exchanger in figure 2 (b) showed that the average PCM temperature reached

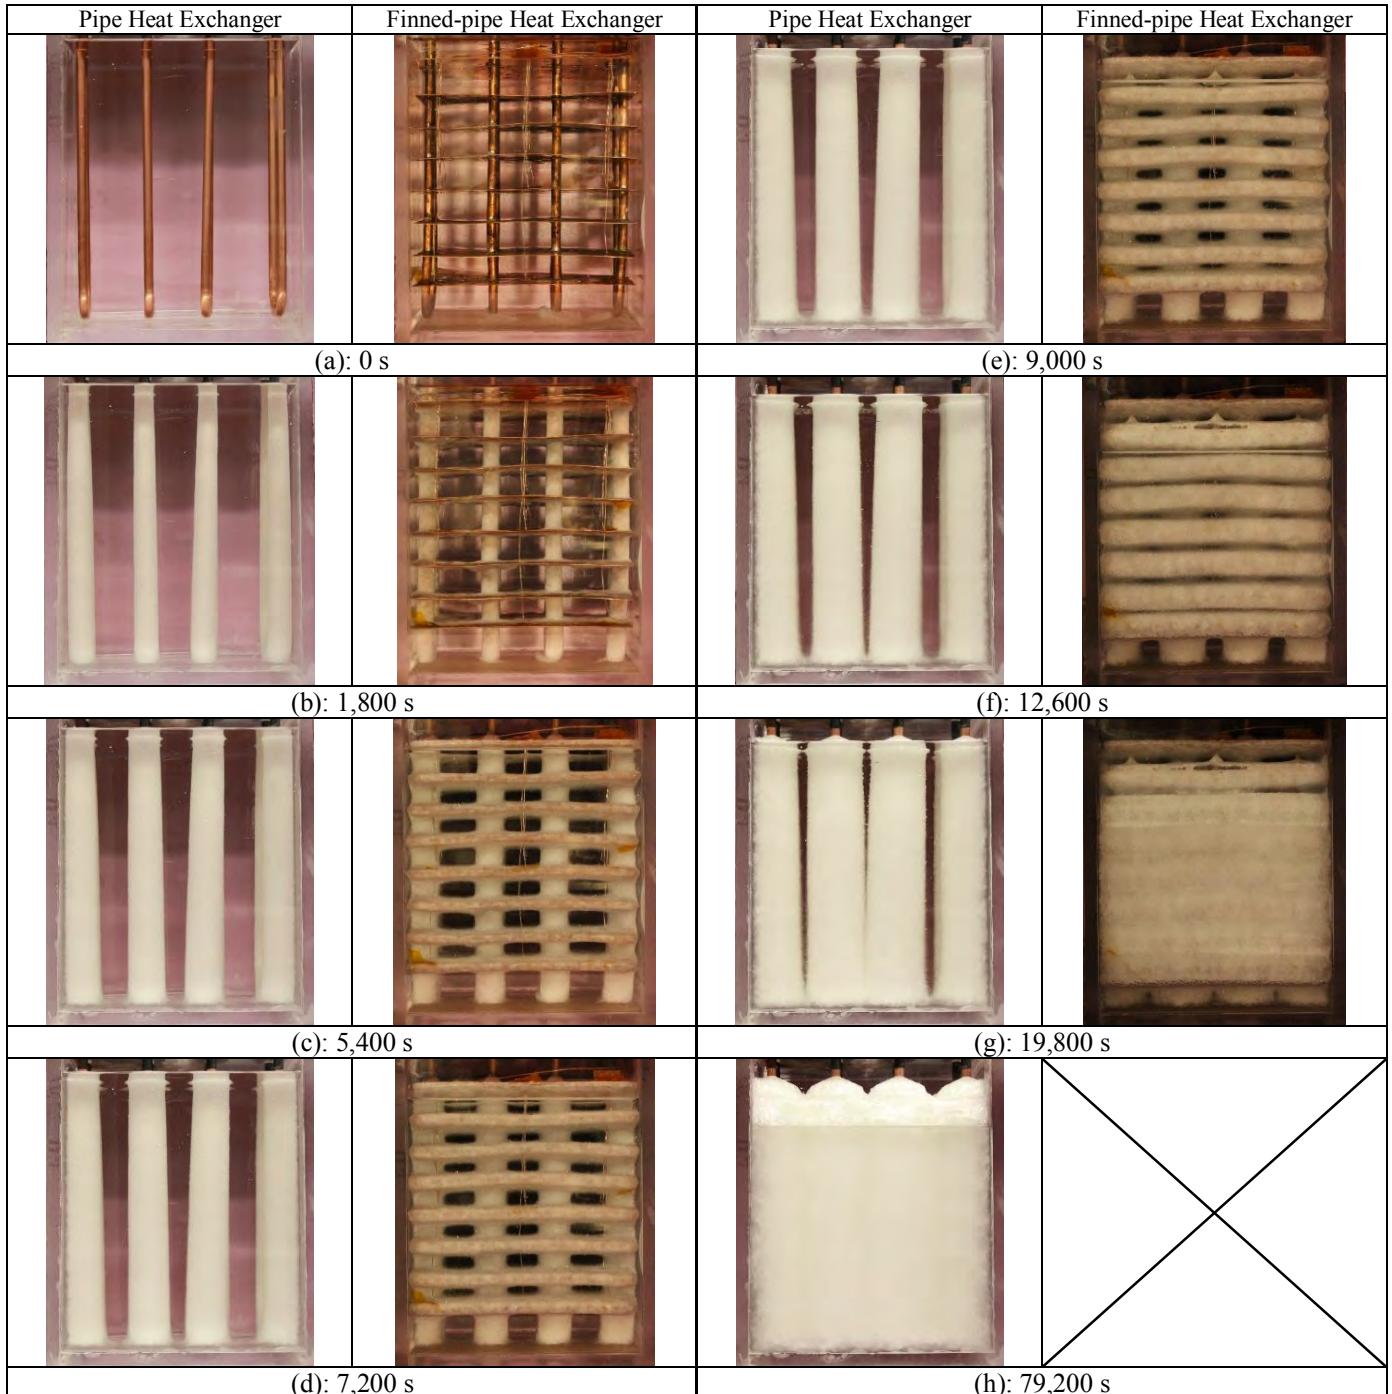

Figure 3: Different visualization captures for different times of the solidification experiments of the pipe heat exchanger versus finned-pipe heat exchanger. For the finned-pipe heat exchanger, the solidification process ends at 19,800 s and that is why no figure is provided to the last row (h) in the right column.

to 8.5°C after 19,000 seconds of cooling. When the fins were added to the TES system, 54,000 seconds was reduced.

#### B. Visualization of the solidification process

Figure 3 shows visualization pictures captured of the solidification experiments of the pipe heat exchanger versus

finned-pipe heat exchanger for different times from 0 second to 79,200 seconds (a-h). The left column represents the pipe heat exchanger experiment, and right column represents finned-pipe heat exchanger experiment. Each row represents a visualization comparison between pipe heat exchanger versus finned-pipe heat exchanger for the same boundary and thermal

conditions at a certain time. In general, the PCM is liquid when its temperature is higher than the melting point temperature (18°C), and it solidifies when its temperature is lower. At 0 second, the PCM is liquid, and the temperature of the PCM is 20°C. The solidification process is initiated when cold water at 5°C is bypassed through the copper pipes any time after 0 second. It is observed that the amount of the solid PCM increases with time progression for both heat exchangers. Also, it is noticed that the amount of the solid PCM in finned-pipe heat exchanger is higher than the pipe heat exchanger.

#### IV. CONCLUSION

An experimental set-up was constructed to investigate the solidification process of two heat exchangers (pipe heat exchanger versus finned-pipe heat exchanger). The PCM used in this study was RT-18 that has a melting point temperature of 18°C. Water was used as heat transfer fluid. Two experiments were performed under identical initial, thermal and boundary conditions to investigate the performance of pipe heat exchanger versus finned-pipe heat exchanger. Periodic temperature distribution and visualization results of the solidification process inside the TES system were presented. Generally, the PCM is liquid when its temperature is higher than the melting point temperature (18°C), and it solidifies when its temperature is lower. Also, PCM releases heat as it solidifies. Results for both heat exchangers showed that the amount of the solid PCM increases with time progression. Temperature distribution results indicated that the amount of the solid PCM in finned-pipe heat exchanger is higher than the pipe heat exchanger at a fixed time. To reach 8.5°C in the solidification process, the average PCM temperature of pipe heat exchanger needed 75,000 seconds and the average PCM temperature of finned-pipe heat exchanger needed 19,000 seconds. Therefore, 54,000 seconds is reduced once the fins were added to the TES system.

**Abstract**—Desiccant coated heat exchanger (DCHE) is developed from the combination of desiccant absorbents and the conventional fin-tube heat exchanger. The performance of the DCHE is mainly due to the adsorption properties of the coated absorbents. Therefore, to improve the DCHE performance, we fabricated porous ion exchange resin (IER) particles which have highly increased contact areas to be used as the DCHE absorbents. The water uptake and adsorption ratio of the porous and non-porous absorbents were both measured and compared against each other. The results showed that the absorbents with porous structure possessed higher water capacity and adsorption rate than that of the non-porous IER.

**Keywords:** air-conditioner; exchanger; desiccant; porous; ion exchange resin

## I. INTRODUCTION

Generally, the dehumidification and humidification are achieved via refrigerating to condense the moist air below the dew point or heating the liquid water above the vapor temperature. Both directions of the humidity control caused plenty of energy waste, which decreased the coefficient of performance (COP) as well [1-7]. Recently, to control the indoor humidity and improve the COP of the conventional air-conditioning system, researches on adsorption refrigeration technology has increased due to many advantages such as utilizing solar and geothermal energies and wastes heat [6-12]. The desiccant coated fin-tube heat exchanger a kind of the DCHEs, developed from the classic fin-tube heat exchanger which is widely used in nowadays air-conditioning system [14-20].

Absorbents such as active carbons, silica gel, zeolites or ion exchange resins are the key component of the desiccant coated fin-tube heat exchanger [2,8,11,13]. Great efforts have been

dedicated to investigating the performance of these materials. For example, silica gel has been both analytically and experimentally studied [11-13]. Computer simulation was also applied to optimize the performance of the adsorption refrigeration [14-15].

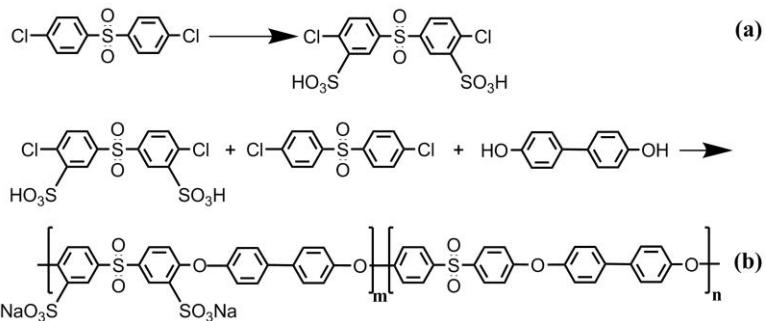

Compared to those inorganic porous materials, IER can directly attach to the fin surfaces instead of mixing with epoxy resin, which avoids the decreasing of the contact area of the absorbents. However, the IER swells while absorbing water and shrinks after evaporation. The frequent dimensional change of the resin caused the serious decline in durability. Besides, the adsorption properties are

In this work, we propose IER with aromatic chain structures to provide high thermal and mechanical stabilities, which improves the longevity of the absorbents. The aromatic IER was also fabricated with porous structures to increase contact surface areas. The test results showed improved humidity adsorption rate and capacity due to the porous surfaces.

## II. EXPERIMENTAL

### A.

### Synthesis of IER

*Scheme 1. Preparation scheme of the sulphonated poly ether sulfone ion exchange resin (SPESIER).*

*B.* *Synthesis of the SPESIER*

The ion exchange resin was synthesized via two major steps as shown in Scheme 1. First, sulphonated bis (4-chlorophenyl) sulphone was obtained via a typical sulphonating procedure utilizing fuming sulfuric acid and bis (4-chlorophenyl) sulphone [21]. Then the sulphonated bis (4-chlorophenyl) sulphone was added into a three-necked, round-bottomed flask with  $K_2CO_3$ , biphenol and DMSO (solvent). The SPESIRE was polymerized via aromatic nucleophilic substitution polycondensation. The resulting polymer was washed with DI water and ethanol after polymerization.

*C.* *Preparation of porous absorbents particles.*

The size of the common used absorbents particles are usually in the range of 60~100  $\mu m$ . Therefore, to develop the absorbents with porous surfaces, the pore size should be much smaller than that of the particle.

In this work, the porous structure was fabricated by the solution casting method. First, the SPESIER was dissolved into NMP with the solid content of 10% and stirring for 12h at room temperature to get a homogeneous solution. Secondly, 1-Ethyl-3-methylimidazolium tetrafluoroborate ( $EMMBF_4$ ) was separately added into the solution at concentrations of 50wt% of the SPESIER. The mixtures were then stirred for another 12h to ensure uniform dispersion. The casting solution was filtered before pouring onto a flat glass substrate. The glass plates with casting solution on top were first held in the oven at 60°C for 12h and then 80°C in vacuum for another 24h to remove solvents. The dried polymers were then removed from the glass plate and boiled in methanol until constant weight to remove the  $EMMBF_4$  and residuals. The porous polymers were powdered into small particles and the pore structure was observed under SEM.

*D.* *Water uptake*

Water uptake was measured after completely drying of the samples at 120°C in vacuum. Then their weights ( $W_{dry}$ ) were recorded before immersing into DI water. Tests were carried out at different temperatures (20 °C, 40 °C, 60 °C, 80 °C and 100 °C). The  $W_{wet}$  were measured after 10mins at each temperature. The water uptake of these membranes was calculated and compared as percentages by the following equation:

$$\text{Water uptake (wt\%)} = (W_{wet} - W_{dry})/W_{dry} \times 100 \quad (1)$$

*E.* *Adsorption rate*

The adsorption rate of the porous IER particles was measured and compared against the non-porous absorbents. The absorbent powder was first dried in the oven at the

temperature of 120 °C until constant weight which was recorded as  $W_{dry}$ . Then the absorbents were placed in a cube with the salt bath of KCl to create a constant relative humidity (RH) atmosphere. The weight change of these absorbents was continuously measured every 100 seconds.

The adsorption ratio was evaluated by the following equation:

$$\text{Adsorption ratio (wt\%)} = (W_{wet} - W_{dry})/W_{dry} \times 100 \quad (2)$$

### III. RESULTS AND DISCUSSION

*A.*

#### Morphology

$EMMBF_4$  was used as the pore-forming agent due to its extraordinary compatibilities with polymers. 50wt% of the  $EMMBF_4$  was added into the system and removed by methanol after membrane casting. The choice of solvent for membrane casting plays an important role in the manufacture of uniform pore size distribution. To lower the evaporation speed and avoid the split phase, NMP was used in the work. Figure 2 shows the field emission scanning electron microscopy (FESEM) images of the porous absorbents. The morphological structure exhibited uniform pore size distribution with an average diameter of 0.32  $\mu m$ .

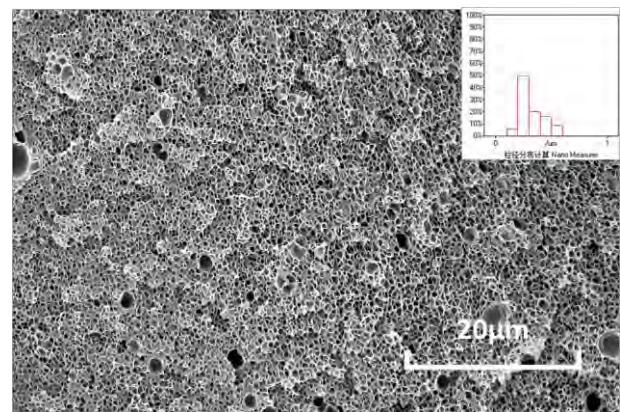

Figure 2. The SEM images of the porous IER.

*B.*

#### Water uptake

Water uptake at various temperatures could reveal the highest water capacity of the absorbents. As expected, both the porous and non-porous absorbents exhibited improved water uptake along with the increasing of temperature. Besides, as we can see in Fig. 3, the porous absorbents outperformed that of non-porous absorbents over the entire range of temperatures. The porous absorbent have a higher water uptake ratio of 5.9 wt% than the non-porous particles (5.6 wt%) after 10mins immersed into water at 20°C , indicating the enhancement of the porous surfaces on water uptake.

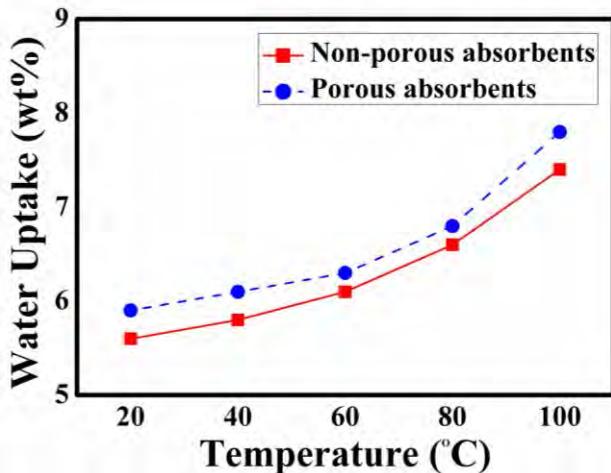

Figure 3. Water uptake of both porous and non-porous absorbents.

### C. Adsorption

KCl salt bath was placed in a cube to create constant RH atmosphere. The RH was continuously measured until constant for 5mins (68.7% RH). Then the dried porous and non-porous absorbents were both placed in the oven and the weight change was recorded for comparison. Both samples exhibited high adsorption rate at first and slowed down after 300s. The porous absorbents showed higher adsorption rate than that of non-porous samples. As shown in figure 4, the porous absorbents also had higher adsorption ratio (6.3 wt%) after fully absorbed.

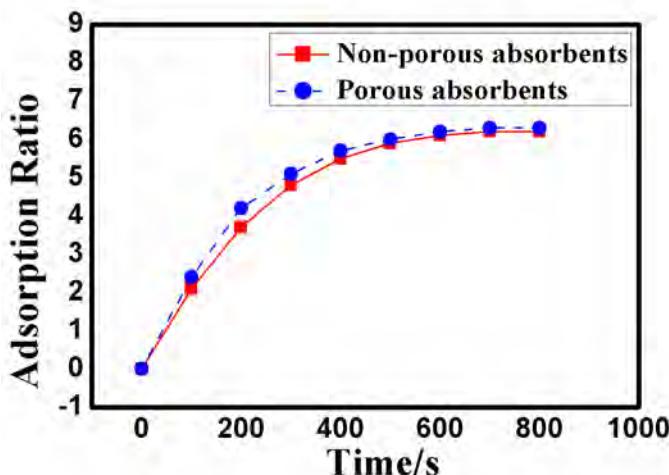

Figure 4. The adsorption ratio of both porous and non-porous absorbents.

### IV. CONCLUSION

The sulphonated poly ether sulfone ion exchange resin was successfully synthesized. To improve the adsorption capacity, the IER was fabricated with porous structure to increase the contact area with the moist air. Water uptake and adsorption ratio are investigated and compared with the non-porous

absorbents. It turns out the porous absorbents exhibit both higher humidity adsorption rate and capacity due to the morphological changes. This works may provide a new method for developing high-performance desiccant coated heat exchangers.

### ACKNOWLEDGMENT

We would like to thank the supporting of Hisense Air Conditioner R&D Centre on this work.

# Effectiveness-NTU Relationships of Parallel-Plate Moving Bed Heat Exchangers

Pedro A. Isaza, Markus Bussmann\*

Department of Mechanical and Industrial Engineering  
University of Toronto  
Toronto, Ontario, Canada, M5G-3S8

**Abstract**—Moving bed heat exchangers (MBHEs) are used in various industrial processes. Recently, analytical solutions to several MBHE heat transfer problems have been presented in the literature. In this work, the mathematical procedure by which these new solutions are used to construct effectiveness-NTU relationships is presented, for parallel-plate configurations. Expressions for both co- and counter-current orientations are outlined. Effectiveness-NTU plots are then generated, and contrasted with those of fluid-fluid systems. As expected, a functionality with respect to the Number-of-Transfer-Units and the Capacity Ratio is observed. A novel dependency with respect to the Biot number is also demonstrated, whereby effectiveness decreases with increasing Biot number, due to the increasing resistance imparted by the diffusion of energy through the solids bulk. These effectiveness-NTU plots can serve as a design platform, which engineers can use to size and rate MBHEs.

## I. INTRODUCTION

Describing energy transport into and out of beds of granular solids has been an area of active research for a number of years. Recently, research in the field has given increased attention to the mathematical modeling of heat transfer in moving bed heat exchangers. MBHEs typically consist of a bed of particulate solids flowing downwards by gravity, which exchanges thermal energy across a separating wall with a heating or cooling fluid. Compared with alternative technologies like fluidized beds, moving beds offer reduced investment costs, energy consumption and maintenance requirements [1, 2]. These competitive advantages have prompted their use in processes ranging from nickel production [3, 4] and food sterilization [5], to flue gas abatement and biomass combustion [6, 7]. Most recently, MBHEs have found a use in solar power generation [8].

Moving bed heat exchangers can be organized in various configurations (i.e. parallel-plate, vertical pipe, etc.) and can accommodate different flow orientations (i.e. counter-current, co-current, or cross flow). Recent mathematical investigations into some of these heat transfer problems have identified

analytical solutions for both parallel-plate and vertical pipe configurations [9-12]. The results outlined provide a sizing platform that engineers can now use to design and rate the thermal performance of these systems. One step that is absent in this new body of work, is the transformation of these expressions into effectiveness-NTU relationships that are commonly found in the heat exchanger literature.

The purpose of this paper is to detail the mathematical procedure by which effectiveness-NTU relationships can be established for parallel-plate MBHEs, using the recently presented analytical solutions. From the expressions, effectiveness-NTU curves are generated as a function of the dimensionless groups found in the fluid-fluid heat exchanger literature (i.e. Number-of-Transfer-Units and Capacity Ratio), as well as a new dimensionless group (i.e. Biot number).

## II. GOVERNING EQUATIONS

The experimentally validated assumptions behind the energy model formulated for the parallel-plate MBHE, outlined by Isaza et al. [9, 10], include: The system operates under steady-state conditions, and the solids move with constant velocity under local thermal equilibrium [13-17]. The solids enter the exchanger at a constant temperature, and the thermo-physical properties are constant and isotropic. Heat conduction in the solids occurs in the lateral direction only [9] (i.e. negligible axial heat conduction – explored and validated in [12]), while convection occurs in the axial direction. Energy transfer in the cooling/heating fluid takes place via convection only (i.e. a convective coefficient quantifies transport by means of a Sieder-Tate style correlation [18]). An overall heat transfer coefficient ( $U_o$ ) comprised of resistances in series due to contact (i.e. nearby wall effects) [13-14, 17, 19-20], wall conduction and convection into the heating/cooling fluid describes energy transfer between the domains. Negligible axial heat conduction takes place along the exchanger wall [11]. Viscous energy dissipation, radiation effects, and sources of thermal energy are negligible. Figure 1 presents a schematic of the co- and counter-current parallel-plate MBHEs under consideration.

Based on the Cartesian geometry in Fig. 1 and the above assumptions, the MBHE problems can be formulated as follows:

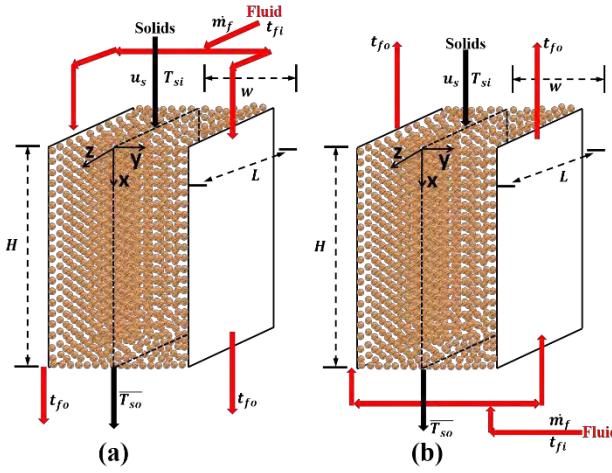

Figure 1 Co-current (a) and counter-current (b) parallel-plate MBHE schematics

$$\rho_s C_{ps} u_s \frac{\partial T_s(x,y)}{\partial x} = k_s \frac{\partial^2 T_s(x,y)}{\partial y^2} \quad x > 0; 0 < y < w \quad (1)$$

$$T_s(0,y) = T_{si} \quad \text{at } x = 0 \quad (2)$$

$$\left. \frac{\partial T_s(x,y)}{\partial y} \right|_{y=0} = 0 \quad \text{at } y = 0 \quad (3)$$

$$-k_s \left. \frac{\partial T_s(x,y)}{\partial y} \right|_{y=w} = U_o [T_s(x,w) - t_f(x)] \quad \text{at } y = w \quad (4)$$

where the complementary fluid problem is the following:

$$U_o \cdot L [T_s(x,w) - t_f(x)] = \pm \frac{m_f}{2} \cdot C_{ps} \frac{dt_f(x)}{dx} \quad x > 0 \quad (5)$$

$$t_f(0) = t_{fi}(+) \quad \text{or} \quad t_f(H) = t_{fi}(-) \quad (6)$$

Note that the plus and minus signs correspond to the equations for the co-current [9] and counter-current [10] orientations respectively.

Like other heat transfer investigations, the analytical solutions to the above problems are presented subject to the following nondimensional variables [9, 10]:

$$y^* = \frac{y}{w}; \quad x^* = \frac{x}{H}; \quad \theta_s = \frac{T_s - t_{fi}}{T_{si} - t_{fi}} \quad \theta_f = \frac{t_f - t_{fi}}{T_{si} - t_{fi}} \quad (7)$$

Applying these to Eqs. (1) – (6) yields:

$$\frac{\partial^2 \theta_s(x^*,y^*)}{\partial y^{*2}} = \frac{Bi}{NTU} \frac{\partial \theta_s}{\partial x^*} \quad x^* > 0; 0 < y^* < 1 \quad (8)$$

$$\theta_s(0,y^*) = 1 \quad \text{at } x^* = 0 \quad (9)$$

$$\left. \frac{\partial \theta_s(x^*,y^*)}{\partial y^*} \right|_{y^*=0} = 0 \quad \text{at } y^* = 0 \quad (10)$$

$$\left. \frac{\partial \theta_s(x^*,y^*)}{\partial y^*} \right|_{y^*=1} = Bi \cdot [\theta_f(x^*) - \theta_s(x^*,1)] \quad \text{at } y^* = 1 \quad (11)$$

$$\frac{d\theta_f(x^*)}{dx^*} = \mp NTU \cdot C \cdot [\theta_f(x^*) - \theta_s(x^*,1)] \quad x^* > 0 \quad (12)$$

$$\theta_f(0) = 0 (-) \quad \text{or} \quad \theta_f(1) = 0 (+) \quad (13)$$

where the minus and plus correspond to the equations for the co-current [9] and counter-current [10] orientations. In Eqs. (8) – (13) the Biot number ( $Bi$ ), Number-of-Transfer-Units ( $NTU$ ) and Capacity Ratio ( $C$ ) dimensionless groups are defined as:

$$Bi = \frac{U_o \cdot w}{k_s}, \quad NTU = \frac{U_o \cdot H}{\rho_s C_{ps} u_s w}, \quad C = \frac{\dot{m}_s \cdot C_{ps}}{\dot{m}_f \cdot C_{pf}} \quad (14)$$

### III. ANALYTICAL SOLUTIONS

Isaza et al. [9,10] present the analytical solutions of the differential equations outlined by Eqs. (8) – (13). The method of solution begins with the application of a Laplace transformation. Once in the Laplace domain, the solid and fluid problems are decoupled, resulting in a well-posed second-order ordinary differential equation problem. Using standard techniques, the problems are solved and the Laplace inverse transform is identified by means of either the standard or the generalized expansion theorem detailed by Luikov [21]. As discussed in [10], to obtain a correct inverse transform for the solids temperature function in the counter-current case, the inverse transform needs to be examined separately for  $C < 1$ ,  $C = 1$  and  $C > 1$ . This special analysis is driven by the expansion theorem, which requires the identification of the simple roots in the denominator function of the Laplace domain solution. Unlike co-current systems, in the counter-flow problem the roots are a function of  $C$ , which requires a case-by-case examination. Complete details of the methodology are presented by Isaza et al. [10].

#### A. Co-Current Analytical Solution

Following the methodology discussed, Isaza et al. [9] obtained the solution for the co-current problem. As will become evident later, for the purpose of developing effectiveness-NTU relations only the expression quantifying the solids average temperature at the exit is needed. That expression is given as:

$$\bar{\theta}_{so} = \frac{C}{1+C} + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} + 2\lambda_n + \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi}} \cdot \frac{\sin(\lambda_n)}{\lambda_n} \quad (15)$$

which is subject to the transcendental equation:

$$\frac{\lambda_n \sin(\lambda_n)}{\left[ \frac{C}{\lambda_n} \sin(\lambda_n) + \cos(\lambda_n) \right]} = Bi \quad \text{where } n = 1, 2, 3, \dots \quad (16)$$

#### B. Counter-Current Analytical Solution:

For the counter-current configuration, the fluid outlet temperatures in [10] are required to build the effectiveness-NTU relationships. Recall that for counter-flow, the analytical solutions are a function of the capacity ratio, and the case-by-case expressions are presented below:

##### Fluid Outlet Temperature - $C < 1$ :

$$\theta_{fo} = \frac{\frac{C}{1-C} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi}} \frac{\sin(\lambda_n)}{\lambda_n}}{\frac{1}{1-C} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi}} \frac{\sin(\lambda_n)}{\lambda_n}} \quad (17)$$

Fluid Outlet Temperature -  $C = 1$ :

$$\theta_{fo} = \frac{\frac{1}{(1+\frac{Bi}{3})} \left( NTU + \frac{Bi^2}{45(1+\frac{Bi}{3})} \right) + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}}{1 + \frac{1}{(1+\frac{Bi}{3})} \left( NTU + \frac{Bi^2}{45(1+\frac{Bi}{3})} \right) + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}} \quad (18)$$

Fluid Outlet Temperature -  $C > 1$ :

$$\theta_{fo} = \frac{\frac{C}{1-C} + C \left[ \frac{4 \sinh(\mu)}{\frac{4C \sinh^2(\mu)}{\mu} - 2\mu - \sinh(2\mu)} \right] \sinh(\mu) e^{\frac{\mu^2 \cdot NTU}{Bi}} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}}{\frac{1}{1-C} + C \left[ \frac{4 \sinh(\mu)}{\frac{4C \sinh^2(\mu)}{\mu} - 2\mu - \sinh(2\mu)} \right] \sinh(\mu) e^{\frac{\mu^2 \cdot NTU}{Bi}} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}} \quad (19)$$

subject to the transcendental equations:

$$\frac{\lambda_n \cdot \sin(\lambda_n)}{\left[ \frac{C}{\lambda_n} \sin(\lambda_n) + \cos(\lambda_n) \right]} = Bi \quad \text{where } n = 1, 2, 3 \dots \quad (20)$$

$$\frac{\mu \cdot \sinh(\mu)}{\left[ \frac{C}{\mu} \sinh(\mu) - \cosh(\mu) \right]} = Bi \quad (21)$$

#### IV. EFFECTIVENESS – NTU RELATIONS

The effectiveness of a heat exchanger is defined as the ratio of the actual and the maximum heat transfer rate which is achievable in a given system [18, 22]. In the case of the MBHE, the actual heat transfer rate can be defined in terms of the energy lost or gained by the solids or the heating/cooling fluid. The maximum rate of energy transfer on the other hand, is established as the product of the largest temperature differential available in the system and the minimum capacity rate (i.e. the min capacity rate is defined as  $c = \dot{m} \cdot C_p$ ). Mathematically, the effectiveness of the MBHE can then be defined as:

$$\varepsilon = \frac{1}{1+C} - \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} + 2\lambda_n + \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}} \quad \text{for } C \leq 1 \quad (25)$$

$$\varepsilon = \frac{C}{1+C} - C \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} + 2\lambda_n + \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}} \quad \text{for } C \geq 1 \quad (26)$$

$$\varepsilon = \frac{[\dot{m} \cdot C_p \cdot \Delta T]_{s \text{ or } f}}{[\dot{m} \cdot C_p]_{min} \cdot \Delta T_{max}} \quad (22)$$

and  $[\dot{m} \cdot C_p]_{min}$  is associated with either the solids or the fluid depending on the conditions examined. Note that the definition applies regardless of the flow configuration.

Equation (22), however, requires further examination as a function of  $C$ . In cases where  $C$  is less than or equal to 1, the fluid capacity rate exceeds that of the solids (i.e.  $\dot{m}_s \cdot C_{ps} < \dot{m}_f \cdot C_{pf}$ ) and the effectiveness expression adopts the form:

Effectiveness -  $C \leq 1$ :

$$\varepsilon = \frac{\dot{m}_s \cdot C_{ps} \cdot [\bar{T}_{so} - T_{si}]}{\dot{m}_s \cdot C_{ps} \cdot [t_{fi} - T_{si}]} = \frac{\dot{m}_f \cdot C_{pf} \cdot [t_{fi} - t_{fo}]}{\dot{m}_s \cdot C_{ps} \cdot [t_{fi} - T_{si}]} = 1 - \overline{\theta_{so}} = \frac{\theta_{fo}}{C} \quad (23)$$

Conversely, when  $C > 1$  the effectiveness expression becomes:

Effectiveness -  $C \geq 1$ :

$$\varepsilon = \frac{\dot{m}_s \cdot C_{ps} \cdot [\bar{T}_{so} - T_{si}]}{\dot{m}_f \cdot C_{pf} \cdot [t_{fi} - T_{si}]} = \frac{\dot{m}_f \cdot C_{pf} \cdot [t_{fi} - t_{fo}]}{\dot{m}_f \cdot C_{pf} \cdot [t_{fi} - T_{si}]} = \theta_{fo} = C [1 - \overline{\theta_{so}}] \quad (24)$$

#### A. Co-Current Effectiveness Relationships:

Substituting Eq. (15) into Eqs. (23) and (24) the effectiveness-NTU relations for the co-current MBHE are found to be the following:

Note that for the special case where  $C = 1$ , Eq. (26) simplifies to Eq. (25) as expected.

#### B. Counter-Current Effectiveness Relationships:

Substituting Eqs. (17) - (19) into Eqs. (23) and (24), the effectiveness-NTU relations for a counter-current MBHE are found to be:

$$\varepsilon = \frac{\frac{1}{1-C} + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}}{\frac{1}{1-C} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}} \quad C < 1 \quad (27)$$

$$\varepsilon = \frac{\frac{1}{(1+\frac{Bi}{3})} \left\{ NTU + \frac{Bi^2}{45(1+\frac{Bi}{3})} \right\} + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}}{1 + \frac{1}{(1+\frac{Bi}{3})} \left\{ NTU + \frac{Bi^2}{45(1+\frac{Bi}{3})} \right\} + \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}} \quad C = 1 \quad (28)$$

$$\varepsilon = \frac{\frac{C}{1-C} + C \left[ \frac{4 \sinh(\mu)}{\frac{4C \sinh^2(\mu)}{\mu} - 2\mu - \sinh(2\mu)} \right] \sinh(\mu) e^{\frac{\mu^2 \cdot NTU}{Bi}} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}}{\frac{1}{1-C} + C \left[ \frac{4 \sinh(\mu)}{\frac{4C \sinh^2(\mu)}{\mu} - 2\mu - \sinh(2\mu)} \right] \sinh(\mu) e^{\frac{\mu^2 \cdot NTU}{Bi}} + C \cdot \sum_{n=1}^{\infty} \left[ \frac{4 \sin(\lambda_n)}{\frac{4C \sin^2(\lambda_n)}{\lambda_n} - 2\lambda_n - \sin(2\lambda_n)} \right] e^{-\frac{\lambda_n^2 \cdot NTU}{Bi} \cdot \frac{\sin(\lambda_n)}{\lambda_n}}} \quad C > 1 \quad (29)$$

Several important observations can be made of Eqs. (25) – (29). Like fluid-fluid systems [18, 22], the effectiveness of the MBHE is also a function of the Number-of-Transfer-Units (*NTU*) and the Capacity Ratio (*C*). This dependency exists regardless of the flow configuration. A new functionality of the MBHE effectiveness with respect to the Biot number is clear from Eqs. (25) - (29). As defined, the Biot number quantifies the magnitude of the resistance associated with lateral energy transfer through the particulate solids. In what follows, the effectiveness dependency on these dimensionless groups is explored graphically.

## V. EFFECTIVENESS – NTU GRAPHICAL ANALYSIS

For ease of heat exchanger design, it is common for engineers to use the graphical representation of the effectiveness-NTU relations. This is particularly useful during rating exercises, where the area of the exchanger is known and the outlet temperatures need to be determined. As explained by Serth and Lestina [18], this calculation requires an iterative procedure which can be circumvented through the use of effectiveness-NTU plots. This ease of calculation is even more important for MBHEs, due to the presence of the infinite series in the above relations. For all of the plots presented below, the functions are evaluated with 600 terms. This provides sufficient accuracy for the range of dimensionless groups explored [9].

### A. Co-Current MBHEs: Effectiveness vs. NTU

In fluid-fluid heat transfer, it is well known that the effectiveness depends only on *C* and *NTU* [18, 22, 23]. Equations (25) and (26), however, clearly demonstrate that for MBHEs  $\varepsilon$  also depends on *Bi*. Figure 2 presents effectiveness-NTU curves for the co-current configuration, as a function of *C* and *Bi*. For comparison purposes, the predictions of the fluid-fluid expressions available in the literature are included in the plots.

From Fig. (2a) – (2c), like the fluid-fluid expressions, as the capacity ratio increases (i.e. from 0 to 1) the MBHE effectiveness decreases. This trend exists for all of the Biot numbers explored. Per the definition given by Eq. (22), an effectiveness of one describes a system where the maximum heat transfer rate is achieved. For a co-current system, this occurs when *C* = 0, and outlines conditions where the heating/cooling fluid undergoes phase change (i.e.  $m_f \cdot C_{pf}$  tends to infinity). Similarly, when *C* = 0.5 and *C* = 1 (i.e. Figs. (2b) and (2c)) a maximum effectiveness of 0.67 and 0.5 is obtained. These values agree with the theoretical limits available under co-current conditions, whereby the effectiveness tends to  $\frac{1}{1+C}$  as *NTU* goes to infinity (i.e. obtained by evaluating the fluid-fluid expressions and Eq. (25) as *NTU*  $\rightarrow \infty$ ). At first glance, Figure (2d) would appear to deviate from this tendency; however, recall from Eqs. (24) and (26) that the effectiveness definition for the MBHE changes when *C* is greater than one. Unlike fluid-fluid problems, the definition of *C* here is static (i.e. *C* is defined as the capacity rate of the solids divided by that of the fluid for all problems), rather than as the ratio of the minimum and maximum capacity rates. This requires the correction of multiplying by *C*, which exists between Eqs. (23) and (24). Having made this correction, Eq. (26) tends to the expected fluid-fluid effectiveness maxima of 0.6 for *C* = 1.5. Furthermore, it can be readily shown that as *C* increases beyond 1.5, the effectiveness will again tend towards one.

Figure 2 also demonstrates the effect of the Biot number. Figures. (2a) – (2d) show that as the Biot number increases, from 0 (i.e. a “fluid – fluid” analog) to 100, the *NTU* required to reach the maximum effectiveness increases. In other words, as the Biot number increases, the area of heat transfer required to reach a given effectiveness also increases. This behavior is independent of the magnitude of *C*, and aligns with the physics of the problem considered. A large Biot number corresponds to a system where the diffusional resistance to lateral heat transfer within the solids is controlling. Under such conditions, the energy exchange

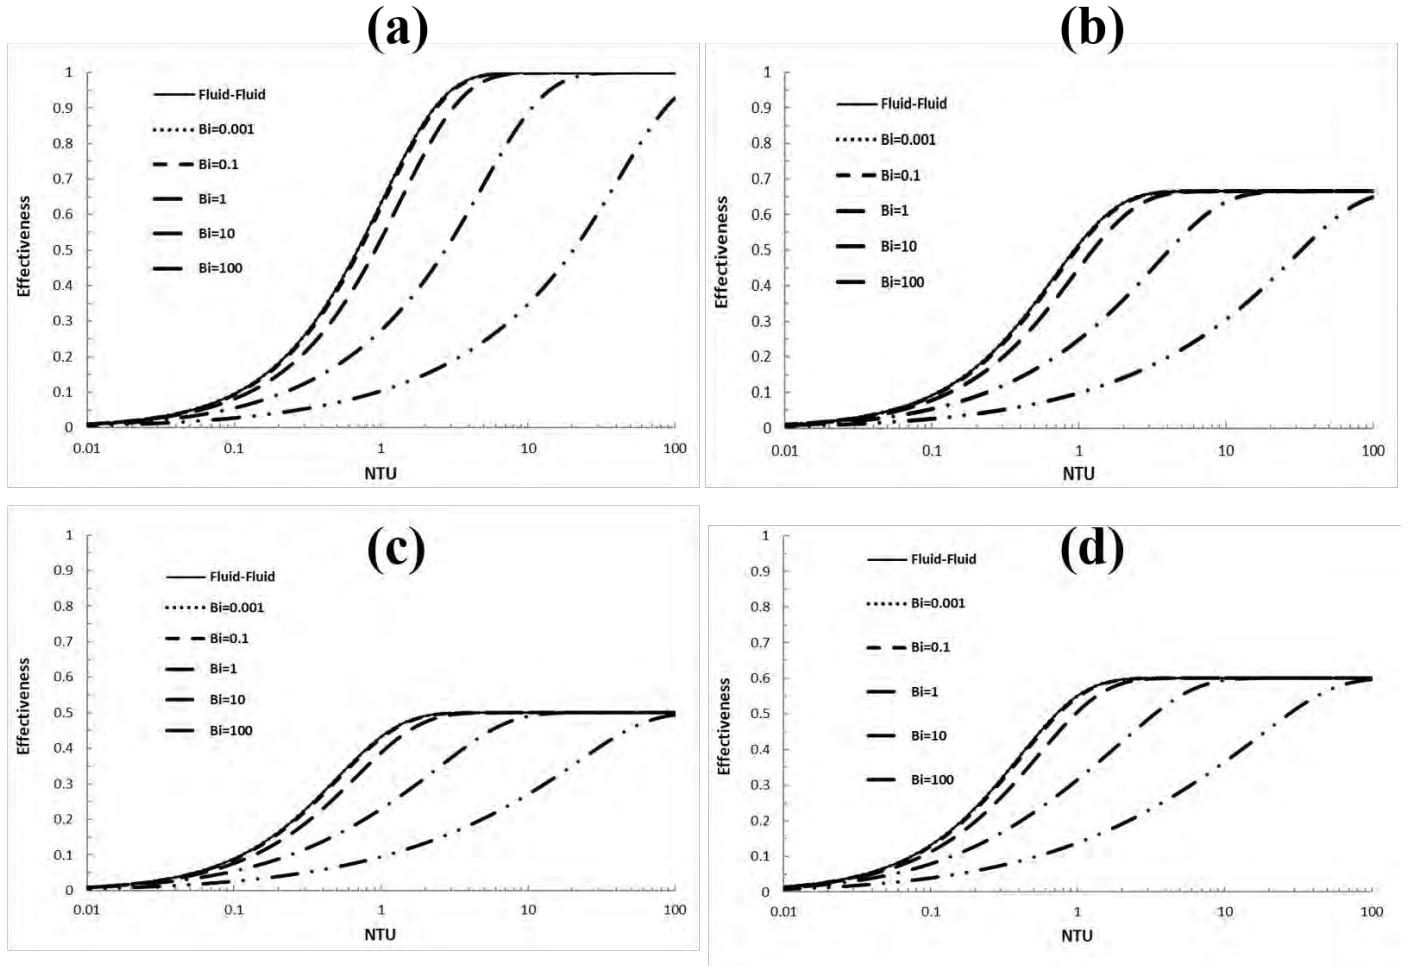

Figure 2. Effectiveness-NTU curves for co-current MBHEs with capacity ratios of (a)  $C = 0$ , (b)  $C = 0.5$ , (c)  $C = 1$ , and (d)  $C = 1.5$

between the two domains is no longer controlled by the overall heat transfer coefficient (i.e.  $U_o$ ) and heat transport is controlled by diffusion through the solids bulk. This behavior has been explained in detail by Isaza et al. [9].

#### B. Counter-Current MBHEs: Effectiveness vs. NTU

Now we consider the effectiveness-NTU behavior of the counter-current MBHE. As discussed in the literature, counter-flow configurations can achieve higher heat transfer rates than co-current systems [24, 25]. As such, for a given amount of energy a smaller area is required. As discussed above, the effectiveness of counter-current fluid-fluid systems depends only on  $C$  and  $NTU$  [18, 22, 23]. Equations. (27) - (29), however, also demonstrate a Biot number dependency for counter-current MBHEs. Figure 3 presents the effectiveness curves for the counter-current configuration as a function of  $NTU$ ,  $C$  and  $Bi$ . For comparative purposes, the predictions of the fluid-fluid expressions in the literature are included.

The results presented in Fig. 3, display some of the well-established characteristics of fluid-fluid systems. First, for all  $C$  (i.e. Figs (3a) - (3d)) the effectiveness tends to one. This

behavior arises from thermodynamic considerations. In a counter-flow system, given a sufficiently large heat transfer area (i.e. a sufficiently large  $NTU$ ), the outlet temperature of the solids will tend to the fluid inlet temperature when  $C < 1$ . From Eq. (23), if  $\bar{T}_{so} \sim t_{fi}$  the effectiveness of the unit tends to one, as per Figs. (3a) - (3c). A similar analysis when  $C > 1$  also demonstrates that given a sufficiently large area, the fluid outlet temperature will tend to the solids inlet temperature. From Eq. (24), one arrives at the expected maximum effectiveness of 1 observed in Fig. (3d). Secondly, for Figs. (3a) - (3c), as the capacity ratio increases, the  $NTU$  required to achieve a given effectiveness also increases. This pattern is independent of the Biot number. For instance, for a Biot number of 1, the  $NTU$  required to reach an effectiveness of 0.95 is 4.05, 6.31 and 25.35 for  $C$  equal to 0, 0.5 and 1 respectively.

Figure 3 also depicts some of the Biot number dependencies discussed for the co-current system. For instance, when  $C = 0$  and  $NTU = 1$  (i.e. Fig (3a)), the effectiveness are 0.63, 0.62, 0.53, 0.27 and 0.1 for Biot numbers of 0.001, 0.1, 1, 10 and 100 respectively. Clearly, as the Biot number increases, the effectiveness decreases even under counter-current conditions.

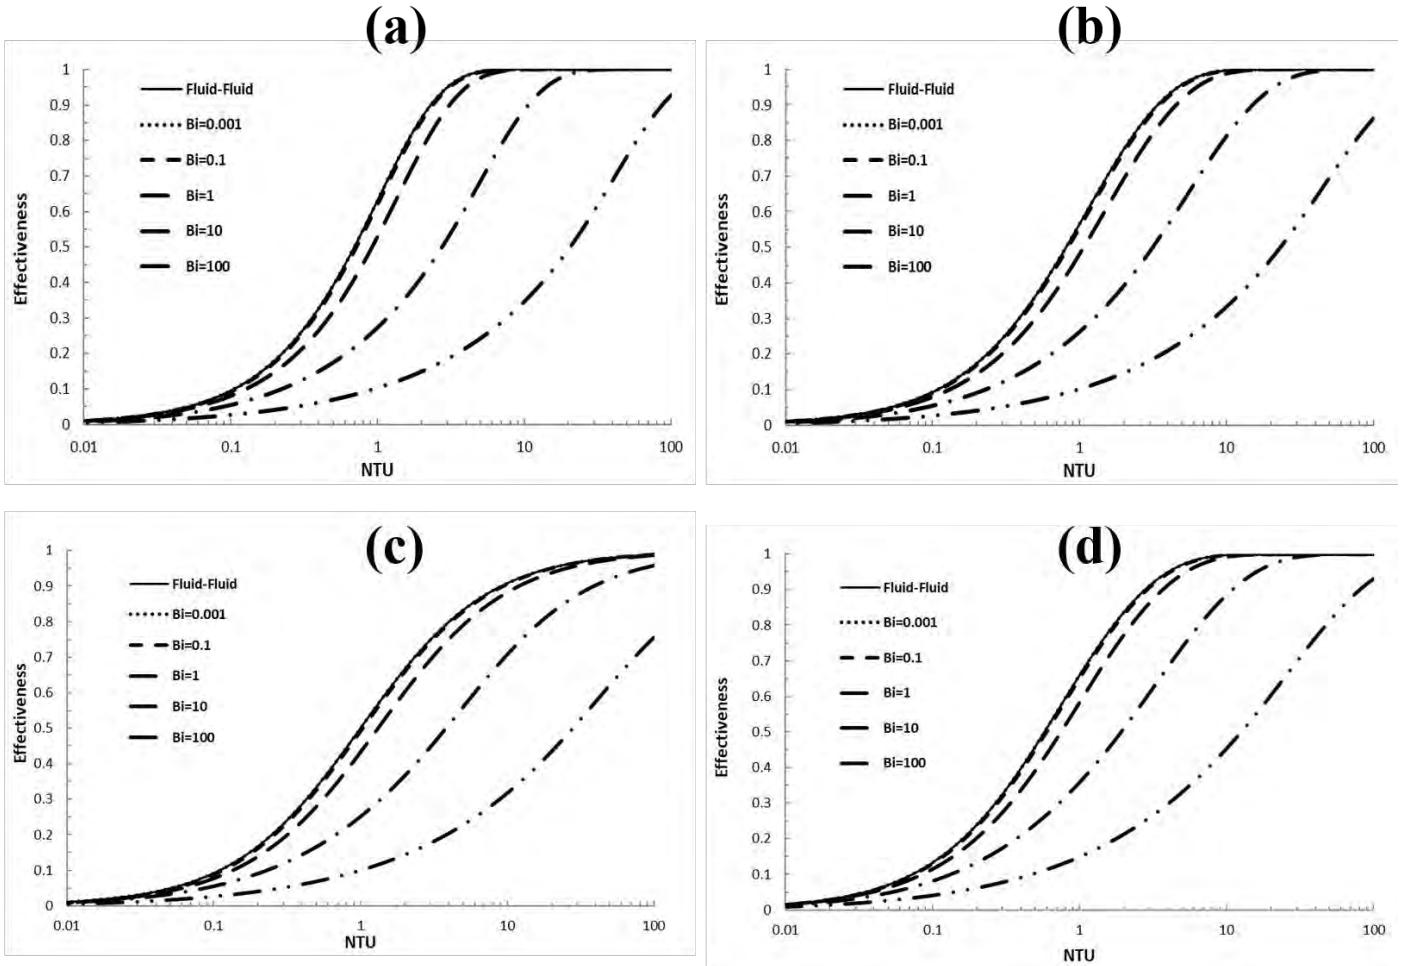

Figure 3. Effectiveness-NTU curves for counter-current MBHEs with capacity ratios of (a)  $C = 0$ , (b)  $C = 0.5$ , (c)  $C = 1$ , and (d)  $C = 1.5$

By examining Figs. (3a) - (3d), it can be concluded that this dependency exists for all capacity ratios. In other words, regardless of the magnitude of  $C$  the effectiveness of the MBHE will decrease with increasing Biot number. As discussed in Section V, large Biot numbers represent a system with a significant diffusional resistance in the solids. This results in the reduced effectiveness that's observed

## VI. CONCLUSIONS

This work presents a methodology for obtaining effectiveness-NTU relationships for parallel-plate MBHEs, based on new analytical solutions found in the literature. Relationships for both co- and counter-current systems are presented. Like fluid-fluid systems, the effectiveness-NTU expressions are found to be a function of the Number-of-Transfer-Units and the Capacity Ratio. Both orientations are shown to be in alignment with the thermodynamic expectations of the systems, and with the corresponding results for fluid-fluid exchangers. A novel dependency of the effectiveness with respect to the Biot number is observed. In particular, as the Biot

number increases the effectiveness of the MBHE decreases. This is the case for both co-current and counter-current orientations. A large Biot number is associated with an increased diffusional resistance through the solids bulk, explaining the reduced effectiveness. The relationships and curves presented in this work can serve as a sizing and rating platform for design activities.

## VII. NOMENCLATURE

$Bi$	Biot number, $= \frac{U_o w}{k_s}$
$C$	Capacity ratio, $= \frac{\dot{m}_s \cdot c_{ps}}{\dot{m}_f \cdot c_{pf}}$
$c_{pf}$	Fluid specific heat capacity
$c_{ps}$	Solids specific heat capacity
$H$	Plate height
$k_s$	Solids "effective" thermal conductivity
$L$	Plate depth

$\dot{m}_f$	Fluid mass flow rate	[5] J. J. Saastamoinen, "Heat exchange between two coupled moving beds by fluid flow," <i>Int. J. of Heat and Mass Transfer</i> , vol. 47, no. 6, pp. 1535-1547, Mar. 2004. doi: <a href="https://doi.org/10.1016/j.ijheatmasstransfer.2003.10.011">10.1016/j.ijheatmasstransfer.2003.10.011</a> .
$\dot{m}_s$	Solids mass flow rate	[6] H. W. Pennline and J. S. Hoffmann, "Flue gas cleanup using the moving bed copper oxide process," <i>Fuel Process. Technol.</i> , vol. 114, pp. 109- 117, Oct. 2013. doi: <a href="https://doi.org/10.1016/j.fuproc.2013.03.020">10.1016/j.fuproc.2013.03.020</a> .
$n$	Integer number, positive	[7] J. Yrjola and J. J. Saastamoinen, "Modelling and practical operation results of a dryer for wood chips," <i>Drying Technol.</i> , vol. 20, no. 6, pp. 1077- 1099, Dec. 2002. doi: <a href="https://doi.org/10.1081/DRT-120004041">10.1081/DRT-120004041</a> .

# Numerical Simulation of Fluid Flow and Heat Transfer of the Supercritical Water in Different Fuel Rod Channels

Huirui Han, Chao Zhang

Mechanical & Materials Engineering

Western University

London, Canada

czhang@eng.uwo.ca

**Abstract**— The supercritical water-cooled reactor was proposed as one of the Generation IV nuclear systems. Although many research works on the fluid flow and heat transfer of supercritical water in circular channels have been conducted, there is still lack of research on the fluid flow and heat transfer process in fuel bundles used in supercritical water-cooled nuclear reactors. Besides, fuel bundles have multiple fuel rods, the flow is an external flow, not internal flow as that in circle channels, which will cause the difference in the fluid flow phenomenon and heat transfer on the fuel rod cladding surface. In this work, the heat transfer and fluid flow characteristics of the supercritical water in the single-rod channel and the multi-rod channel are simulated numerically. The results show that there are secondary flows in both channels. The circumferential cladding surface temperature variation is large and should be considered in the future fuel rod design. With the same flow rate and heat flux input, the maximum cladding surface temperature in the multi-rod channel is much higher than that in the single-rod channel. Since the maximum cladding surface temperature is an important parameter for the safety of the nuclear reactor operation, it is recommended to use the multi-rod channel model to conduct numerical simulations for the fluid flow and heat transfer of the supercritical water in the Canadian SCWR.

**Keywords-** SCWR, heat transfer, single-rod, multi-rod, cladding surface temperature

## I. INTRODUCTION

With the rapid growing population, the electricity generation amount is in high demand. Nuclear reactor power plants can provide higher power-to-sources rate, compared with thermal power plants using coals or natural gas. Canada has a long history in the development of the CANada Deuterium Uranium Pressurized Heavy Water Reactor (CANDU-PHWR), which has been operating for about half century. The Supercritical Water-Cooled Reactor (SCWR) is proposed as one of the six selected Generation IV reactor systems in the world since 2002 [1], which has unique

advantages, such as higher thermal efficiency, lower coolant mass flow to the thermal power rate, and simpler components.

The studies for the flow in rod bundles have been conducted by several researchers. Kjellstrom [2] did the flow profile measurements of air flows in a triangular rod bundle. Trupp and Azad [3] changed the pitch-to-diameter ratios of hexagonal lattices between 1.2 and 1.5 and measured detailed turbulence profiles of the air flow. The eddy viscosity showed strong anisotropy. Carajilescov and Todreas [4] and Vonka [5] used Laser Doppler Anemometry to measure the water flow characteristics in triangular subchannels. They found that the secondary flow velocity was less than 1% of the mean flow velocity.

Many researchers have investigated the turbulent mixing rate of the fluids in channels. Jeong et al. [6] defined a new mixing factor and then evaluated all the experimental data from previous researchers on the turbulent mixing. It was found that the turbulent mixing of fluids depends strongly on the ratio of the distance between the center of two adjacent sub-channels and the hydraulic diameter of a sub-channel. Only very few experimental studies were carried out for the heat transfer and flow phenomenon of supercritical fluids because of the experiment environment restrictions. Xi et al. [7] did an investigation on the supercritical water flow between two heated parallel channels. Both inlet mass flow rate and outlet temperature oscillations were observed. Verma et al. [8] carried out the experiments using a scaled test facility of AHWR (Advanced Heavy Water Reactor) rod bundle. The effect of the spacer on the turbulent mixing rate in subchannels was investigated. The results showed that the turbulent mixing rate increased with the increase in the average Reynolds number.

The simulation results for the flow of the supercritical water in fuel bundles showed that the anisotropic turbulence models are more accurate. Gu et al. [9] simulated the supercritical water flow in a SCWR fuel bundle using the sub-channel method. The simulation results demonstrated that the turbulent mixing rate was sensitive to the asymmetric boundary condition. Mukohara et al. [10] conducted the sub-channel analysis in High Temperature Fast Supercritical Water-cooled Reactor (HTF-SCWR). It was found that the cladding surface

temperature was sensitive to both the local power peak value and the sub-channel area. Yu et al. [11] developed a sub-channel analysis code to analyze the thermo-hydraulic behavior of the CANDU-SCWR. The simulation results showed that this code can successfully simulate the steady state flows in sub-channels.

The Canadian SCWR concept is based on CANDU. Because of the sharp variation of the supercritical water properties around the pseudo-critical point, it is important to use appropriate anisotropic turbulence models for the simulations of the supercritical water flow behaviors and heat transfer phenomenon in fuel bundles. Previous researchers Cheng et al. [12] and Zhang et al. [13] have proved that the anisotropic model RSM (Reynolds Stress Model) can give a better agreement with the experimental results for the supercritical water flow in channels compared with the isotropic two-equation turbulence models.

Previous numerical studies mainly focused on the flow and heat transfer phenomenon of the supercritical water in circle channels. However, the fuel bundle used in the SCWR has multiple fuel rods. It is time-consuming to simulate the fluid flow and heat transfer in the channel with multiple rods. Therefore, some researchers conducted simulations using simplified geometries, such as the work by Sun et al. [14], where the multiple fuel rod system was simplified as a single-rod system. Therefore, in this study, the CFD (Computational Fluid Dynamics) simulations are carried out for the fluid flow and heat transfer of the supercritical water in both the single-rod channel and multi-rod channel under the same operating conditions in order to compare the difference in the results between them. The CFD simulations are conducted with the RSM using ANSYS FLUENT 15.0.

## II. GOVERNING EQUATIONS AND NUMERICAL MODELS

The governing equations for 3D steady flow and heat transfer are conservations of mass equation, momentum equation and energy equation, which is shown as follows in the Cartesian tensor [15]:

$$\frac{\partial}{\partial x_i}(\rho \bar{u}_i) = 0 \quad (1)$$

$$\frac{\partial}{\partial x_j}(\rho \bar{u}_i \bar{u}_j) = -\frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j}(\mu \frac{\partial \bar{u}_i}{\partial x_j} - \rho \bar{u}_i \bar{u}_j) + \rho g_i \quad (2)$$

$$\frac{\partial}{\partial x_i}(\bar{u}_i \rho c_p T) = \frac{\partial}{\partial x_i}[(\lambda + \frac{c_p \mu_t}{Pr_t}) \frac{\partial T}{\partial x_i}] + \phi \quad (3)$$

Here,  $\bar{u}$  is the velocity,  $T$  is the temperature,  $\mu$  is the dynamic viscosity,  $\rho$  is the density,  $\lambda$  is the thermal conductivity,  $c_p$  is the specific heat,  $\mu_t$  is the turbulent viscosity, and  $Pr_t$  is the turbulent Prandtl number. The RSM with the enhanced wall treatment is chosen in this study based on the recommendations from the previous studies [13]. ANSYS Fluent 15.0 is used to solve the governing equations. The SIMPLE scheme is selected for pressure correction, and QUICK method is used for the

spatial discretization. The convergence criteria for continuum is  $10^{-3}$ , for the momentum and turbulence parameters are  $10^{-5}$ , and for the energy equations is  $10^{-6}$ .

## III. CONFIGURATIONS OF THE CHANNELS

The cross-section views of the single-rod channel and the multi-rod channel are shown in Fig. 1 and Fig. 2, respectively. The working fluid is the supercritical water, and its properties are from Wagner [16]. The length of the channel is 1.5 m. For the single-rod channel, the channel diameter is 9mm and the rod diameter is 4mm. And for the multi-rod channel, the outer diameter is 9 mm. There are 5 rods in the channel and their diameter is 1.788mm, so, the total cross-section areas of all 5 rods is equal to the cross-section area of the rod in the single-rod channel. The supercritical water flow in these channels is upward based on the configuration of the proposed SCWR [17]. The reference pressure is 25MPa [17].

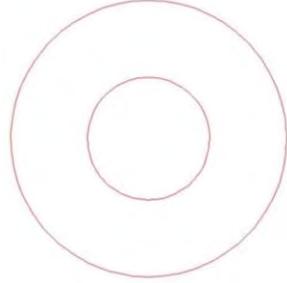

Figure 1. Cross-section view of the single-rod channel

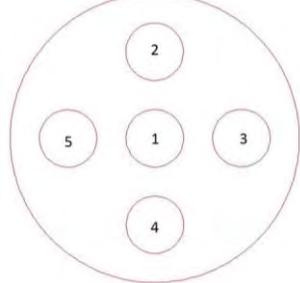

Figure 2. Cross-section view of the multi-rod channel

Boundary conditions are as follows:

Inlet: The inlet velocity for each channel is 3m/s, and the inlet temperature is 623.15K. Turbulence intensity is set as 5%, and the hydraulic diameters are specified based on the geometrical shapes of the channels.

Outlet: Outflow is selected for each channel.

Walls: They are all smooth walls with the no-slip condition. The heat flux on the fuel rod surface is  $10^6$  W/m<sup>2</sup> based on the operating condition of the SCWR [17].

The cross-section views of the meshes for these two channels are shown in Fig. 3 and Fig. 4, respectively. The

mesh refinement near the wall is performed so that the non-dimensional distance to the wall is approximately 1.

#### IV. RESULTS AND DISCUSSIONS

Fig. 5 shows the outlet velocity vectors colored by the velocity magnitude of the supercritical water in the single-rod channel and the multi-rod channel. It is shown that there are secondary flows at the outlet plane in the single-rod channel and the multi-rod channel, especially near the fuel rod cladding surfaces. Fig. 6 shows the contours of the outlet velocity magnitudes in the single-rod channel and multi-rod channel. The velocity magnitudes at the outlets of these two channels are quite different. The velocity magnitude in the single-rod channel is much lower than that in the multi-rod channel. The maximum velocity at the outlet is 4.5 m/s in the single-rod channel and 7m/s in the multi-rod channel. The velocity field will affect the heat transfer in the channel. Therefore, using a single-rod channel to replace the multi-rod channel used in the Canadian SCWR will cause inaccurate results.

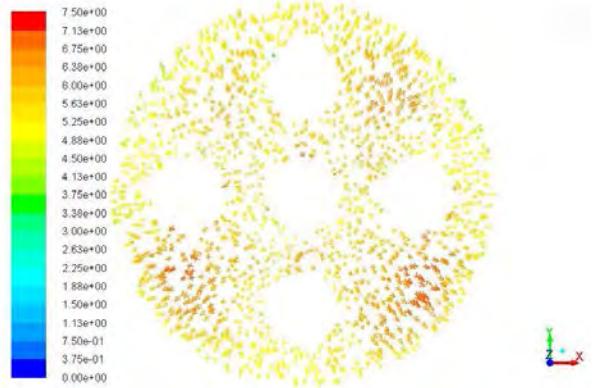

The cladding surface temperature distribution in the single-rod channel is shown in Fig. 7. The difference in the cladding surface temperature along the circumference in the single-rod channel is less than 50K. Fig. 8 shows the cladding surface temperature distribution in the multi-rod channel. It can be seen that the cladding surface temperature difference along the circumference in the multi-rod channel can reach to about 150K.

Fig. 9 to Fig. 11 show the maximum and minimum cladding surface temperatures of each fuel rod at  $z=0.1\text{m}$ ,  $z=0.8\text{m}$ , and  $z=1.5\text{m}$  in the multi-rod channel. It can be seen that the maximum cladding surface temperature at these three planes all occur at the fuel rod #4. And the minimum cladding

surface temperature at these three planes occur at the fuel rods #1, #5, #5, respectively. The largest difference of maximum and minimum cladding surface temperatures occurs at the fuel rod#4 at the outlet plane  $z=1.5\text{m}$ , which is 78.537K. The maximum cladding surface temperature is 670K for the single-rod channel and 780K for the multi-rod channel. The difference is 110K. Therefore, the multi-channel model should be used in the simulation to generate more accurate data used for the control system designs since the maximum cladding surface temperature is an important parameter for the safety of nuclear reactors.

## V. CONCLUSIONS

In this study, the fluid flow and heat transfer characteristics of the supercritical water in the single-rod channel and the multi-rod channel are compared. The results show that there are secondary flows in the single-rod channel. The maximum cladding surface temperature in the multi-rod channel is about 110K higher than that in the single-rod channel. Besides, the cladding surface temperature distributions are also not same between the single-rod channel and multi-rod channel. The

difference of the circumference cladding surface temperature for the multi-rod channel can be up to 78.537K. The large circumferential temperature difference should be considered in the Canadian SCWR fuel bundle design. Since the heat transfer characteristics for the single rod channel and the multi-rod channel are not similar, the numerical simulations of the Canadian SCWR should be performed for the multi-rod channel in order to obtain more accurate results.

**Abstract**—Thermal oil heaters can be considered as an alternative to steam boilers for process heating use. Instead of boiling water, thermal oil heaters use heat transfer oils with high boiling points which allows operation at low pressures. To increase thermal oil heater efficiency, a nanofluid consisting of a common heat transfer oil, the synthetic TH66, and copper nanoparticles has been proposed. Based on existing correlations for nanofluids, a figure of merit (FOM) was created to evaluate heat transfer performance while factoring in pumping power increases. A maximum FOM increase of 13% was found for a thermal oil heater using the nanofluid when compared to one that uses the base fluid oil.

**Keywords-** *Thermal Oil Heater; Nanofluid; Heat Transfer; Feasibility Study.*

## I. INTRODUCTION

Traditionally, water boilers are used to provide steam or heat for residential or industrial process applications. To reach the high temperatures required for process applications, high pressure steam is required. In lieu of using a steam boiler, a thermal oil heater is used to heat the oil. In general, the heaters are gas fired with a burner located in the center of a helical coil. The hot exhaust gases generally travel several passes over the coil to heat the thermal oil. Heat transfer fluids such as thermal oils, can be used as a substitute for steam and can reach much higher temperatures at minimal system pressures. The use of thermal oils also eliminates freezing and corrosion concerns, and no water treatment is necessary. Synthetic heat transfer oils provide higher stability at elevated temperatures, and offer higher thermal conductivity than other heat transfer fluids ( $0.1 \text{ W m}^{-1} \text{ K}^{-1}$ ) but still relatively low compared to water ( $0.6 \text{ W m}^{-1} \text{ K}^{-1}$  at room temperature).

In 1995, Choi published a paper showing the enhancement of thermal physical properties of a basefluid with dispersed nanoparticles, referred to as a nanofluid [1]. Since then, many papers have been published on the topic of nanofluids, mainly showing the thermal conductivity enhancement of water based

nanofluids. Although the quantity of research is much smaller, significant enhancement has also been found for oil based nanofluids [2-6]. Thermal conductivity enhancement generally follows Maxwell's effective medium theory (EMT), but some studies have shown results that far surpass those predicted by EMT [7-8]. Several mechanisms have been proposed to explain the unusual enhancements, including Brownian motion, the interfacial layer model, and particle agglomeration, but no conclusive evidence has been found and the topic remains widely debated.

The present study will examine the feasibility of copper nanoparticles dispersed in a Therminol 66 (TH66) oil as base fluid for use in thermal oil heaters. TH 66 is a widely used and readily available, high temperature liquid phase heat transfer fluid. It is a modified terphenyl heat transfer oil with stability up to  $345^\circ\text{C}$  and provides excellent fouling resistance. Copper nanoparticles were chosen mainly due to their high thermal conductivity. Singh et al. showed that with the use of surfactants, copper nanoparticle suspensions in TH66 were stable [4]. Furthermore, Timofeeva et al. showed stable concentrations of up to 7% for a TH66 nanofluid [3]. Published correlations and data will be used to evaluate any increase in heat transfer rates, but also any drawbacks, including increased pumping power and erosion.

## II. THERMOPHYSICAL PROPERTIES OF NANOFLOUDS

In order to assess the improvements in convective heat transfer given by a nanofluid, several thermophysical properties must be determined. The effective density  $\rho$  of a nanofluid with particle volume fraction  $\phi$  is given by the rule of mixtures [9]:

$$\rho_{nf} = \rho_p \phi + \rho_{bf} (1 - \phi) \quad (1)$$

where the subscripts  $nf$ ,  $p$ , and  $bf$  denote nanofluid, particle, and basefluid respectively. The aforementioned subscripts will be used throughout this paper. Similarly, the effective specific

heat capacity  $c$  of a nanofluid can also be given by the rule of mixtures [9]:

$$c_{nf} = \frac{1}{\rho_{nf}} [\rho_p c_p \phi + \rho_{bf} c_{bf} (1 - \phi)] \quad (2)$$

Unlike density and specific heat, thermal conductivity is a much more complicated and widely debated topic. One way is to use Maxwell's effective medium theory (EMT) to estimate the thermal conductivity  $k$  of spherical nanoparticles suspended in the base fluid based on the volume fraction as follows [10]:

$$\frac{k_{nf}}{k_{bf}} = 1 + \frac{3(k_p - k_{bf})\phi}{(k_p + 2k_{bf}) - (k_p - k_{bf})\phi} \quad (3)$$

Hamilton and Crosser [11] introduced a modification of Maxwell's EMT which included a shape factor that accounted for the sphericity of the particles. More recently, Nan et al. [12] introduced a further modification to Maxwell's theory which included the particle geometry and the interfacial heat flow resistance. For spherical particles and negligible interfacial resistance, both the Hamilton and Crosser and the Nan et al. models reduce to equation (3). Although some studies have shown abnormal enhancements of thermal conductivity [7-8], a review by Buongiorno et al. [13] showed that EMT accurately predicts the thermal conductivity of a nanofluid. The model proposed by Nan et al. was shown to be accurate for nanofluids within a narrow band of  $\pm 10\%$  when compared to a wide range of published data.

Finally, particle suspensions cause an increase in the viscosity of a fluid. An analytical solution for effective viscosity  $\mu$  of a solid-fluid suspension is given by Einstein's expression [14]:

$$\mu_{nf} = \mu_{bf}(1 + 2.5\phi) \quad (4)$$

At the low concentrations typical of nanofluids, equation (4) results in values very close to  $\mu_{bf}$  which contributes to an underestimation of the viscosity at low concentrations. Furthermore, experimental data suggests that the effective viscosity of a nanofluid is significantly higher than the base fluid, and higher than the results suggested by equation (4). Unfortunately, no general correlations exist for the viscosity of a nanofluid as they depend on the shape and material of nanoparticles. Empirical correlations exist but must be derived from a specific set of data pertaining to the base fluid and nanoparticle used. Aberoumand et al. [15] derived the following equation for the viscosity of a heat transfer oil based nanofluid using experimental data:

$$\mu_{nf} = \mu_{bf}(1.15 + 1.061\phi - 0.5442\phi^2 + 0.1181\phi^3) \quad (5)$$

It is important to note that equation (5) may provide an overestimation of the nanofluid viscosity. As the concentration

goes to zero,  $\mu_{nf}$  will approach  $1.15\mu_{bf}$ . This may result in an overestimation of the viscosity at low concentrations. Due to the minimal research done on oil based nanofluids, and experimental results for a Cu-TH66 nanofluid only existing up to 120°C [4], equation (5) will be used as an approximation. To not skew results, equation (5) will be used as an upper bound, and equation (4) will be used as a lower bound for viscosity.

### III. MATHEMATICAL MODEL

To assess the feasibility of nanofluids for use in a thermal oil heater, a mathematical model will be proposed in this section. Two main factors will be evaluated to determine if nanofluids are feasible for use in a thermal oil heater; the heat transfer coefficient (HTC)  $h$  and the pumping power  $P$ . For single phase forced convection, the heat transfer coefficient will effectively show the heat transfer capability of the fluid. Although the nanofluid will have an increased thermal conductivity and specific heat capacity, which contribute to an increased HTC, a nanofluid will also have an increased viscosity, which will require an increase in pumping power to attain the same heat transfer. Therefore, both the HTC and pumping power required will need to be evaluated. There are two ways to compare single phase forced convection heat transfer; constant fluid velocity and constant pumping power. For the purposes of this work, constant fluid velocity will be used to simplify the model.

#### A. Heat Transfer Coefficient

A review by Prahbat et al. [17] concluded that nanofluids achieved no real enhancement of the HTC other than that caused by the augmentation of the thermal conductivity and the increase in viscosity. Prahbat et al. found that studies that showed an abnormal increase in HTC, defined their Reynolds number  $Re$  in terms of the viscosity of the nanofluid at room temperature. When Reynolds number calculations were done using temperature dependent properties, the heat transfer coefficient matched those given by the Dittus Boelter correlations, within uncertainties.

Williams et al. [16] examined the turbulent convective heat transfer behavior of alumina and zirconia water based nanofluids. It was shown that if temperature dependent viscosities and thermal conductivities were used when calculating Reynolds, Prandtl, and Nusselt numbers, the Dittus Boelter correlations reproduced the convective HTC measured in the study. Therefore, the Dittus Boelter correlation for heating (equation (6)) will be used to evaluate the internal heat transfer coefficient of the thermal oil heater.

$$h = 0.023Re^{0.8}Pr^{0.4} \quad (6)$$

#### B. Pumping Power

Although the addition of nanoparticles will increase the thermal conductivity of a fluid, the added particles will also increase the viscosity of the fluid. If the viscosity increase is

too great, the increase in pumping power may counteract the added heat transfer benefits of the nanofluid.

For a circular pipe of diameter  $d$  and length  $L$ , and a turbulent internal flow with velocity  $V$ , the pumping power required is given by the following equation:

$$P = Q\Delta p = \frac{\pi d^4 V}{4} \frac{2fV^2 L}{d} \quad (7)$$

where  $f$  is the friction factor within the pipe. The above equation assumes that all pressure losses are given by major frictional losses. For heating, the friction factor is given by the Blasius equation:

$$f = 0.0791 Re^{-0.25} \quad (8)$$

### C. Figure of Merit

In order to assess the effectiveness of a nanofluid as a heat transfer fluid, a figure of merit (FOM) will be used to compare the performance of a nanofluid to the basefluid at various compositions and temperatures. The heat transfer coefficient (HTC) ratio will show the increase in  $h$  for a nanofluid.

$$\frac{h_{nf}}{h_{bf}} = \left( \frac{\rho_{nf}}{\rho_{bf}} \right)^{0.8} \left( \frac{c_{pnf}}{c_{pbf}} \right)^{0.4} \left( \frac{\mu_{nf}}{\mu_{bf}} \right)^{-0.4} \left( \frac{k_{nf}}{k_{bf}} \right)^{0.6} \quad (9)$$

Although the HTC ratio will show an increase in heat transfer rate for a given fluid, the increased viscosity of the nanofluid can have adverse effects. The increased viscosity will increase the pumping power needed to maintain the same fluid velocity, thus decreasing the overall efficiency of the system. A simple figure of merit proposed by Yu et al. [18] compares the increase in heat transfer of a nanofluid to the basefluid, while accounting for pumping power.

$$FOM = \left( \frac{h_{nf}}{h_{bf}} \right) \left( \frac{P_{bf}}{P_{nf}} \right) \quad (10)$$

Substituting equations (6), (7), and (8) into equation (10) gives:

$$FOM = \left( \frac{\rho_{nf}}{\rho_{bf}} \right)^{32} \left( \frac{c_{pnf}}{c_{pbf}} \right)^{\frac{2}{5}} \left( \frac{\mu_{nf}}{\mu_{bf}} \right)^{\frac{26}{55}} \left( \frac{k_{nf}}{k_{bf}} \right)^{\frac{3}{5}} \quad (11)$$

A FOM larger than 1 indicates a nanofluid that will have better overall heat transfer performance than the basefluid, and the higher the FOM, the better the nanofluid will perform as a heat transfer fluid.

### IV. RESULTS AND DISCUSSION

In order to assess the performance of a Cu-TH66 as a nanofluid, two methods were considered while using the FOM presented in equation (11):

- Varying concentration phi at a constant temperature. A temperature of 300 °C was chosen as it gives a reasonable representation of a practical thermal oil heater operating temperature.
- Varying temperature at a constant concentration phi. A range of 0-6% was used to give a large cross section of data while staying within the stable range shown by Timofeeva et al. [3].

Thermophysical properties of TH66 were obtained from the manufacturer [19]. Figure 1 shows the increase in the FOM with increasing concentration. The higher viscosity estimated by equation (5) gives a FOM that is less than 1 for low concentrations. At  $\phi \approx 0.02$ , the FOM becomes greater than one showing an improvement from the base fluid. This is in alignment with published experimental data. Furthermore, as equation (5) most likely overestimates the viscosity at low concentrations, the point at which the nanofluid becomes beneficial lies between the curve using Einstein's viscosity relationship and thus, will occur at a lower concentration. A maximum FOM of 1.13 and 1.15 were found at  $\phi = 6\%$  using the Aberoumand and Einstein models, respectively. The curves continue to trend upward, but the question of fluid stability must be asked at higher volume fractions. Assuming the real curve lies somewhere between the two curves, a significant increase in efficiency could be obtained from the use of the TH66 Cu nanofluid.

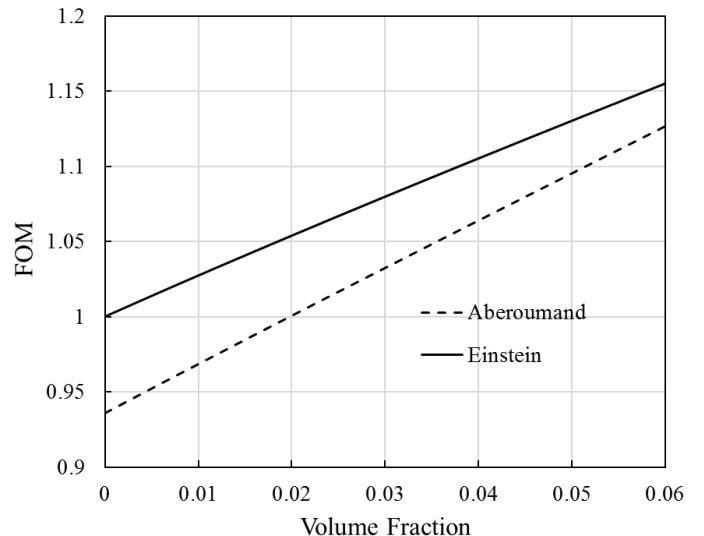

Figure 1. FOM of Cu-TH66 Nanofluid at 300°C with varying volume fraction

Figures 2 and 3 show the effects of increasing the temperature of the nanofluid at select volume fractions. These figures show that apart from the conservative values given by

equation 5 for  $\phi = 0.01$ , a FOM increase is observed for all reasonable temperatures. It is also important to note that a minimum FOM value is observed at  $T \approx 100\text{-}150^\circ\text{C}$ . This minimum efficiency may be important when considering inlet temperatures to a thermal oil heater.

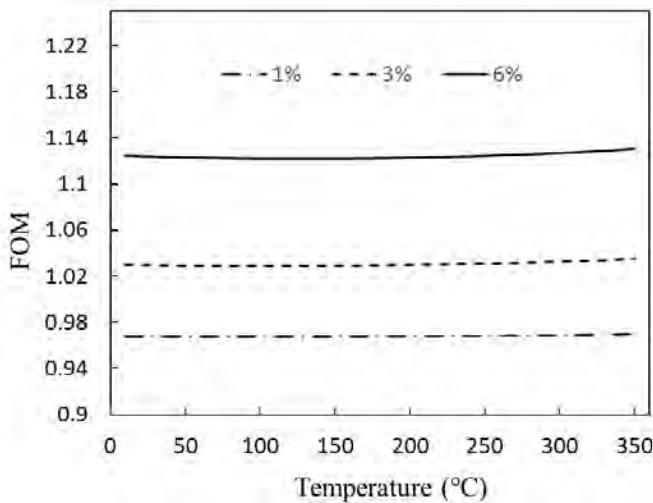

Figure 2. FOM using Aberoumand's viscosity correlation

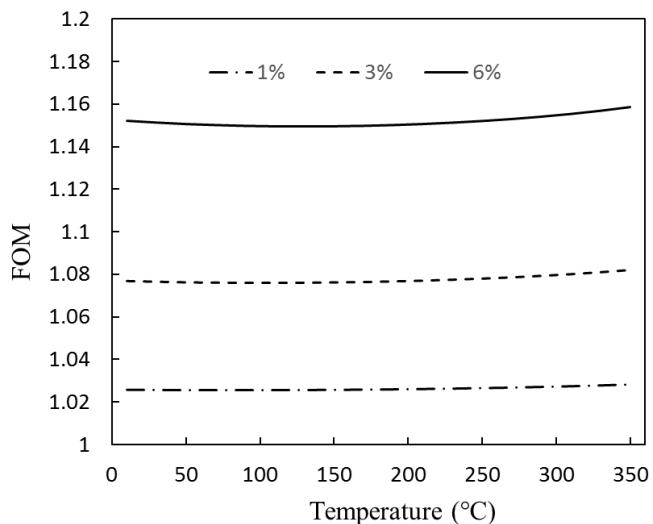

Figure 3. FOM using Einstein's viscosity correlation

In addition to the heat transfer performance increases, the nanofluid must be compatible with existing materials and not introduce unwanted corrosion or erosion effects. Molina et al. [20] tested the effects of an alumina ethylene glycol nanofluid on common cooling system materials, including aluminum and copper. Although little effects were observed on the copper specimens, there was a large surface roughness increase on the aluminum samples. Bubbico et al. [21] tested the effects of various nanofluids on many common process materials including copper, stainless steel, and aluminum. No effects were observed on the copper and stainless-steel specimens, but significant damage was caused to the aluminum specimens. It is important to note that the erosion observed was caused

entirely by chemical corrosion due to the pH of the nanofluids rather than mechanical erosion.

It was also noted in the study that increased viscosity of the nanofluid caused pump failures. A separate test conducted by Routbort et al. [22] similarly showed effects on the pump system. In a process environment, it will be important to make sure that pump reliability will not be affected by the nanofluid. Increased pump capacity may also need to be considered to account for the increased nanofluid viscosity.

## V. RECOMMENDATIONS AND CONCLUSIONS

From the above figures, it appears that it is feasible to use nanofluids in a thermal oil heater. Even with conservative values given by Aberoumand's viscosity correlation, the figure of merit (FOM) was found to be larger than 1 for all temperatures and  $\phi > 0.01$ . In order to further assess the applicability, several further steps are needed to obtain a more precise answer:

- A more accurate viscosity relationship will be needed. Experimental viscosity data will be needed for a Cu-TH66 nanofluid to give a relationship of the accepted form  $\mu_{nf} = \mu_{bf}[1 + A\phi + B\phi^2]$ , which will allow for more accurate heat transfer performance calculations.
- The FOM given in equation (11) does not directly apply to a thermal oil heater. Although equation (11) gives a reasonable idea of the overall heat transfer performance of a nanofluid, it does not accurately model a thermal oil heater; rather heat transfer for turbulent flow in a pipe. A thermal oil heater model will be required to determine the exact performance increases, but that was not the scope of the present study.
- If an accurate thermal oil heater model can be formulated, an economic analysis can be performed using exact performance increases, upgrade costs, and fluid costs.

**Abstract**— Effective zones of high pressure coolant (HPC) have been identified in turning performing a wide range of machining operations on 304 stainless steel using uncoated carbide inserts. The effects of triple coolant jets on tool-chip interface temperature were studied. In addition, their performance are evaluated in terms of machining parameters by comparing with those of conventional coolant and dry cut. Chipping and catastrophic failure are the dominant factors of insert rejection for dry cut and conventional coolant, whereas progressive flank wear is observed for HPC within its effective zones at lower feed rate and higher cutting speed. It is found that the cutting force is reduced, surface finish is improved, chip width is narrowed and cooling effect is better with the use of HPC. The enhanced heat dissipation by triple jets is accredited as the primary reason for the reduction of cutting forces, surface roughness and tool wear.

**Keywords**-high pressure coolant; 304 stainless steel; tool wear; cutting forces; chip formation; surface roughness

## I. INTRODUCTION

Machining is a manufacturing process where a sharp cutting tool penetrates the surface of a work material. The penetration causes shear deformation of the workpiece in order to remove material from the surface in the form of chips. During the formation of chips, the mechanical energy applied by the insert converts to heat energy [1]. Plastic deformation of the work material and friction between tool rake face, and flowing chips foster intense amount of heat at the cutting zone [2]. Machining of stainless steel and other difficult to cut materials requires instant heat transfer from the cutting edge of tool to aid tool life. Supply of high volume and HPC often provides the best answer. Conventional coolant does not reach the real cutting area near the cutting edge of the tool and vaporizes before it reaches the cutting area as the heat is very intense during machining [3]. 304 stainless steel is mainly used for Heat Exchangers, bushings, springs, bearings, gears, and shafts. Despite the increased usage of 304 stainless steel, they have relatively poor machinability characteristics compared to other metals, because of their poor thermal conductivity [4].

They are very difficult to machine and intense amount of heat generates during machining which must be reduced to enhance product quality and dimensional accuracy by proper application of coolant [5].

The concept of HPC may be a possible solution for high speed machining in achieving intimate chip-tool interaction, low cutting temperature and slow tool wear while maintaining cutting forces at reasonable levels. [6] Based on the necessity and versatility of HPC in machining, this study focuses on the machinability assessment of AISI 304 stainless steel by using uncoated carbide inserts at dry, conventional coolant, and triple jets HPC lubrication. The evaluation of HPC has been executed in two steps: firstly, based on the ability of HPC to reduce the cutting temperature, and secondly, the relevance of this temperature lowering with favorable curbing of the cutting force, tool wear, surface quality, and chip formation.

## II. EXPERIMENTAL PARAMETERS AND PROCEDURES

In this research, a round bar (120 mm diameter by 500 mm length) of an austenitic stainless steel AISI 304 was investigated during turning. The chemical composition of the material is shown in Table 1. To reveal the workpiece microstructure, a sample of the AISI 304 was prepared, polished and etched with Glycergia solution (1 mL Glycerol + 20 mL hydrochloric Acid (HCl) + 20 mL HNO<sub>3</sub>). The microstructure of the AISI 304 workpiece was characterized using a Nikon ECLIPSE IV 100 equipped with UC30 camera, see Figure 1. The turning process was performed using a Nakamura-Tome Sc-450 lathe. The cutting tool (Manufacturer: Kennametal) used for the experiments was an uncoated cemented carbide insert with WC/6%Co. The designation of the insert is ISO WNMG432-SM with the following geometry characteristics: back rake angle,  $\lambda_0 = 7^\circ$ ; clearance angle,  $\alpha_0 = 0^\circ$ ; wedge angle,  $\beta = 82^\circ$ ; edge radius,  $r = 34 \mu\text{m}$  and nose radius,  $R_e = 0.8 \text{ mm}$ . Tool-holder used for high pressure cooling was an ISO PWLNR 16-4DHP with three cooling nozzles used, supplied by Sandvik (Figure 2). The high pressure coolant was applied at a flow rate of 30 L/min via three nozzles directed toward the rake face of the

cutting tool at a pressure of 70 bar. The cutting fluid chosen was semi-synthetic coolant-CommCool™ 8800, manufactured by the Wallover Company (Harrow, ON, Canada), at a concentration of 7%, typically used with stainless steel alloys.

0.08	0.75	2.0	0.045	0.03	20	0.50	0.1

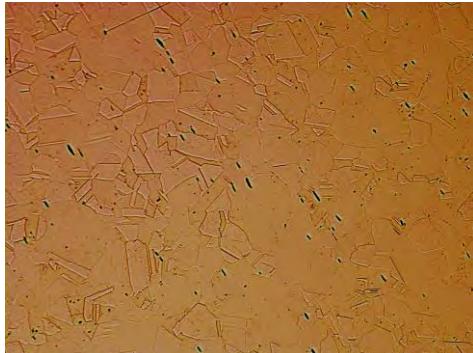

Figure 1. The microstructure of AISI 304 with an austenitic structure.

The investigations have been performed with respect to varied cutting speed (60–100–150 m/min), feed rate (0.1–0.2–0.3 mm/rev) and cutting conditions (Dry-Convention coolant – (a) HPC). During turning operation the depth of cut was kept constant at 0.5 mm and a new tool insert was used for each run for all the machining runs.

The tool flank wear was measured using a KEYENCE – VHX 5000 digital microscope, equipped with a CCD camera and image analyzer software. The tool life criterion was set to a flank wear of 0.3 mm according to the recommendation of the ISO 3685 Standard [8]. During the tests, the cutting tools were analyzed by SEM, using a Vega 3-TESCAN.

The chip compression ratio, the shear angle and the friction coefficient at the tool-chip interface were determined using standard methods [9]. The surface roughness of the machined workpiece was measured across the tool feed direction by means of an Alicona Infinite Focus-with the Profile roughness module. The procedures of surface roughness measurements were performed according to EN ISO standard 25178 [10]. Roughness measurements were taken with a cut-off wave length of 800  $\mu\text{m}$ , a vertical resolution of 100 nm and a lateral resolution of 2  $\mu\text{m}$ .

During the machining tests, the cutting force and chip-tool interface temperature measurements were performed with a 3D component tool holder Kistler dynamometer type with a data acquisition system and thermocouple sensors, respectively. The signals of the forces from the dynamometer were transmitted to a Kistler 5010 type amplifier, and then recorded on a computer using LABVIEW version 14.0 software. To measure chip-tool interface temperature, thermocouple placed just right side of insert through hole made at right side of shim. The signals of the temperature

from the thermocouple were transmitted to analog K-type thermocouple amplifier, and then recorded on a computer using LABVIEW version 14.0 software.

### III. RESULTS AND DISCUSSION

#### A. Effect of High Pressure coolant on Machining Temperature

In this section, an investigation of effect of HPC on machining temperature are discussed. Figure 3 shows the interface of chip-tool and the direction of applied jets. Fluid jets are aimed at chip-tool interface in order to remove the originated heat [12]. The HPC when passed through a small diameter of jet opening produces high volumetric flow rate, which creates a thin boundary layer on impingement surface, and thus enhances heat transfer rate.

In this study, very high velocity of fluid jet induced by high pressure (70 bar) and small nozzle diameter (1 mm) enhance convective heat transfer rate [13]. Accordingly, three turbulent flows acting on the mutually perpendicular surfaces effectively control the cutting temperature by facilitating rapid removal of heat. The heat transfer rate can be enhanced if the jet impinges in the maximum temperature region of the cutting tool.

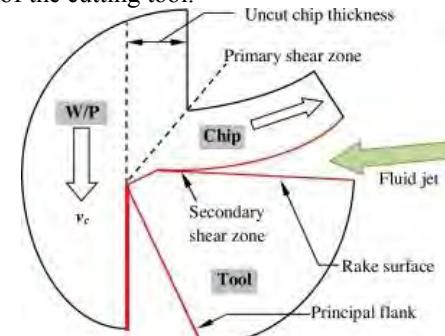

Figure 3: Chip-tool interface and the direction of applied jets [12].

Figure 4a exhibits the movement of chip-tool interface temperature with cutting speed at different feed rates. As it is shown, higher cutting speed is affiliated with elevated

temperature which was expected owing to the dominant nature of endured friction by extended chip-tool contact area [14]. At the same time, the effect of higher feed rate is reflected by an increase in chip-tool interface temperature. This is endorsed to a higher rate of conversion of mechanical to thermal energy by the chip evolution by shearing of solid material [15]. Therefore, the recommended speed is 60 m/min along with 0.1 mm/rev feed rate to originate the minimum temperature of 22.5 °C under the employment of effective HPC jets.

Figure 4b shows the typical temperature profiles of tool-chip interface with machining time for dry cut, conventional coolant, and HPC at the recommended speed and feed. Temperature profiles for dry cut show gradual increase of temperature with machining time. Maximum temperature rise for dry cut is 140°C, for conventional coolant is 36°C, and for HPC is 22°C for the optimum cutting condition. HPC decreases the tool-chip temperature by 38% in comparison with conventional coolant and by 85% in comparison with dry cut indicating better cooling effect. Above results clearly indicate the effectiveness of HPC in reducing the temperature. This is endorsed to a higher rate of conversion of mechanical to thermal energy by the chip evolution by shearing of solid material [16].

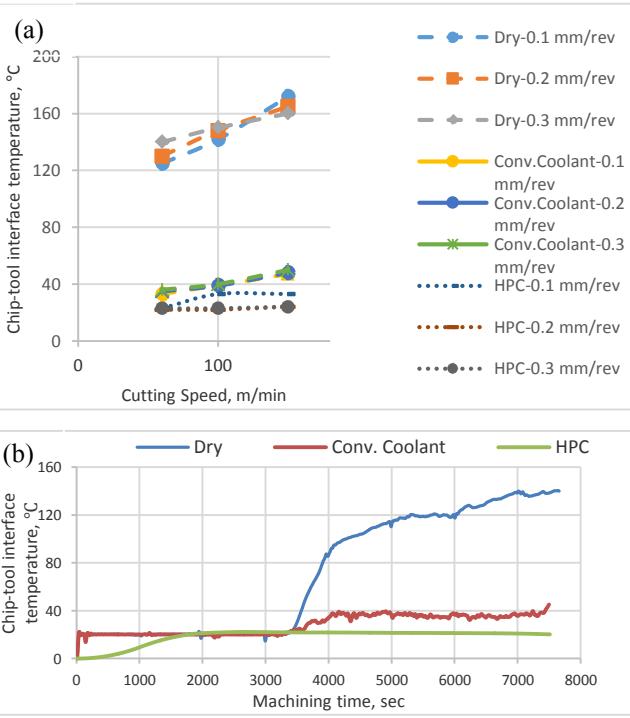

Figure 4: (a) chip-tool interface temperature values at different cutting conditions and corresponding chip-tool interface temperature profiles at optimum cutting conditions.

### B. Effect of High Pressure Coolant on Machining Performance

Force components are almost always utilized to determine chip formation process of engineering materials. Although measuring forces directly help to determine power

requirement for cutting the work material, it is also useful to interpret the whole cutting process [17]. The main cutting forces for the dry and two different cooling at optimum cuing conditions is depicted in Figure 5. As shown, main cutting forces are higher with dry and conventional coolant as compared to HPC. The reduction in the cutting force with HPC could be due to several reasons. HPC jet strikes the chip at a point very close to the cutting edge of insert, resulting in the reduction of the width of the chip. Consequently, the tool chip contact area on the rake face is reduced, which reduces the friction between insert and chip and eventually reduces cutting force. Another reason is that HPC is able to penetrate deeper into the cutting interface, thus providing more efficient cooling as well as lubrication [18-19]. The coolant water wedge created at the tool-chip interface reduces tool-chip contact length and forces, which can be also connected to benefits in friction conditions.

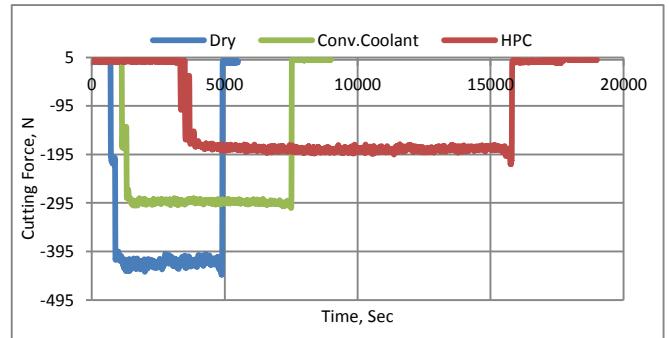

Figure 5: Main cutting forces for dry, conv. coolant and HPC at optimum cutting conditions.

The average surface roughness parameter ( $R_a$ ) has been studied and its behavior with the progression of cutting speed at different feed rates for dry, conventional coolant, and HPC is described in Figure 6a. It is evident from this figure that a reduced roughness is achieved at higher cutting speed. On the contrary, the sliding and adhesion of chips at low spindle speed are accounted for high surface roughness [20]. Also, the surface roughness is increased by the feed rate as a result of the straining effect of high feed rate [19].

In addition, in all the cases, best surface finish is obtained with HPC, followed by conventional coolant and then dry cut, see Figure 6b. When chipping occurs as it is shown in dry condition, the surface obtained is the worst and shows very high value of average surface roughness because of melting of chips on the workpiece surface. The improvement of surface finish with the use of HPC may be because of tool wear rate becomes slower.

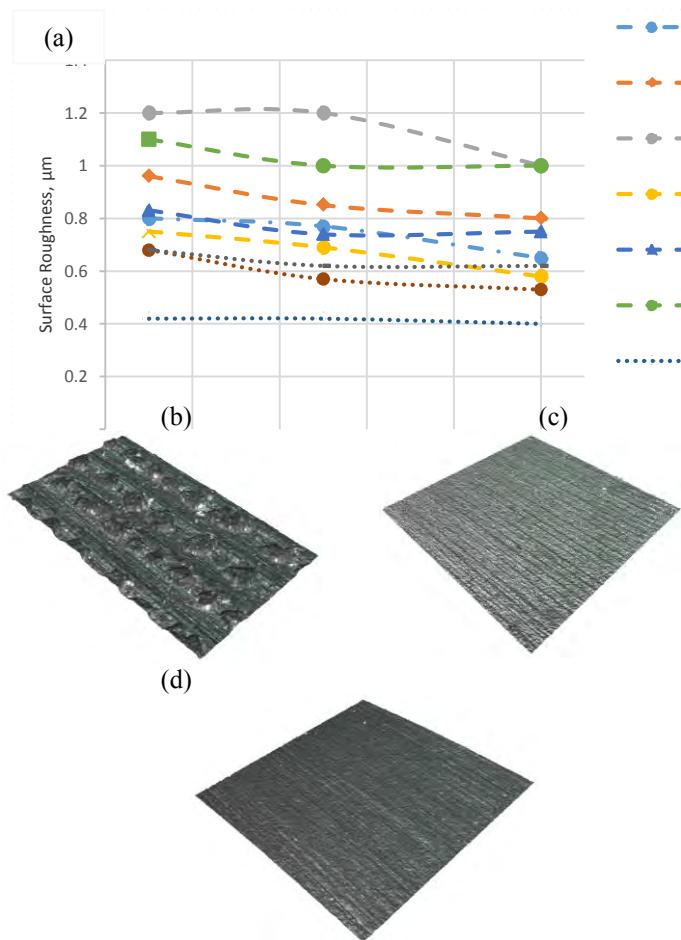

Figure 6: (a) average surface roughness at different cutting conditions and corresponding machined surface for (b) dry, (c) conv. coolant and (d) HPC at optimum cutting conditions.

To study the effectiveness of HPC, the chips were collected and presented in Figure 7. Although continuous and snarled chips are produced under dry and conventional coolant conditions, tubular chips are produced under HPC condition. HPC condition helps to break chips, in particular at lower feed rate by producing shorter tubular chips. In contrast, conventional coolant didn't show distinct effect on chip breakability. Under dry and conventional coolant, chip fracture is due to the negative bending moment created by an obstruction. However, effective chip breaking under HPC is due to the mechanical action of the high pressure jet. The 70 bar coolant pressure is equivalent to a force of approximately 70 N (assume that an area of  $1 \times 1 \text{ mm}^2$ ) on the chip which is large enough to fracture the chip by a positive bending moment, before making contact with an obstruction.

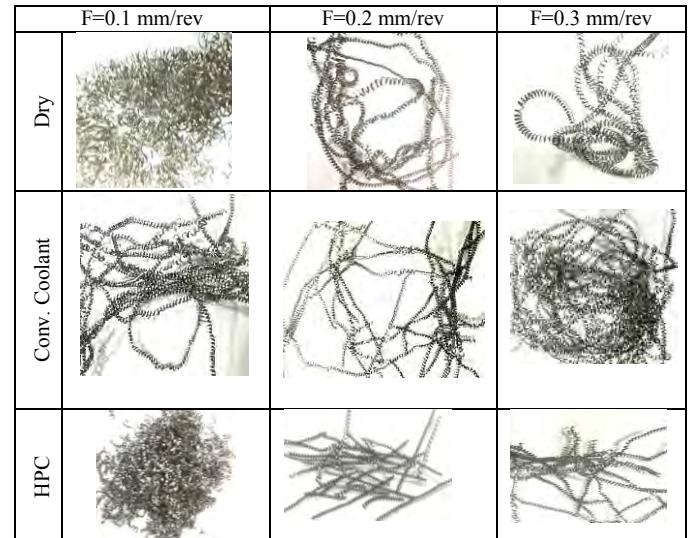

Figure 7: Chip breaking under various cutting condition and feed rates.

Figure 8 shows tool life of carbide inserts with variation of cutting speed and feed rate, respectively. From these figures, HPC is found to be most effective for the cutting conditions of  $f=0.1 \text{ mm/rev}$  and  $v=150 \text{ m/min}$ , which is considered as optimum cutting condition for this high pressure system. Experiments have been carried out by varying speed and feed rate, however one parameter is varied while other two are kept constant at optimum value and thus, effective zones of HPC are identified. At lower speed below 150m/min, the use of HPC is not effective as high speed. At higher speeds, inserts fail due to chipping and excessive flank wear for dry cut and conventional coolant whereas only progressive flank wear is observed for HPC. HPC is also found to be very effective at lower feed rate ( $0.1 \text{ mm/rev}$ ), reducing the chipping of inserts, which is observed for both dry cut and conventional coolant. In contrast at higher feed rate ( $0.3 \text{ mm/rev}$ ), the use of HPC is found to be non-effective. The reasons for that is at lower feed rate, the generation of heat is low and the temperature rise in insert is also low and when the HPC is used, different modes of heat transfer take place. First film boiling starts and persists for very short time. Then vigorous nucleate boiling starts and then forced convection takes place [21]. At lower feed rate, pressure is high enough to remove the heat from the cutting zone. But when the feed rate is high, the temperature rise in the insert is high and film boiling persists for longer time and nucleate boiling may not take place [18]. As a result, no phase change takes place to reduce temperature. For this reason, the temperature rise causing chipping.

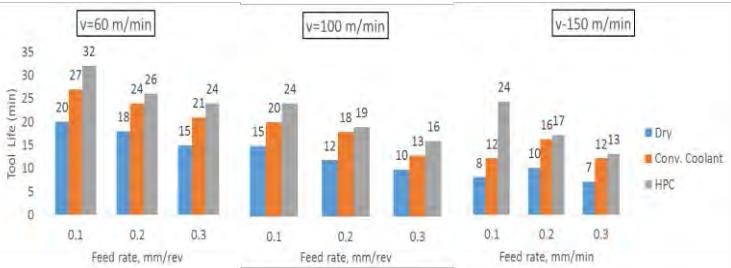

Figure 8. Recorded tool lives at various cutting conditions under dry, conv. coolant, and HPC.

Figure 9 shows SEM images of worn inserts at optimum cutting condition (150 m/min, 0.1 mm/rev). It is clear from the SEM pictures that inserts fail because of chipping for both dry cut and conventional coolant and largest wear zone is observed for dry cut, followed by conventional coolant. No chipping is observed for HPC and wear zone is also the smallest. Also, SEM analysis of the worn inserts show a smooth pattern in dry and conventional coolant conditions, indicating that diffusion wear mechanism is predominant. Diffusion wear is mostly dependent on the temperature at the interface. The HPC system has been to significantly reduce the temperature of the cutting tool which in turn reduces the diffusion wear rate (Figure 9c) and consequently increases tool life.

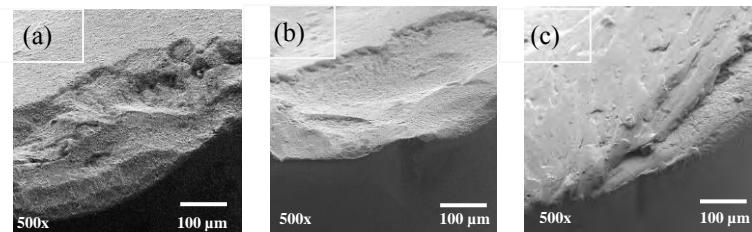

Figure 9. SEM images of worn inserts at optimum cutting conditions under (a) dry, (b) conv. coolant, and (c) HPC.

## Abstract—

In this paper we investigate the effects of stiffness, damping and temperature on the performance of a MEMS vibratory gyroscope. The stiffness and damping parameters are chosen because they can be appropriately designed to synchronize the drive and sense mode resonance to enhance the sensitivity and stability of MEMS gyroscope. Our results show that increasing the drive axis stiffness by 50% reduces the sense mode amplitude by ~27% and augments the resonance frequency by ~21%. The stiffness and damping are mildly sensitive to typical variations in operating temperature. The stiffness increases by 1.25%, while the damping decreases by 3.81%, when the temperature is raised from 0°C to 45°C. Doubling the damping reduces the oscillation amplitude by 80%, but ~1% change in the frequency. The predicted effects of stiffness, damping and temperature can be utilized to design a gyroscope for the desired operating condition.

## I. INTRODUCTION

Microelectromechanical systems (MEMS) based inertial sensors such as accelerometers and gyroscopes are the most commercially successful MEMS sensors to date. With the rapid advancement of semi-conductor based mass manufacturing, the cost, size and power consumption are continuously decreasing, enabling new applications in automotive, aerospace, biomedical and consumer electronics. MEMS vibratory gyroscopes are physical sensors that can detect and measure the angular motion of an object relative to an inertial frame of reference. MEMS vibratory sensors show promising vibration characteristics. Fabrication accuracies are comparable to macro-scale high performance sensors [1]-[4]. A vibratory gyroscope uses a vibrating structure (proof mass) to determine the rate of rotation [5]. The vibrating proof mass tends to vibrate along the same plane even if its support rotates. The Coriolis Effect causes the object to exert a force on its support, and the rate of rotation can be determined from the exerted force. The energy is transferred from the vibrating drive axis to the sense axis through Coriolis

force. The sense mode response detects the angular velocity. The sensing performance of the MEMS gyroscope can deteriorate because of the influence of time-varying parameters such as damping, cross stiffness, and environmental variations. They generate a frequency of oscillation mismatch between the two vibrating axes [6]. Due to fabrication imperfections and environmental effects, true values of resonant frequencies deviate from their nominal values (which is known as frequency mismatching). These lead to considerable reduction in the sensitivity of the gyroscope. Therefore, it is necessary to design proper stiffness and damping for achieving a robust gyroscope.

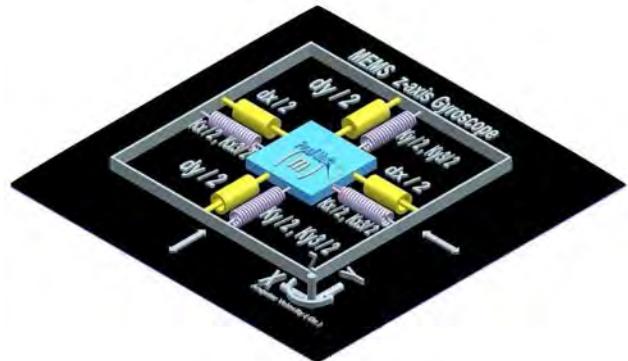

Figure 1. Schematic showing MEMS gyroscope model.

Optimization of time varying system parameters for better performance can be achieved by iterative modelling and simulation procedure. Various modeling techniques, including finite element analysis (FEA) modeling, analytical modeling and simplified lumped parameter modeling are employed [7]. FEA based modeling are robust, flexible and accurate in solving the complete multi-physics problem. Additionally, it can be coupled with controllers and electronics for selecting an appropriate controller [8].

Usually gyroscope displacement measurement varies under open loop scheme which can cause undesirable performance characteristics such as scale factor nonlinearity, limited dynamic range and narrow bandwidth [9]. In MEMS gyroscopes,

manufacturing imperfection and noises often exist which negatively influence the resolution and performance. Errors due to noise are inevitable in actual MEMS gyroscopes, and thus, the controller has to be robust and effectively designed [10]. Post-fabrication modeling of gyroscope using lumped-parameter techniques can shed light to the influence of system parameters, noise and environmental parameters on the gyro performance. This will allow iteration and design of a proper controller.

In this paper, a lumped-parameter model for predicting the gyroscope performance with the influence of various system parameters such as stiffness, damping and environmental condition (temperature) is analyzed. The results can be utilized to design a robust high performance gyroscope with efficient controller.

## II. MATHEMATICAL MODEL

In a vibratory gyroscope the main sensing element is the proof mass, which is suspended above the substrate by several flexible beams. The overall dynamic system is usually modeled as a 2 degrees-of-freedom (2-DOF) spring-mass-damper system, as shown in Figure 1. The proof mass is suspended on the substrate using four springs (Figure 1), the other end of the springs are anchored to the substrate. An electrostatic actuation is used to give an oscillatory motion to the proof mass in the drive axis. When the proof mass is subject to an angular velocity, energy is transferred from drive axis to sense axis, causing it to oscillate. The mechanism for sensing position and velocity of the proof mass along the sense axis is present. Constant velocity of the proof mass and changing angular velocity of gyroscope about the z-axis are assumed. The MEMS vibratory gyroscope model includes proof mass ( $m$ ), drive axis displacement ( $x$ ), the angular velocity input ( $\Omega_z$ ), and sense axis displacement ( $y$ ).

According to Lagrange's [11] equation, the dynamics of the gyroscope can be described by the equations of motion below [12]:

$$m\ddot{x} + d_{xx}\dot{x} + k_{xx}x + k_{xy}y + d_{xy}\dot{y} = u_x + 2m\Omega_z\dot{y} \quad (1)$$

$$m\ddot{y} + d_{yy}\dot{y} + k_{yy}y + k_{xy}x + d_{xy}\dot{x} = u_y + 2m\Omega_z\dot{x} \quad (2)$$

Manufacturing imperfections are translated mainly to the asymmetric spring and damping terms,  $k_{xy}$  and  $d_{xy}$ . The drive and sense axes spring and damping terms  $k_{xx}$ ,  $k_{yy}$ ,  $d_{xx}$  and  $d_{yy}$  are mostly known, but have small unknown variations from their nominal values. The proof mass can be determined accurately, and  $u_x$ ,  $u_y$  are the control forces in the x and y directions.

Dividing gyroscope dynamics by the reference mass, the following equation can be obtained [13]:

$$\begin{aligned} \ddot{q}^* + \frac{D^*}{m}\dot{q}^* + \frac{k_1^*}{m}q^* + \frac{k_3^*}{m} + q^{*3} \\ = \Omega_z^* q^* + S^* q^* + 2S^* \dot{q}^* + u^* \end{aligned} \quad (3)$$

where

$$q^* = \begin{bmatrix} x^* \\ y^* \end{bmatrix}, u^* = \begin{bmatrix} u_x^* \\ u_y^* \end{bmatrix}, D^* = \begin{bmatrix} d_{xx}^* & d_{xy}^* \\ d_{xy}^* & d_{yy}^* \end{bmatrix}, k_1^* = \begin{bmatrix} k_{xx}^* & k_{xy}^* \\ k_{xy}^* & k_{yy}^* \end{bmatrix},$$

$$k_3^* = \begin{bmatrix} k_{x^3}^* & 0 \\ 0 & k_{y^3}^* \end{bmatrix}, S^* = \begin{bmatrix} 0 & \Omega_z^* \\ -\Omega_z^* & 0 \end{bmatrix}$$

Angular rate variation may be considered to be negligible. The equations of motion of the gyroscope are normalized to generalize the model. The final non-dimensional equation is derived in terms of normalized time,  $t^* = \omega_0 t$ . With this, dividing both sides of the equation by the reference frequency and length gives [13]:

$$\begin{aligned} \ddot{q}^* + \frac{d^*}{m\omega_0}\dot{q}^* + \frac{k_1^*}{m\omega_0^2}q^* + \frac{k_3^*}{m\omega_0^2}q^{*3} \\ = \frac{\Omega_z^*}{\omega_0^2}q^* + 2\frac{S^*}{\omega_0}q^* + \frac{u^*}{m\omega_0^2} \end{aligned} \quad (4)$$

where the parameters are defined as follows:

$$\begin{aligned} q = \frac{q^*}{q_0}, d_{xy} = \frac{d_{xy}^*}{m\omega_0}, \Omega_z = \frac{\Omega_z^*}{\omega_0}, u_x = \frac{u_x^*}{m\omega_0^2} \frac{1}{q_0}, u_y = \frac{u_y^*}{m\omega_0^2} \frac{1}{q_0} \\ \omega_x = \sqrt{\frac{k_x}{m\omega_0^2}}, \omega_y = \sqrt{\frac{k_y}{m\omega_0^2}}, \omega_{xy} = \frac{k_{xy}}{m\omega_0^2}, \\ \delta_x = \frac{k_x^3}{m\omega_0^2}q_0^2, \delta_y = \frac{k_y^3}{m\omega_0^2}q_0^2 \end{aligned}$$

Consequently, the non-dimensional representation becomes

$$\ddot{q} + D\dot{q} + qk_1 + k_3q^3 = \Omega_z^2\dot{q} + 2S\dot{q} + u \quad (5)$$

where

$$\begin{aligned} q = \begin{bmatrix} x \\ y \end{bmatrix}, u = \begin{bmatrix} u_x \\ u_y \end{bmatrix}, D = \begin{bmatrix} d_x & d_{xy} \\ d_{xy} & d_y \end{bmatrix}, k_1 = \begin{bmatrix} \omega_x^2 & \omega_{xy} \\ \omega_{xy} & \omega_y^2 \end{bmatrix}, \\ k_3 = \begin{bmatrix} \delta_x & 0 \\ 0 & \delta_y \end{bmatrix}, S = \begin{bmatrix} 0 & \Omega_z \\ -\Omega_z & 0 \end{bmatrix} \end{aligned}$$

Simulation is done to observe the influence of stiffness, damping and temperature on gyroscope performance to minimize time and cost of expensive trial and error with the actual fabrication cycle.

MATLAB Simulink [14] is used for simulation and computation. Spring stiffness, damping coefficient and temperature are known to have significant influence on the output performance of gyroscope. Thus, the objective of the simulation is to quantify the effects of these parameters. The spring stiffness and damping coefficient are varied from half to double of their nominal values. The temperature is varied from  $0^\circ\text{C}$  to  $45^\circ\text{C}$  to observe the temperature effect on stiffness, damping coefficient and on sensing magnitude. For the simulation model, the nominal values for the proof mass, stiffness, and damping are extracted from the literature reported in [12]. Proof mass,  $m = 0.57\text{e}^{-8}\text{kg}$ , damping coefficient along the drive-axis,  $d_{xx} = 0.429\text{e}^{-6}\text{N s/m}$ , damping error due to manufacturing imperfection,  $d_{xy} = 0.0429\text{e}^{-6}\text{N s/m}$ , damping coefficient along the sense-axis,  $d_{yy} = 0.687\text{e}^{-36}\text{N s/m}$ , spring stiffness along the drive-axis,  $k_{xx} = 80.98\text{ N/m}$ , stiffness error

due to manufacturing imperfection,  $k_{xy} = 5$  N/m, spring stiffness along the sense-axis,  $k_{yy} = 71.62$  N/m, angular velocity,  $\Omega_z = 5$  rad/s are considered.

### III. MODEL RESULTS

#### A. Oscillation Frequency

To identify the first resonance frequency, input frequency is varied, a sinusoidal electromagnetic force is introduced at the drive-axis and output is sensed both in drive and sense directions (Fig. 2). Usually the drive mode displacement is higher compared to sense mode due to the energy transfer.

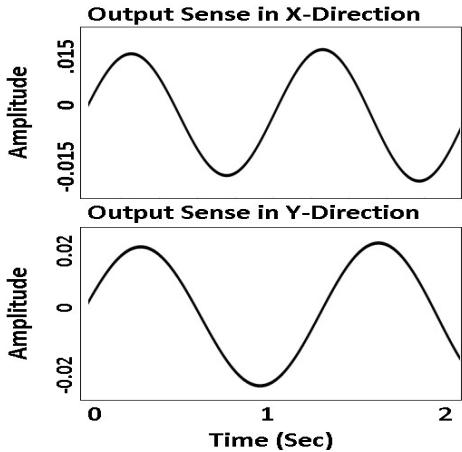

Figure 2. Displacement in drive mode (x) and sense mode (y) direction.

After sweeping the simulation with the frequency range of 1 kHz to 60 kHz (Fig. 3), the resonance frequency is found at around 9.4 kHz. So, for better focusing, the frequency range is restricted from 10 kHz - 30 kHz for other comparisons.

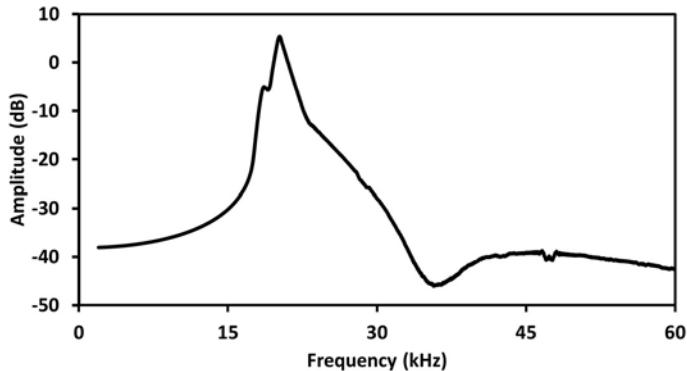

Figure 3. Frequency versus magnitude graph.

#### B. Variation in Stiffness

Suspension beam along drive and sense direction provides the stiffness necessary in each direction. Keeping the  $k_{yy}$  value constant at 71.62 N/m,  $k_{xx}$  is varied from 50% (normalized value 0.5) to 150% (normalized value 1.5). The normalized value of tuned reference stiffness (80.98 N/m) is considered as 1. It is observed that magnitudes at resonance frequencies show linear decreasing trend (Fig. 4) and amplitudes decrease (Fig. 5) as stiffness increases. However, decreasing the stiffness creates phase lag and distortion in output response.

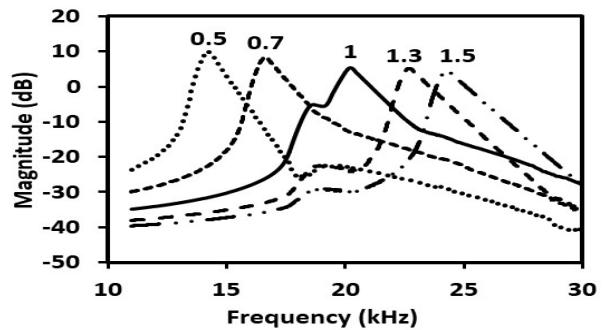

Figure 4. Effect of drive mode stiffness on resonance frequency and amplitude.

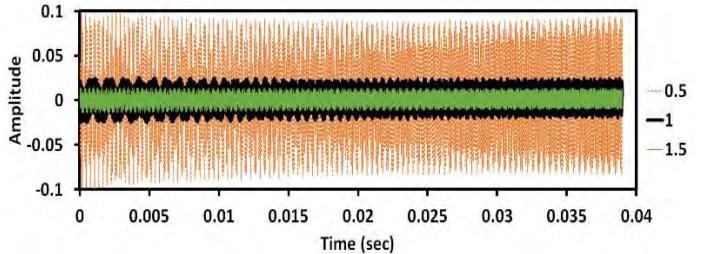

Figure 5. Effect of drive mode stiffness on output sense (sense mode stiffness is constant)

Keeping the  $k_{xx}$  value constant,  $k_{yy}$  is varied. It is observed that shift in resonance frequency is non-significant (Fig. 6).

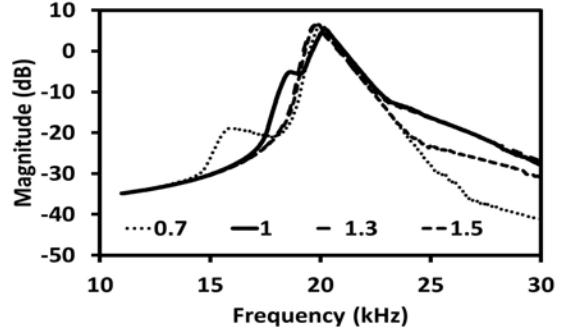

Figure 6. Effect of sense mode stiffness on magnitude (drive mode stiffness is constant).

Variation in stiffness ( $k_{xx}$  and  $k_{yy}$ ) along both axes decreases magnitudes at resonance frequencies and resonance frequencies shift towards higher frequencies (Fig. 7) and amplitudes also decreases as stiffness increases (Fig. 8).

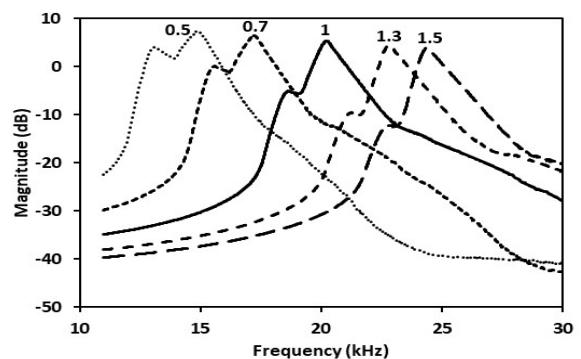

Figure 7. Combined effect of drive mode stiffness and sense mode stiffness on magnitude.

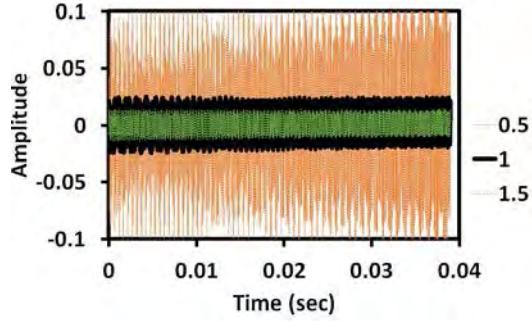

Figure 8. Effect of drive mode stiffness and sense mode stiffness on output sense.

### C. Variation in Damping

Here, damping along drive axis is varied (Fig. 9). It is obvious from the figure that the resonance frequencies do not change that much but slope steepness decreases after resonance frequencies.

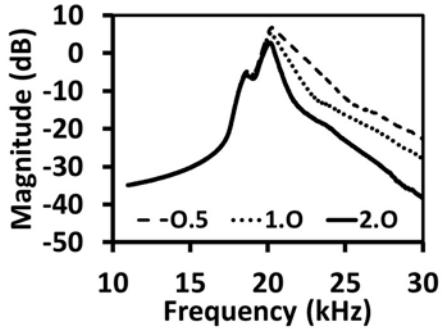

Figure 9. Effect of drive mode damping on magnitude.

### D. Temperature Variation

One key disadvantage of MEMS gyroscope is its high thermal sensitivity. The frequency of oscillation drifts with temperature. Temperature variation mainly affects the stiffness and damping of the supporting beams. Here investigation on the temperature sensitivity for stiffness and damping is done. The variation of stiffness with temperature can be modeled using simplified linear relationship of [7]  $K(T) = K_0(1 - k\Delta T)$ , where  $K_0$  is the stiffness coefficient at reference temperature 300 K and  $k=70$  ppm.

Variation of damping coefficient with temperature can be modeled as [7]  $d(T) = d_0 \cdot 1.28^{\ln(\frac{T}{300})}$ , where  $T$  is temperature in K,  $d_0$  is damping coefficient at reference temperature of 300 K. Magnitude shows positive increasing trend with the increase of temperature when stiffness and temperature relationship shows linear behaviour. The damping coefficient within industrial temperature range shows decreasing trend as temperature increases (Fig. 10, 11).

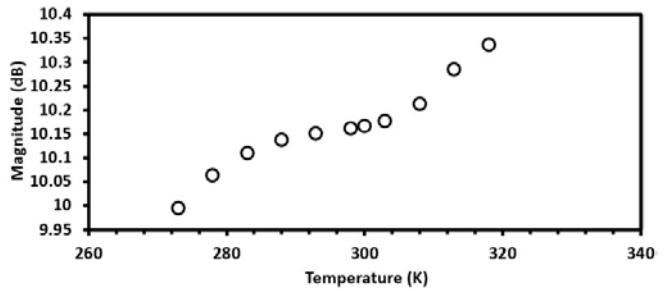

Figure 10. Effect of temperature on linear drive mode stiffness and magnitude

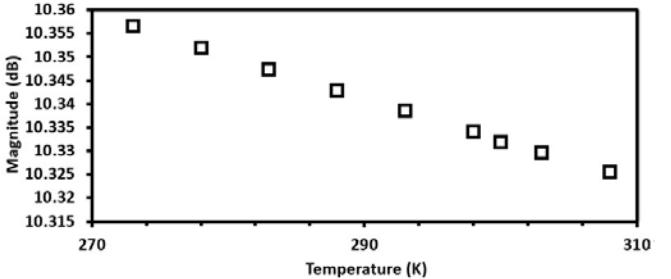

Figure 11. Effect of temperature on non-linear damping and magnitude

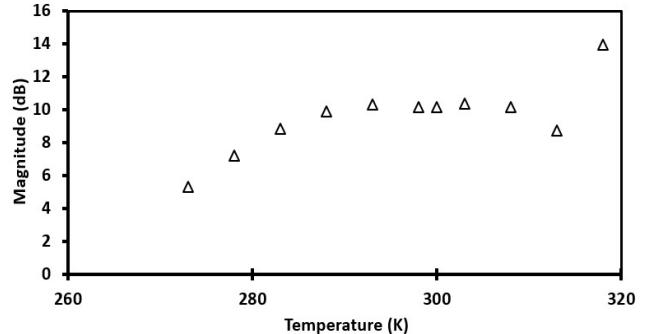

Figure 12. Effect of temperature on non-linear drive mode stiffness and magnitude.

The spring stiffness and temperature relationship shows non-linear behavior, the magnitude increases non-linearly up to a certain point before decreasing. At the end of the industrial temperature range, the magnitude increases drastically (Fig. 12).

## IV. CONCLUSION AND FUTURE WORK

This paper investigates the effect of variation of suspending stiffness coefficient, damping coefficient and temperature on the performance of MEMS gyroscope. Simulation results show how these parameters affect the error i.e. mismatch between the input and sense signals. This will help to design appropriate system parameters and controllers to increase gyroscope accuracy. Simulation results also show that stiffness is the dominant gyroscope parameter. The temperature can negatively impact resonance frequency and sense magnitude. In the future, we plan to extend this by including experimental validation of our results with MEMS gyroscopes and implementing a controller to minimize these effects and maximize the gyroscope performance.

## V. ACKNOWLEDGEMENT

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and University of Windsor for financial support.

# One-dimensional Fully Coupled Heat and Moisture Transfer Study Using the Finite Volume Method

Lam Dang, Wey H. Leong Alan S. Fung

Department of Mechanical and Industrial Engineering

Ryerson University

Toronto, Ontario

lam.dang@ryerson.ca, weyleong@ryerson.ca, alanfung@ryerson.ca

**Abstract**—In this paper, one-dimensional coupled heat and mass transfer is studied using the finite volume method. The simulated results are compared with the experimental results and show good agreements with the experimental data. Soil from Northern Victoria County (silt loam, a medium soil) is compacted in a cylinder with 5 heat pulse probes to measure the thermal and moisture responses. Moisture content at field capacity is used for the soil.

**Keywords:** *Heat and mass transfer, soil, numerical analysis, finite volume method, heat pulse*

## I. INTRODUCTION

Global warming is currently causing serious issues around the world such as typhoons [1], more diseases [2] for humans, and habitat damages [3]. Consequently, many governments around the globe have devoted heavy efforts in reducing global warming which results from heavy consumption of energies (mostly fossil fuels) [3, 4]. Renewable energies have been encouraged to be used as they are more environmental friendly than the fossil fuels. A highly abundant and attractive renewable energy is the solar radiation from the Sun.

In order to store the thermal energy from solar radiation, thermal energy storages (TESs) are needed. A common and widely used TES form is the ground thermal energy storage (GTES). Storing at higher temperatures in the GTESs can better utilize the GTES. Consequently, it is better to store the solar heat in high-temperature (above 40°C) ground because the heat can be readily retrieved for space heating without the use of a heat pump. A first-in-the-world example of successful application of using high temperature GTES is the Drake Landing Solar Community in Okotoks, Alberta, Canada. The GTES can provide 90% space heating needs for the Community. The ground in Okotoks contains mostly clay which has low moisture diffusivity, so the GTES in the Drake Landing Solar Community can store and retain most of the heat in the summer. However, not everywhere in the world has such type of soil. Therefore, understanding how heat and moisture transfer in various soil types at high temperatures is beneficial to the design of high-temperature GTES.

## II. GOVERNING EQUATIONS

Modeling transport phenomena in the ground has been of great interests. The pioneers in modeling include Philip and de Vries [5] and Luikov [6]. Governing equations were developed based on the soil's hydraulic conductivity, temperature gradients, moisture potential, and volumetric moisture content. Heat conduction incorporating latent heat transfer by water vapor diffusion was considered and generalized with moisture and latent heat storage in vapor phase and sensible heat transfer by liquid migration in the soil.

Another early work was done by Demsey [7] who studied the coupled heat and moisture transfer and applied the finite difference method to numerically study the one-dimensional moisture in Lakeland fine sand (AASHO Classification A-3) under isothermal conditions (maximum 25°C). Comparisons with laboratory experimental data showed good agreements between the numerical work and the lab data.

Rees *et al.* [8] and Janssen *et al.* [9] coupled heat and mass transfer equations to study how the moisture content affects the heat losses in underground structures. The researchers found that the coupled calculations give significantly higher heat losses than the calculations from simple heat and moisture transfer. In addition, the latent heat transfer by thermal vapor diffusion has a notable influence on the foundation heat loss.

Fully coupled heat and mass transfer equations can be formulated based on physical processes that occur in the soil can be described as follow [10]:

$$C_{\psi m} \frac{\partial \psi}{\partial t} + C_{Tm} \frac{\partial T}{\partial t} = \nabla \cdot (D_{\psi m} \nabla \psi) + \nabla \cdot (D_{Tm} \nabla T) + \frac{\partial K}{\partial z} \quad (1a)$$

$$C_{\psi T} \frac{\partial \psi}{\partial t} + C_{TT} \frac{\partial T}{\partial t} = \nabla \cdot (D_{\psi T} \nabla \psi) + \nabla \cdot (k_{eff} \nabla T) + C_{pw} \dot{m}_w \cdot \nabla T \quad (1b)$$

where  $C_{\psi m} = C_{\psi l} + C_{\psi v}$ ,  $C_{Tm} = C_{Tl} + C_{Tv}$ ,  $C_{\psi T} = \rho_l \cdot h_{fg} \cdot C_{\psi v}$ ,

$$C_{TT} = C_{soil} + \rho_l \cdot h_{fg} \cdot C_{Tv}, \quad C_{\psi l} = \left( \frac{\partial \theta_l}{\partial \psi} \right)_T, \quad C_{Tl} = \left( \frac{\partial \theta_l}{\partial T} \right)_\psi,$$

$$D_{\psi m} = K + D_{\psi v}, \quad D_{Tm} = D_{Tv}, \quad D_{\psi T} = \rho_l \cdot h_{fg} \cdot D_{\psi v},$$

$$\begin{aligned}
D_{\psi v} &= f(\theta_l) D_{va} \frac{\rho_{vs}}{\rho_l} \frac{\varphi g}{R_w T}, \quad \dot{m}_w = \rho_l u_l, \quad \varphi = \exp\left(\frac{\psi g}{R_w T}\right), \\
C_{\psi v} &= \frac{\rho_{vs} \varphi}{\rho_l} \left[ \frac{(\eta - \theta_l)g}{R_w T} - \left( \frac{\partial \theta_l}{\partial \psi} \right)_T \right], \quad C_{T_v} = \frac{\rho_{vs} \varphi}{\rho_l} \left[ \frac{\eta - \theta_l}{\rho_{vs}} \left( \frac{\partial \rho_{vs}}{\partial T} \right) - \left( \frac{\partial \theta_l}{\partial T} \right)_\psi \right], \\
D_{T_v} &= f(\theta_l) D_{va} \varphi \frac{\rho_{vs}}{\rho_l} \left[ \frac{1}{\rho_{vs}} \frac{\partial \rho_{vs}}{\partial T} - \frac{\psi g}{R_w T^2} + \frac{g}{R_w T} \left( \frac{\partial \psi}{\partial T} \right)_\theta \right] \frac{(\nabla T)_p}{\nabla T} \\
K &= K_{sat} \left[ \frac{1 - |\alpha \psi|^{n-1} (1 + |\alpha \psi|^n)^{-m}}{(1 + |\alpha \psi|^n)^{m/2}} \right]^2, \quad \frac{(\nabla T)_p}{\nabla T} = \xi \cdot \left( \theta_w + \xi_p \theta_p + \sum_{i=1}^n \xi_i \theta_i \right)^{-1}
\end{aligned}$$

and more definitions can be found in [10].

Eq. 1a is the moisture transfer equation in the soil and Eq. 1b is the energy transfer equation in the soil. The terms on the left hand sides correspond to the stored mass and energy due to the temporal change in matric potential and temperature. The first two terms on right hand sides account for the mass transfer (Eq. 1a) and heat transfer (Eq. 1b) respectively due to moisture and temperature gradients. The last term in Eq. 1a represents the mass transfer by gravitational effects while that in Eq. 1b is the sensible heat transfer by bulk liquid flow. The second term in square brackets of  $D_{T_v}$  is significant for  $\psi < -10^{-4} m$  while the third term is needed for  $\psi < -10^{-5} m$  [10].

As indicated by Deru [10], the last term on the right hand side (RHS) of Eq. 1b is significant for only a short period after a large influx of moisture such as rainfall or irrigation. In the present experiment, there is no moisture addition into the soil during experimentation; therefore, the last term on the RHS of Eq. 1b is ignored.

### III. EXPERIMENTAL SETUP

The soil used is called Victoria soil (coded NB2 [11]) from Northern Victoria County in New Brunswick, Canada. It is a silt loam with solid density of  $2540 \text{ kg/m}^3$ , 16.6% clay and 83.4% silt (by mass). The moist soil was prepared and packed carefully into a soil column.

In order to verify the governing equations (*i.e.*, Eq. 1), a soil cell assembly is made as shown in Fig. 1. The heat pulse method is used to obtain soil temperature response due to a heat pulse, and a computer program developed by Knight *et al.* [11] is used to post-process the temperature response data in order to determine soil thermal properties and moisture content.

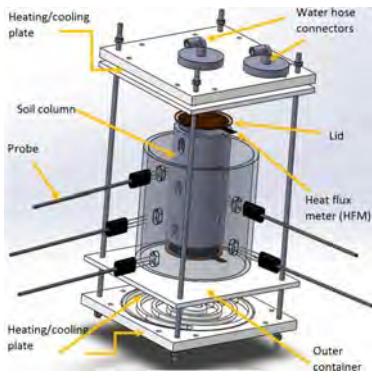

Figure 1. Soil cell assembly.

Fig. 2 shows a close-up view of a heat pulse probe. For ease of viewing the inner soil column in Fig. 1, the outer stainless-steel tube and lids are shown transparently. Water hose connectors are connected to thermally-controlled water baths (which provide the heating and cooling to the aluminum plates) through water hoses. The soil column is a stainless-steel tube (63.5 mm ID, 76.2 mm OD, 147.9 mm length) that has five slots for inserting five heat pulse probes. The heating/cooling plates are made of aluminum. The soil cell assembly is connected to a data acquisition system that collects experimental data.

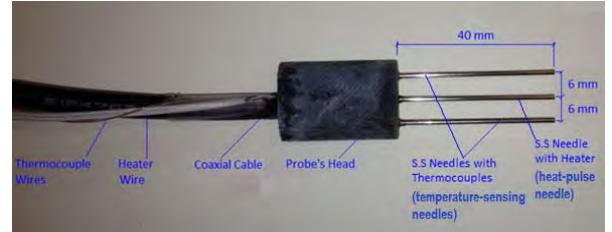

Figure 2. An in-house made heat pulse probe.

### IV. NUMERICAL SOLUTION

#### A. One-dimensional Discretization Formulations – Finite Volume Method

The one-dimensional finite volume formulations are developed according to the discretization scheme shown in Fig. 3 with the following assumptions:

- The height of the soil column is  $h$  (distance from node A to node B)
- There are  $n$  control volumes (CVs) along  $h$
- Each CV has length  $\Delta z$  of  $h/n$
- The distance from node A to node 1 is the same as that from  $n$  to B and is equal to  $\Delta z/2$
- There are  $n+2$  nodes
- The temperatures at nodes A and B are known at all times

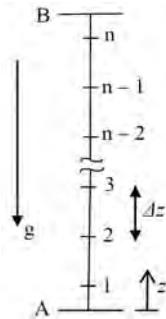

Figure 3. One-dimensional discretization scheme.

Discretizing Eq. 1 for nodes 2 to  $n-1$  gives:

$$a_1 \psi_P + a_2 T_P = a_3 \psi_N + a_4 T_N + a_5 \psi_S + a_6 T_S + G_1 \quad (3a)$$

$$b_1 \psi_P + b_2 T_P = b_3 \psi_N + b_4 T_N + b_5 \psi_S + b_6 T_S + G_2 \quad (3b)$$

where  $a_1 = C_{\psi_m} + a_3 + a_5$ ,  $a_2 = C_{T_m} + a_4 + a_6$ ,  $b_1 = C_{\psi_T} + b_3 + b_5$ ,

$$b_2 = C_{TT} + b_4 + b_6, \quad a_3 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi_m})_n, \quad a_4 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{T_m})_n, \quad \beta = 0.5$$

$$\begin{aligned}
a_5 &= \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi m})_s & a_6 &= \frac{\beta \Delta t}{(\Delta z)^2} (D_{Tm})_s & b_3 &= \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi T})_n & , \\
b_4 &= \frac{\beta \Delta t}{(\Delta z)^2} (k_{eff})_n & b_5 &= \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi T})_s & b_6 &= \frac{\beta \Delta t}{(\Delta z)^2} (k_{eff})_s & , \\

G_2 &= \left\{ C_{\psi T} - \frac{(1-\beta)}{\beta} [b_3^o + b_5^o] \right\} \psi_p^o + \left\{ C_{TT} - \frac{(1-\beta)}{\beta} [b_4^o + b_6^o] \right\} T_p^o & \\
&+ \frac{(1-\beta)}{\beta} \{b_3^o \psi_N^o + b_5^o \psi_S^o + b_4^o T_N^o + b_6^o T_S^o\}
\end{aligned}$$

where the superscript  $o$  means the value at previous time step, P means the centroid of the current CV being considered, N means the north of the CV's centroid, S means the south of the CV's centroid.

The temperatures at nodes A and B ( $T_A$  and  $T_B$ ) are measured in the experiment and therefore they are used as prescribed boundary temperatures. The moisture balance at nodes A and B, for impermeable surfaces due to the stainless-steel lids, is [10]:

$$0 = -K \frac{\partial \Phi}{\partial n} - D_{\psi v} \frac{\partial \psi}{\partial n} - D_{Tm} \frac{\partial T}{\partial n} \quad (4)$$

where  $\Phi = \psi + z$  with  $z$  being positive upwards ( $z = 0$  at node A) and  $\partial / \partial n = \partial / \partial z$ .

As a result of Eq. 4, the matric potential gradients at nodes A and B respectively are:

$$\frac{\partial \psi}{\partial z} \Big|_A = \frac{-1}{K + D_{\psi v}} \left( D_{Tm} \frac{\partial T}{\partial z} \Big|_{z=A} + K \right) \quad (5a)$$

$$\frac{\partial \psi}{\partial z} \Big|_B = \frac{-1}{K + D_{\psi v}} \left( D_{Tm} \frac{\partial T}{\partial z} \Big|_{z=B} + K \right) \quad (5b)$$

Applying Eq. 5a, the discretized governing equations at node 1 are:

$$a_1 \psi_1 + a_2 T_1 = a_3 \psi_2 + a_4 T_2 + a_5 \psi_A + a_6 T_A + G_1 \quad (6a)$$

$$b_1 \psi_1 + b_2 T_1 = b_3 \psi_2 + b_4 T_2 + b_5 \psi_A + b_6 T_A + G_2 \quad (6b)$$

where  $a_1 = C_{\psi m} + a_3 + a_5$ ,  $a_2 = C_{Tm} + a_4 + a_6$ ,  $b_1 = C_{\psi T} + b_3 + b_5$ ,  $b_2 = C_{TT} + b_4 + b_6$ ,  $a_3 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi m})_2$ ,  $a_4 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{Tm})_2$ ,  $a_5 = 0$ ,

$$a_6 = \frac{2 \beta \Delta t}{(\Delta z)^2} [(D_{Tm})_1 + (\Lambda_a)_1], \quad b_3 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi T})_2, \quad b_4 = \frac{\beta \Delta t}{(\Delta z)^2} (k_{eff})_2,$$

$$b_5 = 0, \quad b_6 = \frac{2 \beta \Delta t}{(\Delta z)^2} [(k_{eff})_1 + (\Lambda_b)_1], \quad \Lambda_a = \left( \frac{-D_{Tm} \cdot D_{\psi m}}{K + D_{\psi v}} \right)_1,$$

$$\Lambda_b = \left( \frac{-D_{Tm} \cdot D_{\psi T}}{K + D_{\psi v}} \right)_1, \quad K_1 \text{ means } K \text{ at node 1, and}$$

$(D_{xx})_1$  and  $(k_{eff})_1$  mean  $D_{xx}$  and  $k_{eff}$  of CV 1 respectively

$$\begin{aligned}
G_1 &= \left\{ C_{\psi m} - \frac{(1-\beta)}{\beta} a_3^o \right\} \psi_1^o + \left\{ C_{Tm} - \frac{(1-\beta)}{\beta} [a_4^o + a_6^o] \right\} T_1^o & , \\
&+ \frac{\beta \Delta t}{\Delta z} \left\{ K_2 - K_1 + \left( \frac{\Lambda_a K}{D_{Tm}} \right)_1 \right\} \\
&+ \frac{(1-\beta)}{\beta} \left\{ a_3^o \psi_2^o + a_4^o T_2^o + a_6^o T_A^o + \frac{\beta \Delta t}{\Delta z} \left( K_2^o - K_1^o + \left( \frac{\Lambda_b K}{D_{Tm}} \right)_1^o \right) \right\} \\
G_2 &= \left\{ C_{\psi T} - \frac{(1-\beta)}{\beta} b_3^o \right\} \psi_1^o + \left\{ C_{TT} - \frac{(1-\beta)}{\beta} [b_4^o + b_6^o] \right\} T_1^o . \\
&+ \frac{(1-\beta)}{\beta} \{b_3^o \psi_2^o + b_4^o T_2^o + b_6^o T_A^o\}
\end{aligned}$$

Applying Eq. 5b, the discretized governing equations at node n are:

$$a_1 \psi_n + a_2 T_n = a_3 \psi_{n-1} + a_4 T_{n-1} + a_5 \psi_{n-1} + a_6 T_{n-1} + G_1 \quad (7a)$$

$$b_1 \psi_n + b_2 T_n = b_3 \psi_{n-1} + b_4 T_{n-1} + b_5 \psi_{n-1} + b_6 T_{n-1} + G_2 \quad (7b)$$

$$\begin{aligned}
\text{where } a_1 &= C_{\psi m} + a_3 + a_5, \quad a_2 = C_{Tm} + a_4 + a_6, \quad b_1 = C_{\psi T} + b_3 + b_5, \\
b_2 &= C_{TT} + b_4 + b_6 \quad , \quad a_3 = 0 \quad , \quad a_4 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{Tm})_{n-1} \quad , \\
a_5 &= \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi m})_{n-1} \quad , \quad a_6 = \frac{2 \beta \Delta t}{(\Delta z)^2} [(D_{Tm})_n + (\Lambda_c)_n] \quad , \quad b_3 = 0 \quad , \\
b_4 &= \frac{\beta \Delta t}{(\Delta z)^2} (k_{eff})_{n-1}, \quad b_5 = \frac{\beta \Delta t}{(\Delta z)^2} (D_{\psi T})_{n-1}, \quad b_6 = \frac{2 \beta \Delta t}{(\Delta z)^2} [(k_{eff})_n + (\Lambda_d)_n], \\
G_1 &= \left\{ C_{\psi m} - \frac{(1-\beta)}{\beta} a_3^o \right\} \psi_n^o + \left\{ C_{Tm} - \frac{(1-\beta)}{\beta} [a_4^o + a_6^o] \right\} T_n^o \\
&+ \frac{\beta \Delta t}{\Delta z} \left\{ K_n - K_{n-1} + \left( \frac{\Lambda_c K}{D_{Tm}} \right)_n \right\} \\
&+ \frac{(1-\beta)}{\beta} \left\{ a_3^o \psi_{n-1}^o + a_4^o T_{n-1}^o + a_6^o T_B^o + \frac{\beta \Delta t}{\Delta z} \left( K_n^o - K_{n-1}^o + \left( \frac{\Lambda_c K}{D_{Tm}} \right)_n^o \right) \right\} \\
G_2 &= \left\{ C_{\psi T} - \frac{(1-\beta)}{\beta} b_3^o \right\} \psi_n^o + \left\{ C_{TT} - \frac{(1-\beta)}{\beta} [b_4^o + b_6^o] \right\} T_n^o \\
&+ \frac{(1-\beta)}{\beta} \{b_3^o \psi_{n-1}^o + b_4^o T_{n-1}^o + b_6^o T_B^o\}
\end{aligned}$$

$$\begin{aligned}
\Lambda_c &= \left( \frac{-D_{Tm} \cdot D_{\psi m}}{K + D_{\psi v}} \right)_n, \quad \Lambda_d = \left( \frac{-D_{Tm} \cdot D_{\psi T}}{K + D_{\psi v}} \right)_n, \\
\text{where } K_n &\text{ means } K \text{ at node } n, \text{ and } (D_{xx})_n \text{ and } (k_{eff})_n \text{ mean } D_{xx} \text{ and } k_{eff} \text{ of CV } n \text{ respectively.}
\end{aligned}$$

The initial conditions are as follows:

1. The temperatures at all nodes are at room temperature ( $\sim 23^\circ\text{C}$ )
2. The relative humidity ( $\phi$ ) of dry soil is the same as that of the lab room ( $\sim 23\%$ )
3. The initial moisture content in wet soil can be used to calculate the initial matric potential using van Genuchten's method [12].

## B. Solution Method

For faster convergence, the partial elimination algorithm (PEA) [13] is applied to Eqs. 3, 6, and 7 as follow:

$$a_1\psi_p + a_2T_p = \sum a_F^\psi\psi_F + G_3 \quad (8a)$$

$$b_1\psi_p + b_2T_p = \sum a_F^T T_F + G_4 \quad (8b)$$

where  $\sum a_F^\psi\psi_F = a_3\psi_N + a_5\psi_S$ ,  $G_3 = G_1 + a_4T_N + a_6T_S$

$$\sum a_F^T T_F = b_3T_N + b_5T_S, \quad G_4 = G_2 + b_4\psi_N + b_6\psi_S$$

The expressions for  $a_i$  and  $b_i$ ,  $G_1$  and  $G_2$  can be derived from Eqs. 3, 6, and 7 for the nodes.

Multiplying Eq. 8a with  $b_2$  and Eq. 8b with  $a_2$  and isolating  $\psi_p$ :

$$a_P^\psi\psi_p = \sum a_F^\psi\psi_F + B_P^\psi \quad (9)$$

where  $a_P^\psi = \frac{a_1b_2 - a_2b_1}{b_2}$  and  $B_P^\psi = G_3 - \frac{a_2}{b_2}(\sum a_F^T T_F + G_4)$

Similarly, multiplying Eq. 8a with  $b_1$  and Eq. 8b with  $a_1$  and isolating  $T_p$ :

$$a_P^T T_p = \sum b_F^T T_F + B_P^T \quad (10)$$

where  $a_P^T = \frac{a_1b_2 - a_2b_1}{a_1}$  and  $B_P^T = G_4 - \frac{b_1}{a_1}(\sum a_F^\psi\psi_F + G_3)$

Since the convection and diffusion coefficients are highly non-linear, an iterative approach is adopted from Moukalled and Saleh [13]:

1. Assume reasonable values for  $\psi (\psi_{guess})$  and  $T (T_{guess})$

2. Calculate the physical properties of soil using  $\psi_{guess}$  and  $T_{guess}$

3. Calculate the coefficients in Eqs. 3a, 6a, and 7a using  $\psi_{guess}$  and  $T_{guess}$

4. Obtain the coefficients in Eq. 9 using  $\psi_{guess}$  and  $T_{guess}$

5. Using tridiagonal matrix algorithm (TDMA), solve for nodal  $\psi$  values ( $\psi^i$ ) where  $i$  means current iteration and

$$\frac{a_P^\psi}{\varpi} \Big|_{\psi_{guess}} \psi^i = \sum a_F^\psi \Big|_{T_{guess}} \psi_F^i + B_P^\psi \Big|_{T_{guess}} + \frac{1-\varpi}{\varpi} a_P^\psi \Big|_{\psi_{guess}} \psi^{i-1}$$

6. Calculate the coefficients in Eqs. 3b, 6b, and 7b using  $\psi^i$  and  $T_{guess}$

7. Calculate the coefficients in Eq. 10 using  $\psi^i$  and  $T_{guess}$

8. Using TDMA, solve for nodal  $T$  values ( $T^i$ ) where  $i$  means current iteration and

$$\frac{a_P^T}{\varpi} \Big|_{\psi^i} T^i = \sum a_F^T \Big|_{\psi^i} T_F^i + B_P^T \Big|_{\psi^i} + \frac{1-\varpi}{\varpi} a_P^T \Big|_{\psi^i} T^{i-1}$$

9. Compare  $\psi^i$  and  $T^i$  with the corresponding  $\psi_{guess}$  and  $T_{guess}$  as:

$$\varepsilon_\psi = \frac{\psi^i - \psi_{guess}}{\psi_{guess}} \quad \text{and} \quad \varepsilon_T = \frac{T^i - T_{guess}}{T_{guess}}$$

10. If  $\varepsilon_\psi < 0.001$  and  $\varepsilon_T < 0.001$ , proceed to the next time step. Otherwise, repeat steps 1 – 9 with  $\psi_{guess} = \psi^i$  and  $T_{guess} = T^i$  and  $i$  in steps 5 – 9 becomes  $i+1$  and  $i-1$  becomes  $i$

### C. Matlab Code Validation

The computer code is programmed in Matlab. First, it is necessary to perform a grid sensitivity study for deciding the optimum amount of nodes for subsequent numerical study. Figure 4 shows a graph of the percentage root-mean-square differences of temperature ( $T$ ) and moisture content ( $\theta$ ) vs. number of nodes at time of 30 minutes with a simulation time-step of 1 s in the case of heating top of the soil column to 90°C and cooling the bottom to 10°C. The percentage root-mean-square difference (% RMS Difference) is defined as:

$$\frac{\% \text{ RMS Difference}}{100\%} = \sqrt{\sum_{i=1}^{n_{\text{fewer nodes}}} \left( \frac{\Xi_{2+3(i-1), \text{more nodes}} - \Xi_{i, \text{fewer nodes}}}{n_{\text{fewer nodes}} \cdot \Xi_{i, \text{fewer nodes}}} \right)^2} \quad (11)$$

where  $\Xi_i$  represents  $T_i$  or  $\theta_i$  at node  $i$  and  $n_{\text{fewer nodes}}$  is the total number of finite volumes or nodes in the case of fewer nodes. The successive increase of nodes is by tripling, i.e. more nodes =  $3 \times (\text{fewer nodes})$ , so that the same height points between the case of fewer nodes and the case of more nodes can be compared directly, i.e., node number of  $2+3 \times (i-1)$  in the case of more nodes has the same position as node number  $i$  in the case of fewer nodes.

From Fig. 4, it can be seen that, as the number of nodes increases, the successive percentage RMS differences of  $T$  and  $\theta$  become smaller, which means that the values of  $T$  and  $\theta$  are converging toward an infinite-node solution. Due to limited computing power, memory and time constraint, it is decided to use 4437 finite volumes for the rest of the numerical study. For this number of finite volumes, the percentage RMS differences of  $T$  and  $\theta$  between 4000 and 6000 nodes are less than 1.1%, and the size of each finite volume is about 33.3  $\mu\text{m}$ .

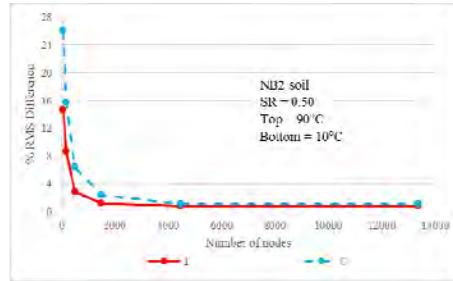

Figure 4. % RMS differences of  $T$  and  $\theta$  vs. number of nodes.

The next step is to validate the Matlab code by simulating two cases, namely: only heat transfer and only moisture transfer. For the first case, a soil column (assumed to be semi-infinite) of height of 2 m, density of 2,000 kg/m<sup>3</sup>, thermal conductivity of 2.51 W/m·K, heat capacity of 837.2 J/kg·K, porosity of 0.50, and initial uniform temperature 293 K are used. The top surface temperature of the soil is suddenly

raised to 310 K (or 37°C) at time  $t = 0$  and held constant. The numerical simulation is used to predict the temperature distribution in the soil after 1, 4, 9, 16, and 25 hours. The simulation time-step used is 1 s. The results obtained are compared to the analytical solution of transient pure conduction in a semi-infinite wall [A64], assuming the heat flows in the vertical direction only. The derivation of the analytical solution assumes constant thermal properties, so Case 1 is limited to small temperature difference of  $\Delta T = 310 - 293 = 17$  K to reduce the effect of temperature on the thermal properties.

Fig. 5 shows the temperature distributions of the semi-infinite soil column at different times from the numerical model (*i.e.*, Eq. 1) and the analytical solution. As shown in Fig. 5, the numerical solution from the Matlab code matches with the analytical solution.

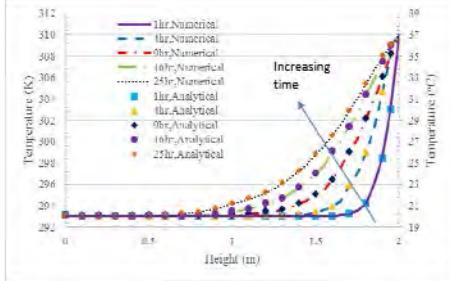

Figure 5. Temperature distributions of semi-infinite soil column at different times from numerical and analytical solutions.

For the second case, a column (0.4 m high, assumed semi-infinite) of Yolo light clay soil is used to study the moisture behavior in the soil under isothermal condition at the room temperature. The soil initially is not fully saturated and subjected to an inflow of liquid water at the top surface such that the matric potential at the top surface (*i.e.*,  $z = 40$  cm) is always constant at 0 or -25 cm. The matric potential at the bottom surface (*i.e.*,  $z = 0$  cm) is always held constant at -600 cm. Neglecting the vapor and thermal effects, the governing equation in one dimension can be written as [15]:

$$\left(\frac{\partial \theta}{\partial \psi}\right) \frac{\partial \psi}{\partial t} = \frac{\partial}{\partial z} \left( K \frac{\partial \psi}{\partial z} \right) + \frac{\partial K}{\partial z} \quad (12)$$

The initial and boundary conditions are:  $\psi(0, z) = -6$  m,  $\psi(t, 0.40)$  m = 0 m or -0.25 m, and  $\psi(t, 0)$  m = -6 m.

Fig. 6 shows the numerical and analytical (from Philip [15]) solutions of moisture distributions at four different times of  $10^3$  s (16.7 mins),  $10^4$  s (2.8 hrs),  $4 \times 10^4$  s (11.1 hrs) and  $10^5$  s (27.8 hrs) after moisture is first added at the top surface of the soil. As shown in the figure, when the top surface is fully saturated (*i.e.*,  $\psi$  is zero) or has a pool of water (*i.e.*,  $\psi$  is positive), more moisture can infiltrate into deeper places of the soil column. In addition, the water slowly infiltrates through the soil as clay is a fine soil which has low moisture permeability. Again, the numerical solution from the Matlab code matches very well with the analytical solution. After the two validations of the code, it is ready to simulate an actual experimental case and compare the results.

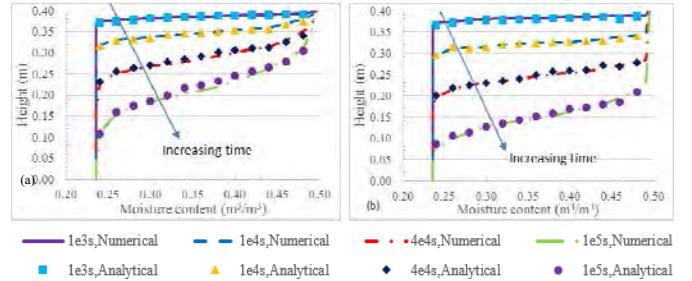

Figure 6. Moisture distributions in Yolo light clay soil column from numerical and analytical solutions for (a)  $\psi(t, 40 \text{ cm}) = 0 \text{ cm}$  and (b)  $\psi(t, 40 \text{ cm}) = -25 \text{ cm}$ .

## V. VERIFICATION OF EQ. 1

A comparison between numerical and experimental results is made for a case of vertical soil column with the top of the soil cell heated to 90°C and the bottom cooled to 10°C. The initial saturation ratio (SR) of the soil is 0.50 throughout the soil column. Each heat pulse probe can measure two positions of soil temperatures and moisture contents. Therefore, there are a total of ten positions from top to bottom of the soil column for the five probes; they are named N1 to N10, respectively. Fig. 7 shows the % Errors (in terms of  $T$  and  $\theta$ ) for all ten positions over the experiment period of 18 hours. The % Error is defined as follows:

$$\% \text{ Error} = 100\% \times \frac{(T \text{ or } \theta)_{\text{Eq.1}} - (T \text{ or } \theta)_{\text{experiment}}}{(T \text{ or } \theta)_{\text{experiment}}} \quad (13)$$

From the figure, it can be seen that the theoretical model (Eq. 1) over-predicts the moisture contents by as much as 6.2% at N1 but under-predicts the temperatures by as much as 2.1% at N1. When the moisture content is over-predicted, the temperature becomes lower as there is more moisture around the region, resulting in higher thermal capacitance of the soil. The top near N1 is the most critical region because it experiences high temperatures and thermal gradients

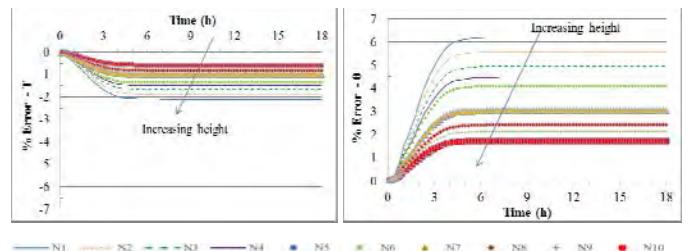

Figure 7. Percentage error of  $T$  and  $\theta$  (from Eq. 1) for NB2 soil ( $SR \approx 0.50$ ) and vertically heated from top.

## VI. CONCLUSION

The theoretical governing equations of fully coupled heat and mass transfer in soils by Deru [10] was used to study how the moisture and thermal responses behaved in a soil column containing a silt loam (NB2 soil) with initial moisture at field capacity, *i.e.* a saturation ratio of 0.5, and temperature settings of 90°C and 10°C at top and bottom plates. The one-dimensional discretization formulations by the finite volume

method were developed to numerically solve the governing equations. The numerical analysis was programmed in Matlab and verified to agree well with the existing literature. Running the Matlab code, the results showed good comparisons with the experimental results. The highest percent error appeared to be 6.2%. This is an encouraging preliminary result. Further experimental and numerical studies with different soils, temperature settings and initial moisture contents will be conducted to fully understand the coupled heat and moisture transfer in soils for high-temperature GTES.

## NOMENCLATURE

$C$	Volumetric heat capacity ( $J/m^3 \cdot K$ )
$C_p$	Specific heat capacity ( $J/kg \cdot K$ )
$C_{Tv}, C_{Tm}$	Thermal vapor and total moisture capacitances ( $K^{-1}$ )
$C_{\psi T}, C_{TT}$	Matric ( $J/m^4$ ) and thermal ( $J/m^3 \cdot K$ ) volumetric heat capacitances
$C_{\psi v}, C_{ym}$	Matric vapor and total moisture capacitance terms ( $m^{-1}$ )
$D_{va}$	Molecular diffusivity of water vapor in air ( $m^2/s$ )
$D_T$	Thermal diffusivity ( $m^2/s$ )
$D_\theta$	Isothermal moisture diffusivity ( $m^2/s$ )
$D_{Tv}, D_{Tm}$	Thermal vapor and total moisture diffusivities ( $m^2/s \cdot K$ )
$D_{\psi v}, D_{\psi m}$	Matric vapor and total moisture diffusivities ( $m^2/s$ )
$D_{\psi T}$	Matric potential heat diffusivity ( $W/m^2$ )
$f), f$	Correction and interpolation factors
$g$	Gravitational acceleration ( $= 9.804 m/s^2$ )
$h_{fg}$	Latent heat of vaporization ( $J/kg$ )
$K$	Hydraulic conductivity of soil ( $m/s$ )
$k$	Thermal conductivity ( $W/m \cdot K$ )
$\dot{m}$	Mass flux ( $kg/m^2 \cdot s$ )
$P$	Total pressure in pore spaces ( $Pa$ )
$P_v$	Partial vapor pressure in pore spaces ( $Pa$ )
$r$	Radius ( $m$ )
$R_w$	Specific gas constant for water vapor ( $= 461.5 J/kg \cdot K$ )
$S$	Surface area ( $m^2$ )
$t$	Time ( $s$ )
$u$	Bulk velocity ( $m/s$ )
$T$	Temperature ( $K$ or $^\circ C$ )
$z$	Vertical distance ( $m$ )

### Greek symbols

$\nabla$	Del operator ( $m^{-1}$ )
$\epsilon$	Convergence criteria
$\eta$	Soil porosity ( $m^3$ of pore space per $m^3$ of soil)
$\kappa$	Permeability of soil ( $m^2$ )
$\mu$	Dynamic viscosity ( $kg/m \cdot s$ )
$\sigma$	Relaxation factor of iteration
$\psi$	Matric liquid (capillary) potential (pressure head) ( $m$ )
$\Phi$	Total soil matric potential for liquid flow ( $m$ )
$\rho$	Density ( $kg/m^3$ )
$\sigma_{wa}$	Surface tension of water in air ( $N/m$ )
$\tau$	Empirical constant used in hydraulic conductivity equation
$\theta$	Volumetric moisture content/fraction ( $m^3$ of water per $m^3$ of soil)
$\Theta$	Degree of saturation
$\varphi$	Relative humidity
$\xi$	Temperature gradient ratio ( $= (\nabla T)_p / (\nabla T)$ )
$\Xi$	Dummy variable that represents another/other variable(s)

### Subscripts

$a$	Air
$c$	Critical

$CV$	Pertaining to control volume
$eff$	Effective
$l$	Liquid
$p$	Pore
$ref$	Reference
$s$	Solid
$sat$	Saturation
$sv$	Saturated vapor
$T$	Pertaining to thermal conditions
$tot$	Total
$\psi$	Pertaining to moisture conditions
$v$	Vapor
$w$	Water

### Superscripts

$T$	Transpose
$i$	Current iteration

**Abstract**— In this paper we study the thermal performance of a 5 kW rectifier module experimentally and numerically, with the aim of changing the cooling methodology from an active cooled (fan cooled) to a passively cooled system. Numerical model of the rectifier for fan cooled operation is developed and experimentally validated, following which the critical components in the system are identified. In this system, magnetic components like transformers were observed to have the poorest thermal performance. Given the lack of attention thermal management of magnetic components has received compared to switching components, we numerically study the thermal performance of a PQ 40/40 transformer in a passive (natural convection) scenario. Modifications to the transformer structure were studied and the heat transfer from the transformer was observed to be convection limited (large convection thermal resistance). Providing a minimum resistance conduction path from effective hot spot to ambient was observed to be the best practice. Further, providing a heat transfer path between the coil and core was observed to be crucial to transformer thermal performance.

**Keywords - thermal management; CFD; passive cooling; PQ 40/40 transformer;**

## I. INTRODUCTION

Power electronic systems play a vital role in telecommunication, aerospace and various other industries. Modern day power electronic systems generally run at high efficiencies due to the application of innovative conversion topologies. Despite this, a significant amount of heat is dissipated, especially for high power rated electronic systems.

The need for thermal management of electronic systems has been accentuated by both the tendency of components to fail at

elevated temperatures and the trend of miniaturization of transistors in switching devices over the years. This is evidenced by the Arrhenius law [1], which states that device failure rates increase exponentially with operating temperature and by Moore's Law which states that the number of transistors in Integrated Circuits (ICs) approximately doubles every two years [2] respectively. This miniaturization of switching components has led to increased heat fluxes due to reduction of area available for heat transfer and increase in power dissipation. Modern day semiconductors are reported to dissipate around 1-100 W/cm<sup>2</sup> of heat [3].

Active cooling methods like fan cooling are the most commonly used cooling methodology for such electronic systems. Although this is a simple method and can handle thermal loads up to 0.04 W/cm<sup>2</sup> [4], it faces some drawbacks. Fan cooled systems generally consume parasitic power [5] and have low reliability. Further, fans produce a lot of noise and cannot be implemented in locations with strict acoustic regulations. The reliability and robustness offered by passive cooling systems has drawn attention, especially in the renewable energy sector for outdoor applications where access for maintenance is limited.

Irrespective of the cooling methodology, providing a system/module level cooling solution would require understanding of component level heat transfer before a foray is made into providing a system level cooling modification. The heat transfer characteristics of switching components like IC's and MOSFETS have been extensively studied by numerous authors [6]-[7] and the thermal bottlenecks have been identified. Magnetic components in such systems has received less attention. Biela and Kolar *et al.* [8] studied thermal performance of a transformer using a heat transfer component as an insert, Pavlovsky *et al.* [9] similarly used a conduction based methodology using a heat pipe for heat

removal from hot spot. Apart from a few studies, most studies on transformer thermal management are limited to large scale oil cooled power transformers [10]-[11].

This study evaluates the thermal management of conventional PQ 40/40 transformers used in power conversion systems to achieve passive cooling.

## II. PROBLEM DEFINITION

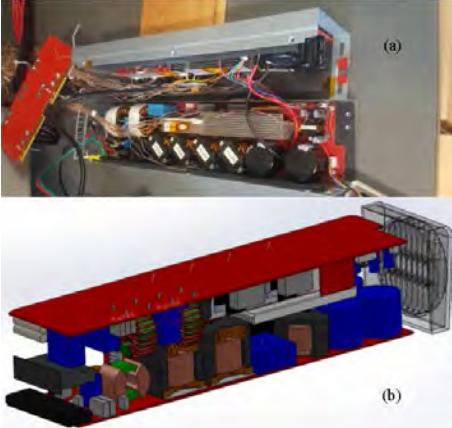

Figure 1. (a) Unbolted module under study. (b) CAD model of the module without chassis to highlight internal details

The objective of our research is to redesign a power module as shown in Fig. 1(a) from an active (fan cooled) to a purely passive design. The system in question is a 5 kW rated rectifier power module operating at 240 V AC input and providing 54 V DC output. The internal geometry of the power module can be visualized in Fig. 1(b) while the unbolted view of the module can be seen in Fig. 1(a).

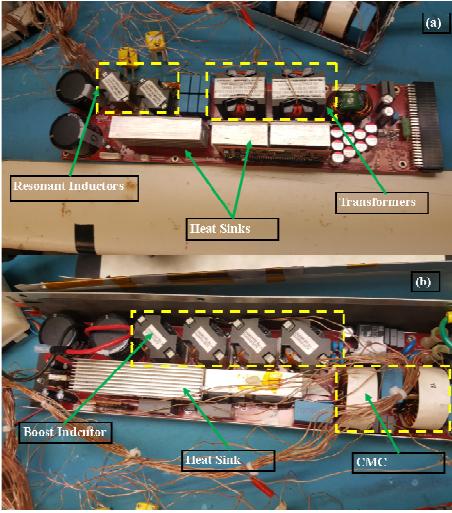

Figure 2. (a) DC-DC converter. (b) PFC converter

This power rectifier module utilizes two distinct topologies, the Power Factor Correction (PFC) converter and the DC-DC converter. The PFC converter provides a modulated signal to the DC-DC converter, which in turn provides the required DC output. The major heat dissipating components on the DC-DC side and PFC side can be seen in Fig. 2(a) and Fig. 2(b)

respectively, with the switching components being mounted on the heat sinks

The two converters constituting the power conversion system are fixed facing each other as seen in Fig. 1 (b) with the PFC side on the top and DC-DC on the bottom. The system runs at an efficiency of 95.7 % at full load and dissipates around 202 W. This configuration has been designed for fan cooling, using a 12 VDC rated Delta model AFB0712SHCCM fan.

Now, to realize passive cooling of such a design, we follow the research methodology as described in Fig. 3.

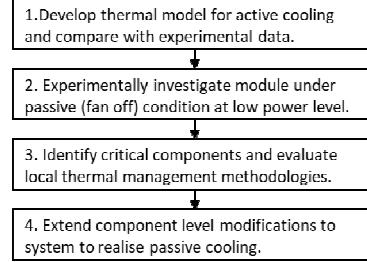

Figure 3: Research Methodology

The first step of our study is to develop a computational model for the current (fan cooled) operation of the system/module and compare with numerical results. This is to help validate our modelling methodology.

Once we have established confidence in our modeling methodology, the module is tested with its fan off at a low power level. This would help us characterize the challenge of passive cooling for such a design and help identify the critical components. Once the critical components are identified, the best practice is to study these components in isolation instead of analyzing their thermal performance in a system/module analysis. Further, if we can locally manage the heat being dissipated from these critical components, the system level thermal management is greatly simplified and the local thermal management methodology can be extended to the system level thermal management concept.

## III. EXPERIMENTAL SETUP

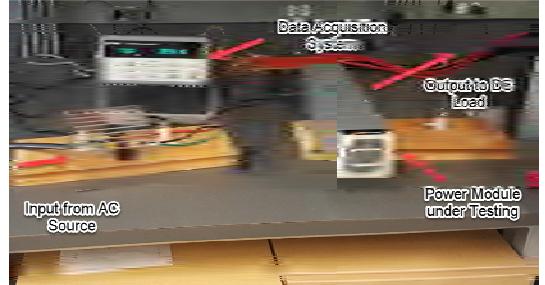

Figure 4: Experimental Setup for module under testing.

The experimental setup can be visualized in Fig. 4. Chroma model 6460 programmable AC source was used to provide a 240V AC input to the unit under testing while a Chroma model 63204 DC electronic load was used as the output. The thermal performance of the module was evaluated by attaching K type

thermocouples to components that dissipate heat. Keystone model 34970A data acquisition system was used to connect to the thermocouples for datalogging.

The fan cooled experimental analysis of the module was run until the temperature variation was less than 2 °C within one hour, which was considered as steady state. In this condition the module was run at multiple power levels. The passive (no fan) thermal testing on the other hand was done at a low power level of 0.5 kW (10% full load) as the module is designed for active (fan) cooling and the thermal performance can be expected to be poor. Further, the real time thermocouple data was closely monitored and the system was shut off when component temperatures were close to their safe operating threshold temperature.

#### IV. NUMERICAL ANALYSIS

This section discusses the numerical methodology followed by this study. This section will be divided into two parts. The first discusses the analysis methodology for active cooling (with fan) of the module (system level simulation) while the other discusses the analysis methodology of an isolated PQ 40/40 transformer (component level) in a natural convection scenario. All simulation results are for steady state.

##### A. Active Cooling of Power Module

The computational domain under study can be seen in Fig. 5. The numerical modelling and simulation is carried out using commercially available CFD software ANSYS Icepak. The dimensions of the domain are 0.08 m, 0.07596 m, 0.37935 m in the x, y and z direction respectively. The module is enclosed by an aluminum chassis. The fan can be seen in Fig. 5 and the flow rate depends on the fan curve, which is provided as an input to the solver. The other face highlighted in dark blue in Fig. 5 is open to the ambient.

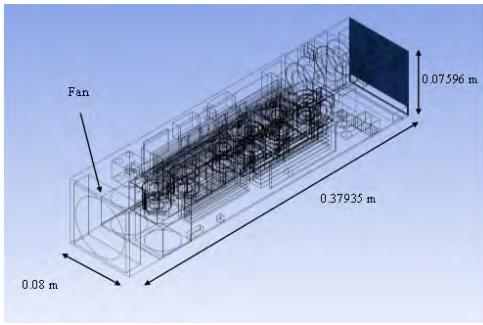

Figure 5: Active cooling computational domain, face open to ambient is highlighted in dark blue.

Convective boundary condition of 5 W/m<sup>2</sup>·K is applied to the external walls of the chassis, while the outlet (highlighted in Fig. 5) is open to ambient pressure (1 atm) and temperature (22 °C). RNG k-ε turbulence model is used to model the turbulent nature of the flow. No slip boundary condition is applied at solid-fluid interfaces.

A control volume method was used to discretize the domain and a semi-implicit method for pressure linked equation (SIMPLE) method was used for pressure-velocity coupling.

The discrete algebraic equations are solved by a point implicit (Gauss Seidel) method in conjugation with an Algebraic Multigrid (AMG) method. This helps reduce the computational time required for each simulation. The conservation equations being solved for are (1), (2) and (3) in the fluid domain and (3) in the solid domain (reduces to simple conduction equation).

$$\frac{\partial \rho}{\partial t} + \nabla(\rho \vec{v}) = 0 \quad (1)$$

$$\frac{\partial}{\partial t}(\rho \vec{v}) + \nabla(\rho \vec{v} \vec{v}) = -\nabla P + \nabla(\bar{\tau}) + \rho \vec{g} + \vec{F} \quad (2)$$

$$\frac{\partial}{\partial t}(\rho h) + \nabla(\rho h \vec{v}) = \nabla[(k+k_t) \nabla T] + S_h \quad (3)$$

Here,  $\rho$  is density,  $\vec{v}$  is velocity vector,  $P$  is pressure,  $\bar{\tau}$  is the stress tensor,  $\vec{F}$  is the source term,  $h$  is enthalpy,  $k$  is the molecular thermal conductivity,  $k_t$  is the conductivity due to turbulent transport,  $T$  is temperature and  $S_h$  is the source term like volumetric heat generation.

The convergence criteria is fixed at  $10^{-4}$  for velocity and  $10^{-7}$  for energy. As for the mesh, unstructured tetrahedral cells are generated by in house meshing software Mesher-HD. The mesh density is higher near the surface of solids to ensure resolution of boundary layer. The total mesh count is around 6531290 cells.

##### B. Isolated PQ 40/40 transformer

The computational domain used for this analysis can be seen in Fig. 6. The dimensions are 0.088 m, 0.053616 m, 0.2 m in the x, y and z directions respectively. The dimensions of the transformer itself can be readily found in manufacturer datasheets [12]. The transformer is mounted on a PCB (highlighted in yellow) and enclosed in an aluminum chassis. The domain is set such that it is representative of the small form factor characteristic of such problems.

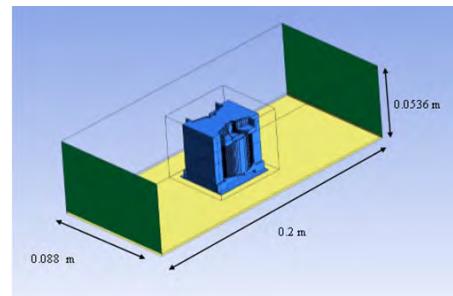

Figure 6: Computational domain for isolated PQ transformer under study, faces open to ambient highlighted in green.

A convective boundary condition of 5 W/m<sup>2</sup>·K is applied to the external walls of the chassis. The other two faces, as highlighted in green, are open to ambient. One of the key assumptions made in modelling such a transformer, is that the windings are approximated/modelled as a foil.

The same conservation equations and solvers have been used as the previous active cooling analysis. The only change is that, in this case the flow is entirely laminar and no turbulence model is employed. But to characterize natural convection, the Boussinesq approximation is used. The convergence criteria is

again set as  $10^{-4}$  for velocity and  $10^{-7}$  for energy. The mesh element count is around 1841815 cells.

## V. RESULTS

The organization of this section will follow the research methodology as described in Fig. 3.

### A. Active cooling: experimental vs numerical

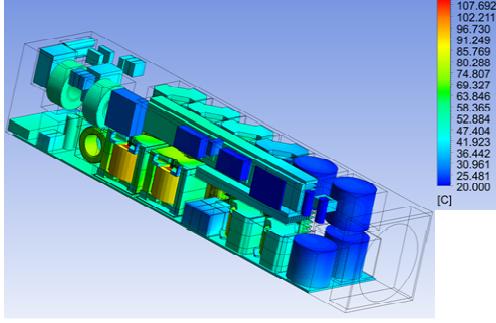

Figure 7: Temperature contour for active (fan cooled) operation of power module at 4.5 kW. The thermal contours of the top PCB is not shown.

The experimental and numerical test was run for multiple power levels. Fig. 7 shows the global temperature contours for the module at a power level of 4.5 kW. Table. 1 shows the comparison between the experimental and numerical results at 4.5 kW. The model can predict temperature within 10-15% of its experimental values. The results for other power levels were excluded for the sake of brevity. Given the complexity of the problem, we were satisfied with our modelling methodology and progressed to the next step of the analysis.

Table 1: Comparison of experimental vs numerical results for a few components at 4.5 kW for active cooling condition.

Component	Experimental (°C)	Numerical (°C)	Error
Transformer winding inside (1 <sup>st</sup> )	112	107	-4.46
Transformer Core	56	53	-5.35
Primary MOSFET	50	55	10
Secondary MOSFET	57	62	8.77
Resonant inductor inside	93	85	-8.6
Resonant capacitor	44	40	-9

### B. Experimental passive cooling (0.5 kW)

Fig. 8 shows the temperature versus time plot for passive (fan off) testing of the module at 0.5 kW. From Fig. 8 we can see that the curve has not yet reached steady state as the test was shut off as specified in the previous sections. The components with the poorest thermal performance are the transformers and the MOSFETs on the DC-DC side. The components on the PFC side of the rectifier show relatively good thermal performance. The temperature within the primary windings of the first transformer (first from the end open to ambient) is the global hot spot in this system. Given the slope of the curve we can assume that the system would have failed if

run for longer. The test is clearly indicative of the transformer being the most critical component in this system.

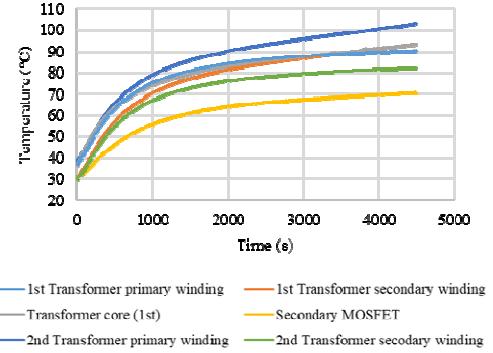

Figure 8: Thermocouple data for fan off testing condition at 0.5 kW. Only critical components are shown.

### C. Isolated PQ 40/40 transfromer (Component Level)

Now that we have established that the transformer is the most critical component in a passive (fan off scenario). We study the results of our component level thermal analysis.

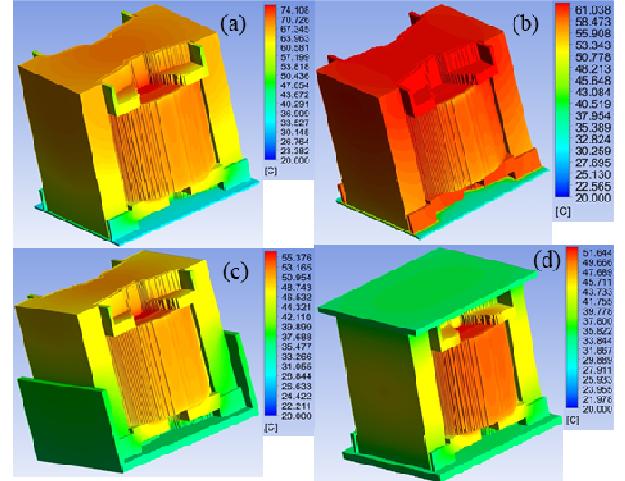

Figure 9. (a) Thermal contour of conventional PQ transformer (5 W loss). (b) Thermal contour of transformer with internal modification. (c) Thermal contour of transformer with external modification 1 (U clamp). (d) Thermal contour of transformer with external modification 2 (double sided cooling).

Fig. 9(a) shows the thermal contour of a conventional PQ 40/40 transformer dissipating a total of 5 W (4 W copper loss and 1 W iron loss). We can observe that the hot spot is predicted to be inside the primary winding. Further we observe a large temperature gradient between the internal structure of the transformer and the core side leg. This is indicative of a large internal thermal resistance.

Now, let us highlight the modifications and their corresponding effects on thermal performance.

1) *Internal Modification* : Change of bobbin material from thermosetting plastic to Ceramic (ALN).

The role of bobbin in a transformer is to provide mechanical support to the winding structure whilst also providing electrical insulation. Bobbins are generally made

from plastics like Polytetrafluoroethylene (PTFE) which are characteristic of a low thermal conductivity ( $k \sim 0.25 \text{ W/m}\cdot\text{K}$ ). Ceramic materials like Aluminum Nitride (ALN) has similar electrical insulating characteristics as plastics (insulation of around 15 kV/mm), while possessing superior thermal characteristics ( $k \sim 150 \text{ W/mK}$ ). The first modification we study is changing the bobbin material from plastic (PTFE) to ALN. Fig. 9 (b) shows the temperature contour for this modification, we can see that heat spreading is greatly improved and the transformer almost behaves like a lumped thermal mass. The hot spot is also reduced by around 13 °C. An interesting property of ferrite cores (3C96 in this case) is lower iron loss and better thermal performance at elevated temperatures (around 100 °C). Hence, providing a heat transfer path between the core and windings is beneficial not just to thermal performance but also the magnetic performance of the core.

2) *External Modification 1* : U clamp made of ceramic, bonded to the bottom of the transformer to provide a conduction path to the chassis of the module. The PCB layer is cut through to provide a direct path to the chassis

Liu *et al.* [13] observed that providing ceramic inserts within the ferrite core is beneficial to heat transfer in a natural conduction scenario. We similarly extended this finding to our case by bonding a U-clamp (base plate:  $0.038 \text{ m}^2 \times 0.0445 \text{ m} \times 0.002 \text{ m}$ , side legs:  $0.038 \text{ m}^2 \times 0.021076 \text{ m} \times 0.001 \text{ m}$ ) to the bottom of the transformer and connecting it directly to the chassis by cutting through the PCB layer. The thermal benefit of such a modification can be seen in Fig. 9(c), we can observe a reduction in hot spot temperature of around 20 °C. Due to the small factor characteristic of such transformers and low heat transfer coefficient (HTC) in natural convection scenario (around 10 W/m<sup>2</sup>·K for the core side leg,) the convective resistance to air within the module is very high and providing a purely conductive heat transfer path to the ambient is greatly beneficial to heat transfer.

3) *External Modification 2*: Double sided cooling to provide a conduction path from the transformer to the chassis on both top and bottom sides.

In this modification, we provide a ceramic interface ( $0.038 \text{ m}^2 \times 0.0445 \text{ m}^2 \times 2 \text{ m}$ ) between both the bottom and top surface of the transformer and the chassis. Generally, most electronic packaging methodologies have a large air gap between the components and the top of the chassis. This air gap is not very beneficial to heat transfer in a natural convection scenario (low HTC, around 5 W/m<sup>2</sup>·K). We circumvent this by directly bonding it the top of the transformer to a ceramic interface. This modification provides a conduction path to the ambient in two directions. The benefit of this modification can be seen in Fig. 9 (d), with a reduction in hot spot temperature of around 24 °C. This holds good with our finding that the heat transfer for a PQ transformer in a natural convection scenario is convection limited and providing a minimum resistance conduction path to the ambient is the best practice for thermal management.

Although the modifications we study are an ideal case, as there is no conjugate heat transfer between different

components and there is a large dedicated chassis area for heat dissipation to ambient, we can clearly see that providing a minimum resistance path from the transformer to the chassis is the best thermal management practice to realize passive cooling.

## CONCLUSION

In this study, experimental and numerical analysis was carried out for a 5 kW rectifier power module. Critical components in this system were identified to be magnetic components like transformers. Numerical model for the fan cooled operation was validated with experimental results. Further, numerical model of a PQ 40/40 transformer was developed and studied from a passive cooling point of view. The heat transfer was observed to be convection limited and providing a minimum resistance conduction path to ambient was observed to be the best practice to realize passive cooling. Modifications of the bobbin material was also studied and the importance of providing a heat transfer path between the core and coil was observed to be beneficial for both heat transfer and general operation of the core. The effect of these changes is yet to be evaluated experimentally.

# Analytical heat conduction model of annular composite fins

Chen Feng, Subramaniam Yugeswaran, Michael Gibbons, Sanjeev Chandra

Mechanical and Industrial Engineering,  
University of Toronto  
Toronto, ON, Canada

**Abstract** — A two-dimensional analytical heat conduction model of an annular composite fin has been carried out. The composite fins composed of a porous polyethylene core, a square aluminum insert, and metallic zinc coating layers, was fabricated using wire-arc spraying technology. Analytical solutions of temperature distribution, energy dissipation and fin efficiency through the fins at natural convection condition have been proposed.

**Keywords – composite fins; heat conduction; analytical model.**

## II. INTRODUCTION

Composite fins are used in industrial applications such as heat exchangers and heat sinks [1]. In such composite fins the thermal conductivities of the coating ( $k_c$ ) and substrate ( $k_s$ ) materials differ and the total heat transfer depends on the thermal conductivity ratio ( $k_c/k_s$ ). If this ratio is less than unity the coating material is less conductive than the substrate and insulates the fin, whereas a ratio greater than unity means that the coating enhances heat transfer.

Cortes [2] developed analytical solutions for heat transfer in composite fins with variable thickness varying the  $k_c/k_s$  from 0.04 to 13.6, which reflects combinations of metals commonly used in practical applications. Luna-Abad and Alhama [3] optimized the dimensions of composite rectangular fins while varying thermal conductivity ratios and convective heat transfer coefficients. Tu [4] derived analytical solutions for the efficiency of composite fins made of a metallic core and a coating with lower thermal conductivity.

In this paper we carry out an analytical model of heat conduction through an annular composite fin, consisting of a polymer substrate on which a thin metal coating was applied by wire arc spraying to enhance heat conduction. This model was developed assuming a two-dimensional conduction in the thicker polymer core and one-dimensional conduction in the thin coating layer because of their transverse thermal resistances. The model was validated by comparing predicted temperature variations with experimental measurements. The model was used to examine the effect of varying coating thickness and fin dimensions on heat dissipation and efficiency of the fins.

## III. FABRICATION AND EXPERIMENTAL SETUP

### A. Fabrication of composite fins

Wire-arc spraying was used in this study, in which an electric arc is struck between the tips of two continuously fed wires to melt them. A high velocity air jet strips the molten metal from the wires and creates a spray of droplets that impact on the substrate. This was used to coat a polyethylene sheet with zinc, which has a relatively low melting point (420°C) and did not damage the substrate during coating.

A composite fin was made by laser cutting a 148 mm diameter disk from a 3.2 mm thick sheet of polyethylene. An aluminum block, 3.2 mm thick and 22 mm square was inserted into the center of the disk as shown in Fig. 1a and bonded to it using thermally conductive epoxy (DP270, 3M, St. Paul, USA). The relatively high thermal conductivity of the aluminum (200 W/mK) ensured a uniform temperature that was used as a boundary condition in the analytical model. The model assumed radial symmetry and the fin was assumed to be an annulus with an internal radius of 11 mm and an outer radius of 74 mm.

An electric wire arc spray system (ValuArc, Sulzer Metro Inc., Westbury, NY), mounted on a robot arm, was used to melt and spray high purity zinc wires (Catalog# 1031592, Sulzer Metro Inc., Westbury, NY) onto the disk and form thin, dense zinc layers on both sides. The average coating thickness was kept at 400  $\mu\text{m}$ . The thermal conductivity of the polyethylene ( $k_1$ ) was 0.3 W/mK and that of the zinc ( $k_2$ ) was 60 (W/mK). The final composite fin after coating is shown in Fig. 1b.

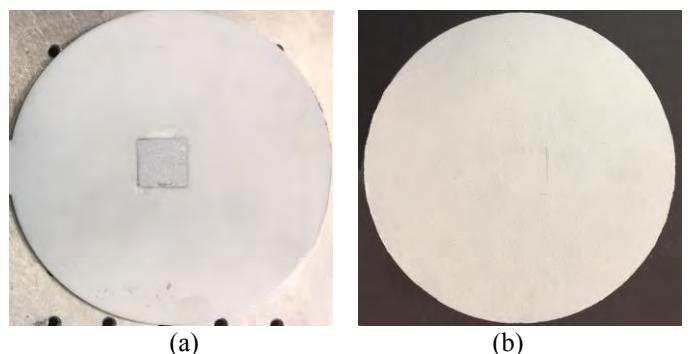

Figure 1. Pictures of the annular composite fin, (a) before spraying, and (b) after spraying.

## B. Experimental setup

The centre of the fin was heated using a flexible, silicone rubber heater, 23 mm square, (35765K126, McMaster Carr, Santa Fe Springs, California, USA) attached to the aluminum insert using thermal tape (TAPE-T404, Aavid Thermalloy, San Jose, California, USA). The other side of the heater was insulated using fiber glass insulation so that the heat lost from it was negligible. Moreover, the temperature variation on the fin surfaces was measured using an infra-red camera. The fin was mounted horizontally with an infrared camera (ThermaCAM SC 5000, FLIR, USA) pointing downwards to record the temperature of the upper surface.

The power supplied to the heart was varied to 1.6, 2.5, 4.0 and 9.0 W, and the fin allowed to come to steady state which took approximately 30 min, and the temperature on the top fin surface recorded.

## IV. ANALYTICAL MODELING

The composite fin was circular with a rectangular cross-section, and the geometry can be simplified for purposes of modelling as shown in Fig. 2. The fin was constructed as a sandwich structure with a polymer core with thickness  $2H$ , an outer radius  $r_o$ , and inner radius  $r_i$ . Heat conduction in the two-dimensional polymer core is governed by the following partial differential equation,

$$\frac{\partial^2 T_1}{\partial r^2} + \frac{1}{r} \frac{\partial T_1}{\partial r} + \frac{\partial^2 T_1}{\partial y^2} = 0 \quad (1)$$

Defining the following non-dimensional variable,

$$r^* = \frac{r - r_i}{L}; \quad y^* = \frac{y}{H}; \quad \theta_1 = \frac{T_1 - T_{air}}{T_b - T_{air}}; \quad \theta_2 = \frac{T_2 - T_{air}}{T_b - T_{air}}$$

Where  $L$  is the characteristic length of the fin, defined as  $r_o - r_i$ ,  $T_b$  is the wall temperature of the aluminum insert and  $T_{air}$  is the ambient air temperature, and  $T_1$  and  $T_2$  the temperature distributions in the polymer core and coating respectively. Substituting these dimensionless variable into equation (1) gives,

$$\frac{\partial^2 \theta_1}{\partial r^{*2}} + \frac{L}{r} \frac{\partial \theta_1}{\partial r^*} + \frac{L^2}{H^2} \frac{\partial^2 \theta_1}{\partial y^{*2}} = 0 \quad (2)$$

The following boundary conditions can be applied for the core,

$$\begin{aligned} r^* = 0, \theta_1 = 1 & ; \quad r^* = 1, \frac{\partial \theta_1}{\partial r^*} = 0 \\ y^* = 0, \frac{\partial \theta_1}{\partial y^*} = 0 & ; \quad y^* = 1, \frac{\partial \theta_1}{\partial y^*} = \frac{k_2}{k_1} \frac{\partial \theta_2}{\partial y^*} \end{aligned}$$

Where  $k_1$  and  $k_2$  are thermal conductivity of the polymer core and the metallic coating layers, respectively.

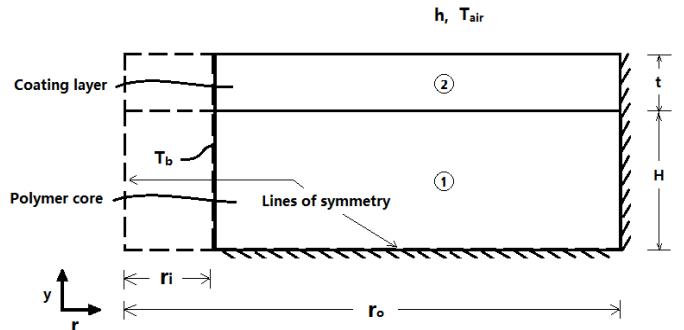

Figure 2. Analytical heat conduction model of the composite fin consisting of two domains.

Since heat transfer in the coating is assumed to one-dimensional, with a temperature gradient only in the radial direction [5], an energy balance gives,

$$k_2 t \left( \frac{\partial^2 T_2}{\partial r^2} + \frac{1}{r} \frac{\partial T_2}{\partial r} \right) - h(T_2 - T_{air}) - \varepsilon \sigma (T_2^4 - T_{air}^4) = k_1 \frac{\partial T_1}{\partial y} \Big|_{y=H} \quad (3)$$

The three terms on the left-hand side of equation (3) represent heat conduction, natural convection, and radiation in heat transfer, respectively. The term  $T_2^4$  can be expanded in a Taylor series [6], and the new expression substitute into equation (3) gives,

$$k_2 t \left( \frac{\partial^2 T_2}{\partial r^2} + \frac{1}{r} \frac{\partial T_2}{\partial r} \right) - h_e (T_2 - T_{air}) = k_1 \frac{\partial T_1}{\partial y} \Big|_{y=H} \quad (4)$$

Where  $h_e = h + 4T_{air}^3 \varepsilon \sigma$  is an effective heat transfer coefficient that combines convection and radiation effects. Non-dimensionalizing equation (4) gives,

$$k_2 t \left( \frac{\partial^2 \theta_2}{\partial r^{*2}} + \frac{L}{r} \frac{\partial \theta_2}{\partial r^*} \right) - L^2 h \theta_2 - \frac{L^2}{H} k_1 \frac{\partial \theta_1}{\partial y^*} \Big|_{y^*=1} = 0 \quad (5)$$

With the boundary conditions,

$$r^* = 0, \theta_2 = 1 \quad ; \quad r^* = 1, \frac{\partial \theta_2}{\partial r^*} = 0$$

Using separation of variables by assuming that we can write  $\theta_1$  as a product of two variable  $R(r)$  and  $Y(y)$  so that  $\theta_1(r^*, y^*) = R(r^*)Y(y^*)$  and substituting in equation (2), gives two equations

$$Y'' + m^2 Y = 0 \quad (6)$$

$$R'' + \frac{L}{r} R' - \frac{m^2 L^2}{H^2} R = 0 \quad (7)$$

Where  $m$  is an arbitrary separation constant. The general solutions of equation (6) and (7) are given [7],

$$Y = c_1 \cos(my^*) + c_2 \sin(my^*) \quad (8)$$

$$R = c_3 I_0 \left( \frac{mL}{H} r^* + \frac{m}{H} r_i \right) + c_4 K_0 \left( \frac{mL}{H} r^* + \frac{m}{H} r_i \right) \quad (9)$$

Where  $I_n(x)$  and  $K_n(x)$  are the solutions to the modified Bessel differential function of the first and second kinds [8], [9]. At the interface between the core and the coating ( $y = H$ ) the temperatures in the core and coating are equal ( $\theta_1(r^*, 1) = \theta_2(r^*)$ ). Substituting  $\theta_2(r^*) = R(r^*)Y(1)$  into equation (5), we obtain,

$$Y' + \frac{H^2 h - k_2 t m^2}{k_1 H} Y = 0 \quad (10)$$

The boundary condition of  $y^* = 0$ ,  $Y' = 0$  gives  $c_2 = 0$  in equation (8). Substituting  $Y = c_1 \cos(my^*)$  into equation (10), we obtain,

$$\tan(m) = \frac{H^2 h - k_2 t m^2}{k_1 H m} \quad (11)$$

In our experiment  $m$  is in a range of 0.028 to 0.032, so we can use the approximation that for small  $m$ ,  $\tan(m) \approx m$  and introducing the fin parameter,

$$M = \sqrt{\frac{h}{k_1 H + k_2 t}}$$

gives

$$m = MH$$

The coefficients  $c_3$  and  $c_4$  in equation (9) can be found by applying the boundary condition at  $r^* = 1$ ,  $\frac{\partial \theta_1}{\partial r^*} = 0$ . Then,

$$c_4 = \frac{I_1(Mr_o)}{K_1(Mr_o)} c_3$$

Combining the solutions for  $R(r^*)$  and  $Y(y^*)$  gives,

$$\theta_1(r^*, y^*) = c_5 \left[ I_0(MLr^* + Mr_i) + \frac{I_1(Mr_o)K_0(MLr^* + Mr_i)}{K_1(Mr_o)} \right] \cos(MHy^*) \quad (12)$$

Where the only unknown parameter,  $c_5$ , can be obtained from the boundary condition that at  $r^* = 0$ ,  $\theta_1 = 1$ .

$$c_5 = \frac{K_1(Mr_o)}{I_0(Mr_i)K_1(Mr_o) + I_1(Mr_o)K_0(Mr_i)} \quad (13)$$

Then,

$$\theta_1(r^*, y^*) = \cos(MHy^*) \frac{I_0(MLr^* + Mr_i)K_1(Mr_o) + I_1(Mr_o)K_0(MLr^* + Mr_i)}{I_0(Mr_i)K_1(Mr_o) + I_1(Mr_o)K_0(Mr_i)} \quad (14)$$

The radial temperatures of the fin core and coating must be the same at their interface so that  $\theta_2(r) = \theta_1(r, H)$ . The radial variation of  $\theta_2$  is, therefore,

$$\theta_2(r) = \cos(MH) \frac{I_0(Mr)K_1(Mr_o) + I_1(Mr_o)K_0(Mr)}{I_0(Mr_i)K_1(Mr_o) + I_1(Mr_o)K_0(Mr_i)} \quad (15)$$

And

$$T_2(r) = \cos(MH) \frac{I_0(Mr)K_1(Mr_o) + I_1(Mr_o)K_0(Mr)}{I_0(Mr_i)K_1(Mr_o) + I_1(Mr_o)K_0(Mr_i)} (T_b - T_{air}) + T_{air} \quad (16)$$

The heat conduction through the fin can be derived from,

$$Q = kA \frac{dT_2}{dr} |_{r=r_i} \quad (17)$$

Where  $A$  is the fin cross-section area at  $r = r_i$ . Evaluating equation (17) gives,

$$Q = \cos(MH) M \frac{I_1(Mr_o)K_1(Mr_i) - I_1(Mr_i)K_1(Mr_o)}{I_1(Mr_o)K_0(Mr_i) + I_0(Mr_i)K_1(Mr_o)} (T_b - T_{air}) \cdot 2\pi r_i (k_1 H + k_2 t) \quad (18)$$

The fin efficiency can be defined as,

$$\eta_{fin} = \frac{q_{fin}}{q_{fin,max}} \quad (19)$$

$$\eta_{fin} = 2 \cos(MH) \frac{1}{ML} \frac{I_1(Mr_o)K_1(Mr_i) - I_1(Mr_i)K_1(Mr_o)}{\left( \frac{T_a}{T_i} + 1 \right) I_1(Mr_o)K_0(Mr_i) + I_0(Mr_i)K_1(Mr_o)} \quad (20)$$

## V. RESULTS

Fig. 3 shows both measured and calculated radial temperature variations on the top surface of the fin for four values of the heater power. The temperature is maximum closest to the heater and decreases radially. Increasing the heater power raises the temperature. Predictions from the analytical model agree well with experimental measurements. In the analytical model the natural convection coefficients are evaluated using the experimental correlation [10], which are 4.3, 5.1, 5.5 and 6.6 W/m<sup>2</sup> K at the base temperature of 30, 39, 44 and 70 °C, respectively, and the radiation heat transfer coefficient,  $4T_{air}^3 \epsilon \sigma$ , is 5.1 W/m<sup>2</sup> K. Radiation therefore plays a significant role in heat transfer from the fin.

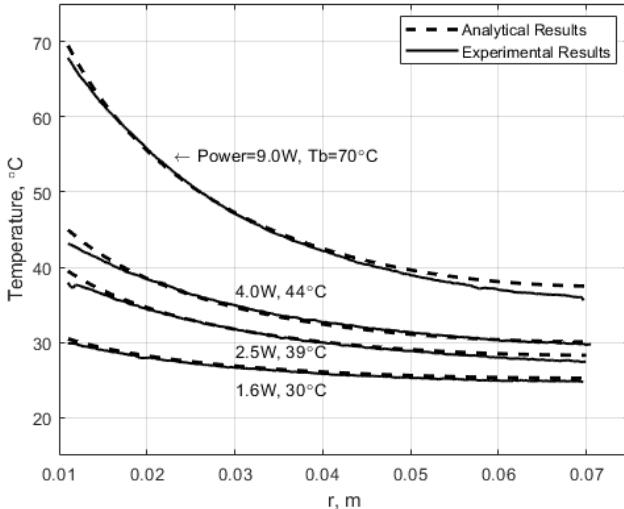

Figure 3. Analytical temperature curves of the composite annular fin (Equation 16) fits the experimental results at four heat input conditions, 1.6, 2.5, 4.0 and 9.0W.

Fig. 4 shows the variation of the base temperature of the fin, measured at the interface between the aluminium insert and the polymer fin, with the applied heater power. The base temperature increases with heater power in both the experimental and analytical results. The thermal resistance of natural convection and radiation is reciprocal to the effective heat transfer coefficient,

$$R = \frac{1}{h_e}$$

Known  $h_e$  equals  $h + 4T_{air}^3\epsilon\sigma$  and is a function of  $Ra$  and the ambient temperature.  $Ra$  number depends on the fin temperature and increases with the base temperature. The natural convection coefficient increases with the power input, so the overall thermal resistance of natural convection and radiation reduces.

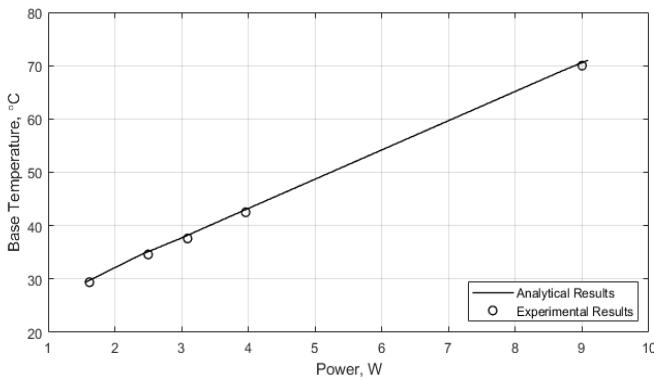

Figure 4. Analytical base temperature result of the composite annular fin (Equation 16) fits the experimental results at four heat input conditions, 1.6, 2.5, 4.0 and 9.0W.

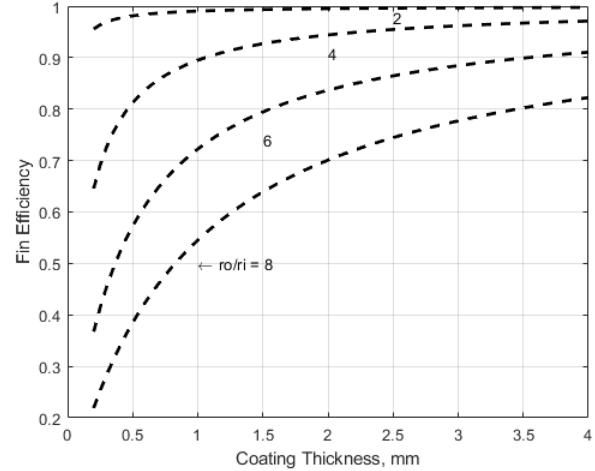

Figure 5. Fin efficiency of the composite annular fin (Equation 20) varies with the coating thickness at different  $r_o/r_i$  ratios.

Fig. 5 shows the variation in fin efficiency of annular composite (polymer/zinc) fins with coating thickness at four different  $r_o/r_i$  ratios. Polymer core thickness, the inner fin radius  $r_i$  and all thermal properties were assumed to be the same as those in our experiment. Fin efficiency increases with coating thickness in all cases because, as seen in Eqn 20, fin efficiency is a function of the fin parameter  $M$  which decreases as coating thickness increases. For the annular fin that was tested in experiments,  $r_o/r_i = 6.7$  and the coating thickness was 0.4 mm, giving a fin efficiency of approximately 50%. Fin efficiency can be improved by reducing the fin radius since heat transfer decreases with distance from the center of the fin, so reducing  $r_o/r_i$  or increasing the coating thickness would both improve efficiency.

## VI. CONCLUSIONS

An annular composite fin composed of a porous polyethylene core, a square aluminum insert, and metallic zinc coating layers, has been fabricated using wire-arc spraying technique. The analytical solutions of two-dimensional heat conduction model show an excellent prediction with the experimental results. The solutions indicate that the coating thickness has highly influence on the fin efficiency, and the fin efficiency can be accurately predicted by a single thermal length (ML), Eqn 20. The proper size of the fin can be determined by following the heat dissipation and fin efficiency curves of the fins in Figs 4 and 5. The solutions of this analytical model provide criteria in the annular composite fin design.

**Abstract**—This paper presents an analytical investigation into the effective thermal conductivity of 3D printed continuous fibre polymer composites (CFPCs) using rule of mixture micro-structural analysis. Two fused deposition modelling techniques were utilized using a off-the-shelf printer and a low-cost modified printer. Results demonstrate significant improvement in the effective thermal conductivity of the composite compared to the base polymer. One samples was experimentally tested to examine the veracity of the model predictions.

## I. BACKGROUND AND LITERATURE

Conductive polymer composites (PC) are utilized in many applications such as heat exchangers because they can offer relatively moderate thermal conductivity in addition to the advantages of light weight, corrosion resistance and low cost. These advantages result in a convenient choice for water desalination and electronic cooling applications [1],[2]. The performance of heat exchangers can be enhanced by increasing the thermal conductivity of the material, adding convective surface area, or increasing the convective heat transfer coefficient through shape complexity and turbulent generators.

Additive manufacturing (AM) techniques such as fused deposition modeling (FDM) can be employed in conjunction with PC to create more complex and effective heat exchangers [3],[4]. The addition of metal and reinforcement or other reinforcing materials such as carbon fiber, graphite and carbon nanotubes can increase the thermal conductivity of the material [5],[6]. However, the discontinuous nature of the reinforcement materials is believed to limit conductivity improvement where the interfacial resistances become dominant specifically at low reinforcement percentages[7],[8].

Recently, continuous fiber AM gained more attention due to the improved stiffness that can be achieved [9],[10]. Modified

and commercial printers were used to investigate the mechanical properties of continuous fiber polymer composites (CFPCs) structures printed with reinforcement materials such as carbon, Kevlar® and glass fibers [11]–[13]. Presently, the thermal properties of CFPCs have not been studied despite the advantages that can be offered.

This study analytically investigates the thermal conductivity of AM CFPCs using two different printing techniques. The first method uses a commercial continuous fiber 3D printer to examine the effect of carbon fiber layers on overall thermal conductivity of the produced composite material. Secondly, a modified conventional FDM 3D printer was used which embeds continuous fibers within the printed structure. In the current stage, continuous metal wires are used as the reinforcing material. The goal of this work is to use high conductivity fibers such as continuous pitch-based carbon fibers and carbon nanotube yarns to produce highly conductive polymer composite structures.

## II. METHODOLOGY

Two 3D printing machines were used in this work. The first 3D printer is the commercially available printer (MarkOne, MarkForged, Somerville, MA) which can print CFPCs using dual extruders, one for the polymer matrix and the other for continuous reinforcing fibers. Although Markforged printers can print different types of fibers such as carbon fibers, Kevlar and glass fibers with high reinforcement volumes, it is believed that the thermal conductivity of these fibers is relatively low compared to ultra-high conductive fibers such as the pitch-based carbon fibers . This will degrade the overall thermal conductivity of the CFPCs due to the existence of the polymer. On the other hand, the method described by Elsayed *et al.* [14] utilize an open-source, modified 3D printer with a single extruder combines polymer with more conductive continuous reinforcements such as Nickel chromium and copper wires within the printed structure. It may be possible to achieve higher overall thermal conductivity with the CFPCs printed with modified printer than the MarkForged components even with lower reinforcement volumes.

## A. Samples Description

### 1) MarkForged samples

To evaluate the thermal conductivity of CFPCs, six samples of different carbon fiber reinforcement volume fractions samples were designed and printed using a commercial CFPC printer (MarkOne, MarkForged, Somerville, MA) and Nylon as the base matrix. Figure 1 shows an example sample geometry, dimensions and fibers layer configuration. Sample geometry was created using computer aided design software (SolidWorks 2017 SP4.0, Dassault Systems, and uploaded to the online based slicing software (Eiger 1.2, MarkForged, Somerville, MA). The software provides information about the total number of fibers and nylon layers in the printed samples which can be used to deduce fiber volume fraction ( $v_f$ ). Table 1 shows sample dimensions and predicted fiber volume fraction by the software. Fibers printing angle was set to zero degree while two build directions were used to investigate the thermal conductivity in the axial and transverse directions of the fibers (Table 1). The physical properties of the 0.375 mm carbon fiber filament manufactured by MarkForged were not provided by the supplier. However, it is assumed that the fiber filament is a combination of polyacrylonitrile (PAN) based carbon fibers and polymeric material that give the filament the apparent stiffness. With this assumption, the mechanical properties and thermal conductivity of these fibers can be inferred.

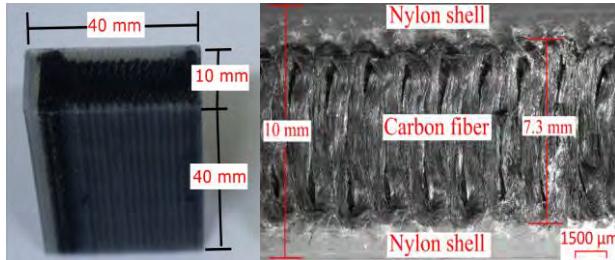

Figure 1. Carbon fiber reinforced sample (0-degree fiber printing angle) Left: sample with dimensions 40x40x25mm. Right: microscope image showing the continuous fiber.

TABLE 1 SAMPLES DIMENSION AND FIBER VOLUME FRACTION

Sample No.	Sample dimensions (L x W x H) (mm)	Fiber printing angle	Fiber volume fraction ( $v_f$ ) %
1	40 x 10 x 40	0	79
2	40 x 10 x 40	0	55
3	40 x 10 x 40	0	31
4	40 x 40 x 10	0	76
5	40 x 40 x 10	0	63
6	40 x 40 x 10	0	51

### 2) Modified printer samples

A FDM printer (Prusa i3, Prusa Research, Czech Republic) was modified to create CFPC components. Six samples of CFPCs were designed using the method described by Elsayed *et al* [14] where Polylactic acid (PLA) filament (1.75mm, Spool 3d, Canada) was fused through the printing nozzle and

combined with Nickel-chromium wires (75 um, McMaster Carr, Ohio, USA), copper wires (75 um, Remington Industries, Canada) and Pitch carbon fiber (Mitsubishi Chemicals Carbon Fiber and Composites, California, USA) to create CFPC samples. Figure 2 shows a Nickel chromium reinforced prototype sample with the geometry, dimensions and reinforcement configuration. The prototype sample was printed using 0.6 mm diameter nozzle, 0.4 mm layer height and 180 degrees Celsius printing temperature. Sample printing code was generated using a custom script (MATLAB, Mathworks, Natick, MA), where the printing angle was set to zero to investigate the thermal conductivity in the axial and transverse directions by changing the build direction of the samples.

Table 2 shows samples dimensions and the nominal reinforcement volume fraction calculated from the input printing parameters.

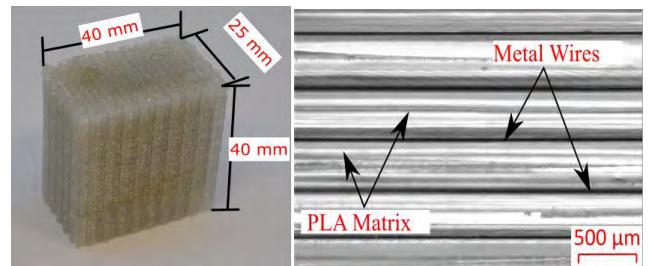

Figure 2. Prototype sample for the modified printer Left: sample with dimensions 40x40x25mm. Right: microscope image showing the continuous reinforced metal wires.

TABLE 2 SAMPLES DIMENSIONS AND REINFORCEMENT VOLUME FRACTION

Sample No.	Sample Dimensions (L x W x H) (mm)	Reinforcement material	Reinforcement printing angle	Reinforcement volume fraction ( $v_f$ ) %
7	40 x 10 x 40	Nickel chromium	0	1.7
8	40 x 10 x 40	Copper	0	1.7
9	40 x 10 x 40	Pitch carbon fiber	0	1.7
7	40 x 40 x 10	Nickel chromium	0	1.7
10	40 x 40 x 10	Copper	0	1.7
12	40 x 40 x 10	Pitch carbon fiber	0	1.7

### B. Experimental setup

Different apparatuses are being used for characterizing materials thermal conductivity based on different operating concepts. The steady state and the transient apparatus families are the most commonly used. Based on the nature of the material being measured and the range of the thermal conductivity, a convenient apparatus can be chosen. A steady state thermal test apparatus was used to assess the thermal conductivity of the CFPC samples. The employed test rig belongs to the steady state category which mainly depends on

transferring heat through the sample and measuring the resultant temperature difference across the sample at steady state conditions. Similar apparatuses were used for measuring thermal conductivity of thermal interface materials[15] and conductive polymers [16]. Fig. 3 shows that the apparatus consists of two sides; one for supplying the heat and the other one represents the sink. Each side consists of two isothermal blocks; one is the main one while the other working as a guard for it. The main block of the hot side has a dimension of 40 mm x 40 mm x 6.35 mm while the guard one is 70 mm x 70 mm x 15.7 mm and has a groove which allows the main to be fixed inside. Its function is to guarantee that all the heat coming from the main heater is going into the sample and eliminate any losses from the main heater sides. This was done by tuning its power until reaching a temperature that follow the main heater temperature. Isothermal conditions for all parts were achieved by manufacturing them from copper material,  $k = 391.2$  w/m k, to produce a uniform temperature field inside it. Moreover, this was validated using numerical simulation. The temperature of both blocks was observed at three different locations where each sensor from the main block is opposite to its analogous one from the guard block. It was postulated that the secondary power is convenient when the temperature difference between each pair did not exceed 0.001 °C at steady-state. Also, it was assumed that the steady state conditions were reached when the time gradient of the temperature for each sensor is less than 0.00001.

The cold side main block has a dimension of 40 mm x 40 mm x 12, while the secondary one is 80 mm x 80 mm x 12 mm. All the blocks and the sample are clamped together against a force gauge. The specimen was manufactured with small thickness to have a negligible heat loss from its side and to verify that the heat flow is one-dimensional. Furthermore, all parts were wrapped by silica aerogel insulating material having a thermal conductivity of 0.014 w/m k.

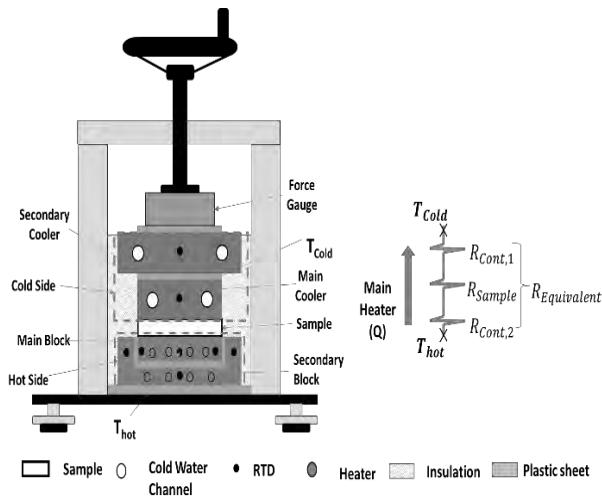

Figure 3. Experimental setup for measuring the thermal conductivity.

The thermal conductivity is calculated using the Fourier conduction equation as follows;

$$k = \frac{Q \Delta t}{A_c(T_{hot} - T_{cold})} \quad (1)$$

where  $k$  is the tested thermal conductivity,  $\Delta t$  is the sample thickness,  $A_c$  is the cross-section area and  $(T_h - T_c)$  is the temperature difference across the sample.

### III. MICROSCOPY

The internal structure of the CFPC samples was examined using stereo-microscope (MZ10 F, Leica, Concord, Ontario). Samples produced using the MarkForged 3D printer and modified printer were examined to investigate the difference between the reinforcement volume fraction given by the software and the actual reinforcement fraction assessed by image processing. Fiber volume fraction measurements are necessary for accurate predication of the thermal and mechanical properties. The samples were sectioned perpendicular to the reinforcement axis using a high-speed abrasive cutting wheel. Thereafter, the samples went through four steps of grinding and polishing using 240, 400, 600 and 1200/4000- grit silicon carbide discs to get a convenient surface for microscopy. Figure 4 shows the cross-sectional microscopy of the two samples showing reinforcement and polymer layers with the air voids existing due to the nature of FDM printing technique. Image processing was performed using image analysis software (ImageJ, National Institutes of Health, Bethesda, Maryland, USA) to measure reinforcement volume fraction across the two samples. For the MarkForged Sample no. 3 the analysis showed 46.7% of fiber volume fraction exist in the sample compared to 31% calculated using the Eiger software. For the custom metal reinforced samples, the analysis determined 1.48 % fiber volume fraction compared to 1.7 %calculated from the input printing parameters for the modified printer prototype sample.

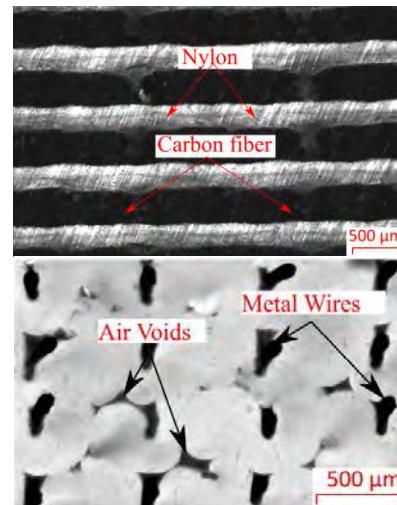

Figure 4. Cross section microscopy of samples Top: MarkForged sample. Bottom: Metallic reinforced CFPC sample

Additionally, a single fiber filament (Carbon Fiber CFF, Markforged, Somerville, MA) used for printing the fiber layers in the Markforged samples was examined under the microscope to evaluate the percentage of the carbon fibers and the polymeric material. Figure 5 shows the filament cross-section at three different positions. It was noticed that the filament was not completely filled with fibers and that the fibers configuration within the filament is not fixed which strengthen the possibility that the fibers are not fully continuous inside the filament. Image processing was performed again and a value of 35.5% of fibers was found within the fiber filament. The value obtained reduces the overall fiber percentage predicted by the software and the one from the image processing of the sample cross section.

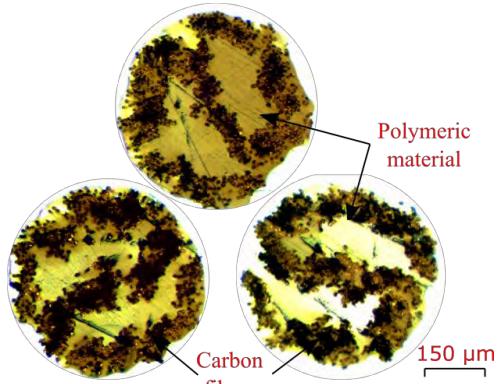

Figure 5. Carbon fiber filament cross-section at three different positions

#### IV. ANALYTICAL MODEL

Different analytical models are available for the prediction of composites material thermal conductivity [17]. Depending on the reinforcement shape, orientation and measurement direction, considerably accurate models can be deduced. One basic model for composites properties description is the rule of mixture.

The reinforcement configurations addressed here are shown in Fig. 6. Here the samples consist of continuous unidirectional reinforcements which allows the straightforward rule of mixture model to be used. This model describes composite properties as a function of constituents properties and reinforcement volume fraction. For CFPCs, rule of mixture can take simple forms of parallel and series models shown in Eqs. 2 and 3, respectively. Where  $k_c$ ,  $k_p$  and  $k_f$  are composite, polymer and fiber thermal conductivity respectively while  $\phi$  is fiber volume fraction. The main limitation for the rule of mixture model in this case is over estimation that can occur due to the neglection of the interfacial resistances especially for the series model.

$$k_c = (1 - \phi)k_p + \phi k_f \quad (2)$$

$$k_c = \left( \frac{1-\phi}{k_p} + \frac{\phi}{k_f} \right)^{-1} \quad (3)$$

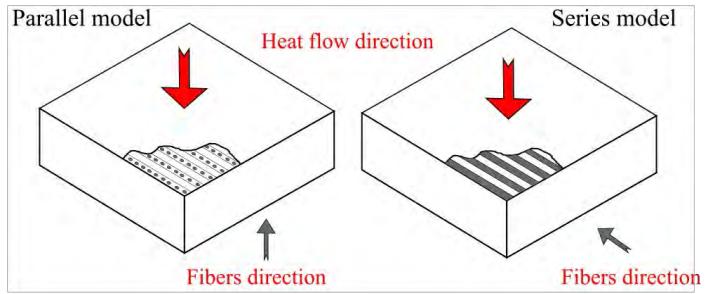

Figure 6. Parallel and series models

Constituents' properties can greatly affect CFPCs overall thermal conductivity. Different reinforcement materials are applied to the model to study the effect of ultra-high conductive reinforcements such as copper and Pitch based carbon fiber on the overall thermal conductivity. Again, the carbon fiber provided by Markforged is believed to be PAN based with relatively low thermal conductivity compared to metal reinforcements. Assumed values for thermal properties provided from [18], [19] shown in Table 3 are used in the thermal conductivity evaluation as there is insufficient information about the thermal properties from the suppliers.

TABLE 3 MATERIALS THERMAL PROPERTIES [18], [19]

Material	Thermal Conductivity (W/m·K)
Nylon	0.3 [18]
PAN Carbon fiber	8 [19]
PLA	0.29 [18]
Nickel chromium	13 [18]
Copper	385 [18]
Pitch carbon fiber	500 [19]

#### V. RESULTS AND DISCUSSION

Using the rule of mixture model described in Section IV, analytically predicted values for the overall thermal conductivity were obtained for both the commercial and modified 3D printers. Samples 1-3 and 7-9 thermal conductivity was predicted using the parallel model in "(2)" as the continuous reinforcement is parallel to the heat flow direction while the series model in "(3)" was utilized for samples 4:6 and 10:12 as the heat flows transversely through the reinforcement. Figure 6 shows the results for the Markforged samples described in Table 1. A maximum value of 6.42 W/m·K was found for sample no. 1 with 79% nominal fibers content when the thermal conductivity is predicted in the axial direction of the fibers. However, this value drops to 2.8 W/m·K when the actual fiber content obtained from the fiber filament microscopy is used assuming that the matrix material in the filament has the same thermal conductivity as Nylon. As well, the thermal conductivity is predicted in the transverse direction where low thermal conductivity (1.13 W/m·K) was obtained even with 76% nominal fibers content

in sample no. 4. The modified printer samples, described in Table 2, showed higher thermal conductivity using copper wires and Pitch carbon fibers (samples 8 and 9) even with as low reinforcement volume fraction as 1.7% (Figure 7). This means that the modified printer is more convenient for creating increasingly conductive CFPCs. The overall thermal conductivity of the CFPCs made by the Markforged printers can be significantly improved if Pitch-based carbon fibers are used due to their high thermal conductivity. Meanwhile for the customized printer, further modification that can increase the reinforcement volume fraction will boost the overall thermal conductivity of the prints. For the experimental results, sample no. 1 was tested using the previously mentioned setup. A value of 1.84 W/m·K was found for the thermal conductivity. The deviation between the measured value and the value predicted by the model with actual fiber content is believed to be caused by uncertainty in the fibers grade and conductivity. Additionally, the possibility that the fibers are not fully continuous within the samples inferred from the filament cross-section in Figure 5 can cause the thermal conductivity to drop. Future work will focus on experimental testing of the rest of the samples to examine the compatibility of the analytical models with the printed samples and increasing fiber volume fraction of the modified printer to achieve higher thermal conductivity.

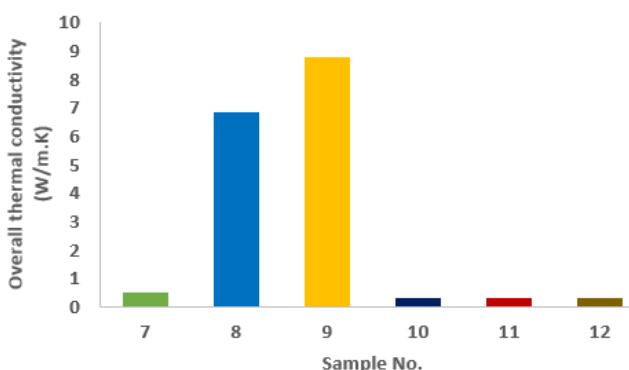

Figure 7. Overall thermal conductivity of the modified printer samples

## VI. CONCLUSIONS

CFPCs can be an attractive choice for thermal applications like heat exchangers by utilizing conductive fibers. Additive manufacturing combined with fiber reinforcement can be used to generate sufficient heat transfer coefficients for thermal applications. The high overall thermal conductivity values shown in this study makes CFPCs comparable to moderate conductive metals such as stainless steel which make it convenient for heat exchanging applications especially for corrosive fluids.

**Abstract**— A first principle study is conducted to explore the phonon thermal transport in a buckled arsenene monolayer ( $\beta$ -As) subjected to tensile strain. The results showed that the thermal conductivity first decreases with strains from 0% to 1%, then it increases with strains from 1% to 5%, and finally it decreases with strains from 5% to 9%. The maximum thermal conductivity occurs at strain of 5%, which is 1.45 times higher than that of unstrained arsenene. Phonon properties are investigated to understand the causes of this thermal response to strain.

Phonon Properties**

## I. INTRODUCTION

Since the discovery of graphene, two-dimensional (2D) materials have attracted a great deal of attention. The appealing thermal [1] and electrical [2] properties of graphene have motivated the scientific community to explore for other 2D materials. This effort has resulted in many other nanomaterials added to the 2D family such as silicene, germanene, boron nitride (BN) and transition metal dichalcogenides (TMDCs) [3,4]. Very recently, group-VA monolayers such as phosphorene (P), arsenene (As), antimonene (Sb) and bismuthene (Bi) have attracted significant attention. As opposed to graphene that does not have a band gap, group-VA monolayers have band gaps in the range of 1-2.5eV [5,6,7], making them intriguing for electronic and optoelectronic applications. From a thermal point of view, materials of this family have a much lower thermal conductivity than graphene [8], making them more suitable for thermoelectric applications. There are two possible atomic structures for these materials: buckled (known as  $\beta$ ) and puckered (known as  $\alpha$ ). The thermal conductivity of buckled structure is isotropic while the puckered structure has a highly anisotropic thermal conductivity in the zigzag and the armchair directions [8]. The focus of this paper is on buckled structures. Figure 1 shows a schematic of the group-VA buckled structure, in which atoms are arranged on a honeycomb lattice similar to graphene, with two atoms per unit cell. What makes these structures different from graphene is the non-zero buckling height  $d$  between two atomic planes

(Fig. 1). The minimum and maximum value of  $d$  are exhibited by  $\beta$ - phosphorene and  $\beta$ - bismuthene, respectively.

**Figure 1.** Lattice structure of group-VA monolayers: (a) unit cell (b) a  $7 \times 7 \times 1$  supercell (c) side view of the supercell. All atoms are the same kind, any of the group-VA elements (P, As, Sb or Bi). Different colors are used to show atoms in the upper and lower planes.

Apart from the value of accurately predicting the thermal conductivity of these novel materials, it is of paramount importance to understand how to tune the thermal conductivity. For that, it is necessary to investigate the thermal transport from a phonon transport perspective. 2D materials are commonly subjected to residual strains in real applications, and it is well known that strain has a considerable effect on the phonon properties and the thermal conductivity of 2D materials. Many studies have been conducted on the effects of strain on 2D materials such as graphene, stanene, germanene and silicene [1,9]. These studies revealed that tensile strain might increase or decrease the thermal conductivity. Also, tensile strain increases the dependency of the thermal conductivity to sample size. Zhang et al. [10] studied the effect of strain on phonon transport of  $\beta$ -Sb based on Boltzmann transport equation (BTE) under single relaxation time approximation (RTA) [11]. They considered strains ranging from -6% to 6%. Based on their results, the buckled structure of  $\beta$ -Sb is not stable for strains less than -1%. For strains from -1% to 6%, they found that the thermal conductivity increases by increasing strain. For instance, the thermal conductivity of  $\beta$ -Sb under tensile strain of 6% is about three times higher

The authors would like to acknowledge support from the Natural Science and Engineering Research Council (NSERC) of Canada.

than that of unstrained structure. However, there are still intriguing questions that need to be answered. For example, is the variation of the thermal conductivity with strain similar in other group-VA 2D materials? What will be the effect of higher tensile strain values on the phonon properties and thermal conductivity of other members of the group-VA family? In this work, we address these questions investigating the thermal properties of  $\beta$ -As, using a rigorous first-principle density functional theory (DFT) approach. We considered the effect of tensile strain (0-9%) on the thermal conductivity and phonon properties of  $\beta$ -As. The rest of this paper is organized as follows: Section II discusses the computational approach, Section III presents the harmonic and anharmonic phonon properties for different strain levels. Finally, Section IV summarizes the key findings.

## II. COMPUTATIONAL APPROACH

The methodology here is based on a full solution of the BTE [11]. Having the harmonic and anharmonic interatomic force constants (IFCs), the BTE can be iteratively solved for the three-phonon scattering lifetime  $\tau_\lambda$  of different phonons. Then, the thermal conductivity along the  $\alpha$  direction,  $\kappa_{\alpha\alpha}$ , is

$$\kappa_{\alpha\alpha} = \frac{1}{Ah} \sum_{\lambda(\mathbf{k}, p)} \hbar \omega_\lambda \frac{\partial n_\lambda^0}{\partial T} v_\lambda^\alpha v_\lambda^\alpha \tau_\lambda \quad (1)$$

where  $\lambda(\mathbf{k}, p)$  shows a phonon mode with  $\mathbf{k}$  being the phonon wave vector and  $p$  the polarization branch,  $A$  is the unit cell area,  $h$  is the thickness of the material,  $\omega$  is the phonon frequency,  $T$  is temperature,  $v_\lambda^\alpha$  is the phonon group velocity in the direction  $\alpha$ , and  $n_\lambda^0$  is the phonon occupation number given by the equilibrium Bose-Einstein distribution.

The DFT calculations were conducted by the QUANTUM ESPRESSO (QE) package [12] with projected augmented wave (PAW) pseudopotential and generalized gradient approximation (GGA) exchange-correlation. First, the structure is fully optimized to obtain the relaxed lattice constant. We used an electronic wave-vector grid of  $25 \times 25 \times 1$  for the Brillouin zone (BZ) integration, and the plane-wave cutoff was set to 70Ry. We also considered a vacuum of 20 Å between  $\beta$ -As monolayers to avoid interaction between adjacent layers. The relaxed lattice constant and buckling height of  $\beta$ -As is found to be  $a_0=3.61\text{\AA}$  and  $d=1.40\text{\AA}$ , respectively (Fig 1). These values are in excellent agreement with previously reported values in [8,13]. Then, the percentage of applied strain is defined as

$$\epsilon = \frac{a-a_0}{a_0} \times 100 \quad (2)$$

where  $a$  is the lattice constant of the strained structure. Strains values studied here are 0%, 1%, 3%, 5%, 7% and 9%. For each value of strain, the phonon calculations are performed on a phonon wave-vector grid of  $7 \times 7 \times 1$ . The anharmonic IFCs

were calculated based on supercells, using a finite-difference method within the *thirdorder* package[11]. We used a  $5 \times 5 \times 1$  supercell, and atomic interactions were considered up to the tenth nearest neighbor. Finally, the thermal conductivities are calculated using ShengBTE code [11] on an  $80 \times 80 \times 1$  phonon wave-grid vector. Rigorous convergence tests with respect to all DFT settings implemented here showed that using the parameters described above led to fully converged phonon properties and thermal conductivities.

Based on Eq. (1), the thermal conductivity depends on the thickness  $h$  of the unit cell. However, the definition of  $h$  is controversial among 2D materials. Here, the value of  $h$  is considered the same as the length of the unit cell along the  $z$  direction, i.e.,  $20\text{\AA}$ , the same strategy as previously used in [10].

## III. RESULTS AND DISCUSSION

Figure 2 shows the variation of the lattice thermal conductivity of  $\beta$ -As with strain (0-9%) at 300K. The thermal conductivity first decreases with strains from 0% to 1%, and then it increases with strains from 1% to 5%. For 5% of strain, the thermal conductivity exhibited its maximum value, which was 1.45 times higher than that of strain 0%. This critical value of strain that resulted in a maximum conductivity, was also observed in silicene, germanene and stanene [9]. Thermal conductivity reduction occurs for strain values higher than 5%. In contrast to what was found in Ref. [10], an increase in the thermal conductivity of  $\beta$ -Sb from 0% to 1% of strain, we found here that the thermal conductivity of  $\beta$ -As slightly decreases from 0% to 1% of strain. Moreover, in Ref. [10], the authors did not consider strain percentages higher than 6%. Based on our results, we conclude that the thermal conductivity response of group-VA 2D materials to strain may differ although they are similar in structure. Also, considering a wider range of strain (in the elastic region) is necessary to obtain a comprehensive picture of the thermal response of 2D materials to strain. Figure 3 shows the variation of the thermal conductivity of  $\beta$ -As for temperatures in the range of 200 to 1000 K. The relative difference of the thermal conductivity between 0% and 5% of strain decreases from 49% at 200K to 43% at 1000K.

Now, we analyze the harmonic and anharmonic phonon properties to shed light into the mechanism responsible for the thermal conductivity variation of  $\beta$ -As with strain. Harmonic properties such as phonon dispersion and phonon group velocity govern the thermal transport in nanomaterials. As an example, the anisotropic thermal conductivity of puckered phosphorene and arsenene ( $\alpha$ -P and  $\alpha$ -As) is directly related to the anisotropic group velocities near the center of BZ [14, 15]. Fig. 4 illustrates the phonon dispersion curve along highly

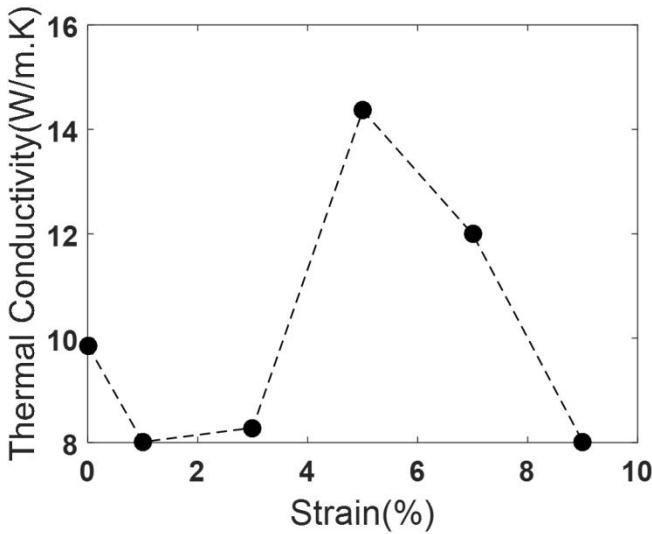

Figure 2. Strain variation of the thermal conductivity of  $\beta$ -As with strain at 300K.

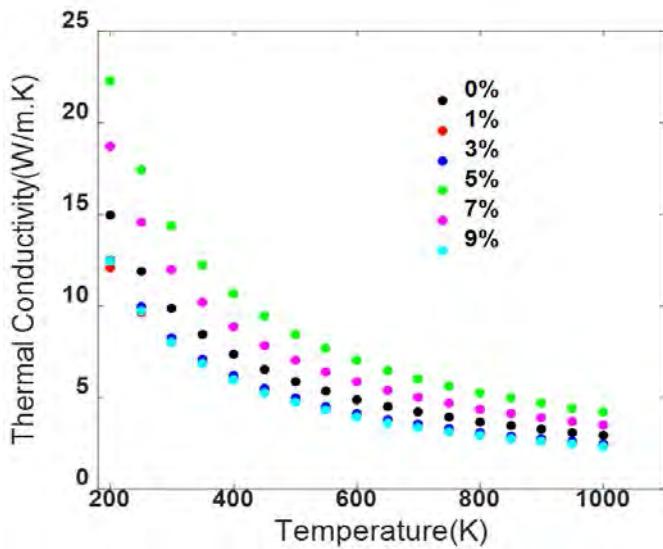

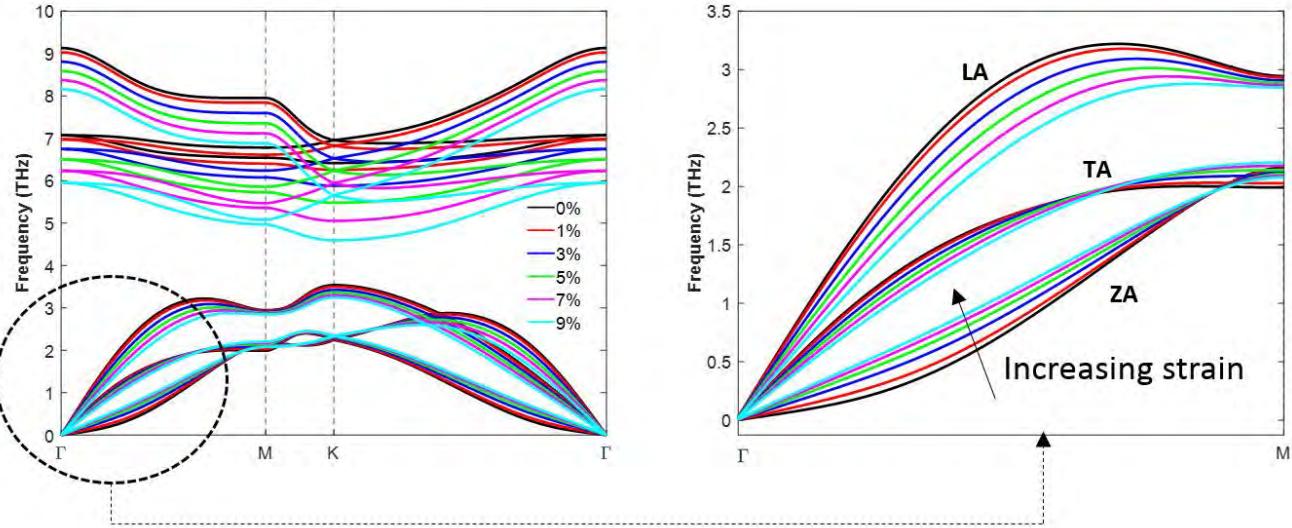

Figure 3. Variation of the thermal conductivity of  $\beta$ -As with temperature for different strain levels.

symmetric directions of the Brillouin zone for strains from 0% to 6%. There are two atoms in the unit cell  $\beta$ -As. Thus, there are six phonon branches: three acoustic modes called ZA, TA and LA; and three optical modes. Fig. 4 shows that increasing strain has not identical effects on different phonon modes. For example, as strain increases the ZA mode becomes more linear (higher phonon frequencies), and the LA mode exhibits a lower slope (lower phonon frequencies). The TA mode is less affected by strain compared to LA and ZA. Optical modes are also affected by strain. All optical modes become lower for higher strains. The same effect was also observed in graphene, silicene, stanene, germanene, and  $\beta$ -Sb [1,9,10].

The group velocity of a phonon mode is defined as the derivative of the phonon frequency with respect to the wave vector. Based on Eq. (1), the thermal conductivity has a strong dependence on the group velocity. We present the group velocity of all phonon modes for strain values of 0%, 3%, 5% and 7% in Fig. 5. In correlation with the responses of the phonon dispersion branches, the strain does not have the same impact on the group velocities of different phonon modes. Regarding the ZA mode, the group velocity near the center of the BZ increases with increasing strain. The group velocity of the ZA near the  $\Gamma$ -point is 0.36 km/s for strain 0% and increases to 1.30 km/s as strain increases to 7%. However, this is not the case for higher phonon frequencies of the ZA mode. As shown in Fig. 5, phonon group velocities of the ZA mode decreases as strain increases from 0% to 7%. Based on Eq. (1), this effect reduces the thermal conductivity. Considering the TA mode, the group velocity decreases near the  $\Gamma$ -point as strain increases. The group velocity is 3.07 km/s in unstrained  $\beta$ -As, and it is 2.68 km/s for strain of 7%. For other frequencies of the TA mode, considerable changes are not observed.

The reduction in group velocities as strain increases is also observed in the LA modes in Fig. 5. Unstrained  $\beta$ -As has the highest group velocities which decrease with increasing strain. In consequence, one could infer that the trend observed in group velocities of the acoustic modes leads to smaller thermal conductivities as strain increases. Group velocities of the three optical modes generally increases as strain increases, which is more obvious in the first two optical modes. However, since the group velocities of optical modes are smaller in magnitude than those of acoustic modes, it is predicted that the most important contribution in thermal conductivity of  $\beta$ -As comes from acoustic phonon modes. Therefore, regarding the group velocities, strain has a decreasing effect on thermal conductivity, as previously reported for  $\beta$ -Sb[10].

The other phonon property that has a crucial role in determining the thermal conductivity of a material is the phonon lifetime. Based on Eq. (1), higher phonon lifetimes result in higher thermal conductivities. The phonon lifetime of the acoustic and optical modes obtained from the iterative solution of BTE is plotted in Fig. 6. Since optical modes have smaller phonon lifetimes and group velocities than acoustic phonon modes, here we limit our discussion to the acoustic modes. Considering the ZA mode, the phonon lifetimes of the low-frequency phonons at 0% of strain are the highest. As shown in Fig. 6, the ZA mode of the unstrained structure has higher phonon lifetimes in the low-frequency region while the phonon lifetimes for 3%, 5% and 7% of strain in the same region are almost the same. However, the situation is different in the high-frequency region. As the strain increases from 3% to 5%, the phonon lifetimes of the ZA mode increases. To summarize, in the low-frequency region, the unstrained structure has the highest lifetimes among all strains considered. In the high-frequency region, 7% and 5% strains

**Figure 4.** The phonon dispersion of buckled arsenene for different values of tensile strain.

result in higher phonon lifetimes than 1%, which in turn exhibits higher lifetimes than 3%. The situation is different in  $\beta$ -Sb [10], where the phonon lifetimes of the ZA mode were found to increase as strain increases from -1% to 6%, both in the low- and the high-frequency region. Regarding the TA and LA phonon modes, the phonon lifetimes increased as strain increased, except for the 0% and 3% strains, with 3% resulting in lower lifetimes than 1%. Overall, for all strain levels considered here, as strain increases, the phonon lifetimes of TA, LA and high-frequency ZA modes also increase. The only exception is for 3% strain, which resulted in lower lifetimes than those for 0% in all acoustic modes. Based on what has been discussed in this section, there is an interplay between group velocities and phonon lifetimes as strain increases. Group velocities are lower at higher strains, while phonon lifetime increases with increasing strain. This interplay is the main reason for the up and down variation of the thermal conductivity versus strain in buckled Arsenene.

#### IV. CONCLUSION

In this work, strain effects on the phonon properties and thermal conductivities of buckled arsenene have been investigated. Six different strains have been considered ranging from 0% to 9%. We found that thermal conductivity decreases as strain increases from 0% to 1%, then it increases for strains in the range of 1% to a critical value of 5%. Afterward, it decreases for strains between 5% and 9%. Harmonic and anharmonic phonon properties have been analyzed to understand the causes of this variation. We observed that the cause of this variation is the interplay between the responses of the group velocities and phonon lifetimes of the acoustic modes to strain. The variation of the thermal conductivity of buckled arsenene with strain is

different than that observed in other materials of the same family, such as buckled antimonene. This study revealed that tensile strain can have different effects on different 2D materials, even if they belong to the same family with similar structure.

**Abstract**— Herein we present the design of infrared mirror coatings for the enhanced performance of incandescent lighting. We consider single and stacked dielectric mirrors comprised of alternating layers of TCO and SiO<sub>2</sub> nanoparticle films to function as infrared mirrors that reduce heat losses in incandescent lights. In this work, thin-film theory was employed to develop MATLAB code that calculates the reflectance and transmittance spectra of dielectric mirrors. In order to validate the MATLAB code, we compared our results to experimental results reported in the literature as well as results calculated using COMSOL Multiphysics software. Our results show that an infrared dielectric mirror coated onto the glass bulb of an incandescent light can increase its efficiency by ~32 %. However, stacked dielectric mirror coatings prevent a significant portion of visible light from transmitting through the glass bulb, and consequently decrease the efficiency of incandescent lights by ~46 %.

**Keywords-** *Infrared Reflectors; Thin-films; Nanoparticle Films; Lighting Technology; Optical films*

## I. INTRODUCTION

Since the invention of early commercial light bulbs in 1880 by Thomas Edison<sup>1</sup>, they have been used widely as a main source of illumination. By heating a filament wire covered by a glass bulb, the incandescent light bulb produces light. Usually the glass bulb is occupied by an inert gas to prevent the filament from burning.<sup>2</sup> However, incandescent lights are being replaced by a new generation of more efficient lights, such as light-emitting diodes.<sup>3</sup> One way to improve the efficiency of incandescent light bulbs is to reduce their radiative heat losses by preventing them from emitting near-infrared light. Herein we consider the design of an optical coating that achieves high reflectance in the near-infrared region and high transmittance in visible region. This can be achieved by using either a dielectric/metal film stack,<sup>4,5</sup> a dielectric multi-layered film,<sup>6</sup> or metallic photonic band gap (PBG) structures<sup>7</sup>. In this study, we focus on a dielectric mirror (often referred to as a Bragg-reflector or one-dimensional photonic crystal) comprised of alternating layers of transparent conducting oxide (TCO) and SiO<sub>2</sub> nanoparticle (NP) films with indices of refraction of n=2 and n=1.3, respectively. In previous work dielectric mirrors

comprised of alternating layers of TCO and SiO<sub>2</sub> NP films have been designed to selectively reflect light strongly over one spectral region while being highly transmissive over other spectral regions. These dielectric mirrors have been used as semi-transparent reflectors in “see-through” and multi-junction silicon-based photovoltaic cells.<sup>8,9</sup> Furthermore, in order to expand the width of the spectral region over which the dielectric mirror reflects light, one can fabricate a coating comprised of two stacked dielectric mirrors.<sup>10</sup> In this work we calculate and compare the efficiency of incandescent mirrors for the case in which the glass bulb is (1) bare, (2) coated with a dielectric mirror with a peak reflection in the infrared region and (3) coated with stacked dielectric mirrors that exhibit an extended reflection peak in the infrared region.

## II. METHOD

A dielectric mirror is comprised of alternating films with a higher (denoted as H) and lower (denoted as L) index of refraction. Thin-film theory can be used to calculate the infrared reflectance and visible light transmittance for a dielectric mirror<sup>11</sup> using the refractive indices and layer thickness of the films within the dielectric stack as input. The theory uses matching boundary conditions for Maxwell's equations, and more information is available in the literature<sup>12</sup>. Using thin-film theory, and with reference to Figure 1, the reflectance, R, and transmittance, T, at a surface are provided by Equations 1 and 2, respectively.

$$R = pp^* = \left[ \frac{\eta_H - Y}{\eta_H + Y} \right] \left[ \frac{\eta_L - Y}{\eta_L + Y} \right]^*$$
 (1)

$$T = \frac{4\eta_H Re(Y)}{(\eta_H + Y)(\eta_H + Y)^*}$$
 (2)

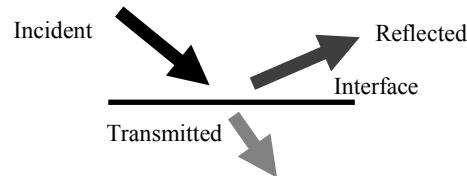

Figure 1. Transmittance and Reflection at an interface between two media

Where  $\rho$  is the amplitude of the reflection coefficient,  $\eta_0$  represents the admittance of the incident medium and  $Y$  is the admittance of the medium. Also,  $Re$  denotes the real part of  $Y$  in the Equation 2. However, Equations 1 and 2 are valid only for normal incidence. For the case of oblique incidence, one can define p-polarized and s-polarized light which are electric vectors parallel and perpendicular to the plane of incidence, respectively (Figure 2). Consequently, the new expressions will be defined with the tilted admittance for s-polarized and p-polarized light as in Equations 3 and 4:

$$\eta_s = y \cos \theta = (n - ik) \cos \theta \quad \text{for s-polarized light} \quad (3)$$

$$\eta_p = y / \cos \theta = (n - ik) / \cos \theta \quad \text{for p-polarized light} \quad (4)$$

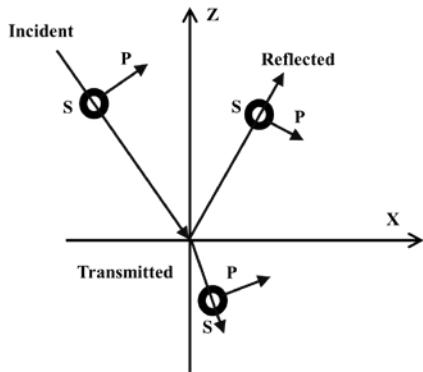

Figure 2. P-polarized and s-polarized light based for oblique incidence.

#### A. Matlab Code Validation

We developed a MATLAB code, based on the methods described in the previous section, that calculates the reflectance and transmittance spectra of dielectric mirrors. To validate the code we calculated and compared the reflectance and transmittance of dielectric mirrors to those studied in the literature. For example, we calculated the reflectance from a dielectric mirror comprised of nine layers of polystyrene and tellurium and the results are compared to experimentally measured results<sup>12</sup> in Figure 3. We also calculated the transmittance of dielectric mirrors comprised of alternating layers of indium-tin oxide (ITO) and SiO<sub>2</sub> nanoparticle films and compared our results to experimentally measured results<sup>10</sup>. As shown in Figure 4, the reflectance and transmittance spectra calculated using our MATLAB code provide a good approximation to those reported in the literature. Discrepancies between the calculated and experimentally measured spectra shown in Figures 3 and 4 are attributed to differences between the thickness or index of refraction values used in the experiment as compared to the values assigned to parameters in the analytical method. We also compared reflectance and transmittance spectra calculated using our MATLAB code and COMSOL Multiphysics software (version 5.3), which offers two separate modules that can be used for thin-film calculations (Ray Optics and Wave Optics). The results from our MATLAB code are compared with those from COMSOL in Figures 5 and 6. The results from both ray optics and wave optics modules agree well with those of the MATLAB code.

### III. DIELECTRIC MIRROR DESIGN

We design a one-dimensional dielectric mirror (otherwise referred to as a Bragg-reflector) to function as a coating for an incandescent light bulb that internally reflects infrared radiation back towards the light filament to reduce radiative heat losses. The term “one-dimensional” in our case refers to the fact that there is no variation in the dielectric function,  $\epsilon$ , along directions excluding  $(z)$ .<sup>14</sup> In this report, TCO ( $n=2$ ) is assumed to be the high index of refraction film, represented by H, and a SiO<sub>2</sub> NP film ( $n=1.3$ ) is assumed to be the low index of refraction film, which is represented as L in the stacking sequence shown in Figure 7.

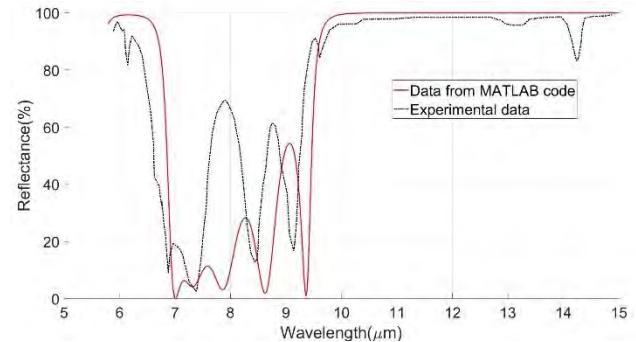

Figure 3. Experimentally measured and calculated (MATLAB code) reflectance spectra of a dielectric mirror comprised of nine layers of polystyrene and tellurium<sup>11</sup>.

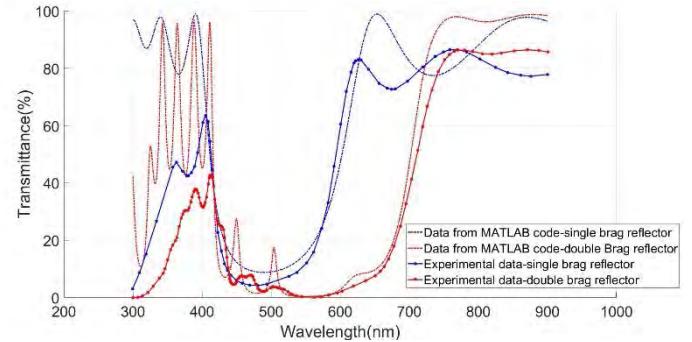

Figure 4. Experimentally measured and calculated (MATLAB code) transmittance spectra of dielectric mirrors comprised of alternating layers of ITO and SiO<sub>2</sub> nanoparticle films<sup>8</sup>.

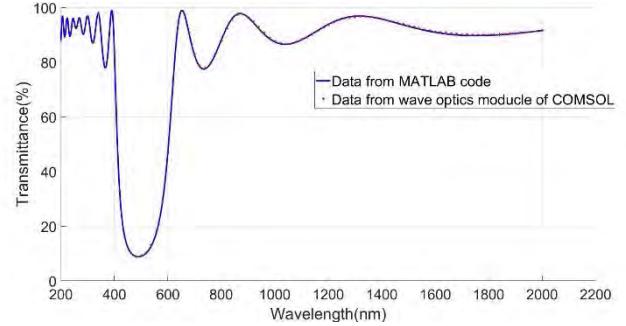

Figure 5. Transmittance of a dielectric mirror comprised of alternating layers of TCO and SiO<sub>2</sub> nanoparticle films calculated using our MATLAB code and COMSOL Multiphysics software (five layers of TCO and SiO<sub>2</sub> with thicknesses of 60 and 90 nm, respectively ).

Figure 7 shows a dielectric mirror with a stacking sequence of [HLH]<sup>10</sup> where H and L represent the TCO and SiO<sub>2</sub> NP films, respectively. As discussed in the following section, the thicknesses of the TCO and SiO<sub>2</sub> films were chosen such that the spectral position of the reflectance peak minimizes the radiative heat losses from the incandescent bulb.

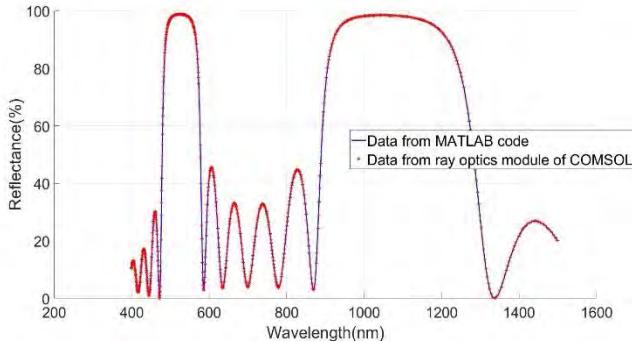

Figure 6. Reflectance spectra from a dielectric mirror comprised of alternating layers of TCO and SiO<sub>2</sub> nanoparticle films calculated using our MATLAB code and COMSOL Multiphysics software (five layers of TCO and

SiO<sub>2</sub> with thicknesses of 73 and 257 nm, respectively).

Figure 7. A one-dimensional dielectric mirror comprised of alternating layers of TCO and SiO<sub>2</sub> films. This dielectric mirror is coated onto glass.

#### A. Light Bulb Blackbody Radiation Spectrum

Herein we assume the spectral distribution of radiation emitted from an incandescent bulb approximates that of a blackbody at a temperature of 3300 K, which is the operating temperature of an incandescent light bulb filament<sup>15</sup>. As can be seen in the Figure 8, the highest intensity emitted from a blackbody at a temperature of 3300 K occurs at a wavelength of 880 nm, and therefore we choose this as the reference wavelength for the Bragg-peak position of the dielectric mirror. It follows that the thicknesses of the TCO and SiO<sub>2</sub> nanoparticle films in a quarter-wave stack with a reflectance peak wavelength of 880 nm is 110 nm and 169.5 nm, respectively. Considering the dielectric mirror with a stacking sequence of [HLH]<sup>10</sup> shown in Figure 7, the values of H and L would be 55 nm and 169.5 nm, respectively. The superscript ‘10’ indicates that the [HLH] stacking sequence is repeated 10 times; in this case the uppermost and bottommost films are 55 nm thick TCO films, which act as optical matching layers that reduce reflection outside the Bragg-reflection peak.

#### B. Results

The reflectance spectrum for the [HLH]<sup>10</sup> stack comprised of 110 nm thick TCO films and 169.5 nm thick SiO<sub>2</sub> NP films is shown in Figure 9. This reflectance spectrum exhibits a strong reflectance peak with a full-width at half-maximum of

360 nm, starting at 770 nm and ending at 1030 nm, and a maximum reflectance value of ~100% in the spectral vicinity of 880 nm. The other spectral regions, including the visible and infrared, show some fluctuations with the reflectance value below 30% over most of these regions. As shown in Figure 8, a large portion of the radiation emitted from a blackbody at a temperature of 3300 K is emitted with a wavelength greater than 1030 nm. In order to extend the high reflectance values for the quarter wave stack shown in Figure 9 to wavelengths beyond 1030 nm, one can stack a second dielectric mirror onto the original dielectric mirror, which will be discussed in the next section.

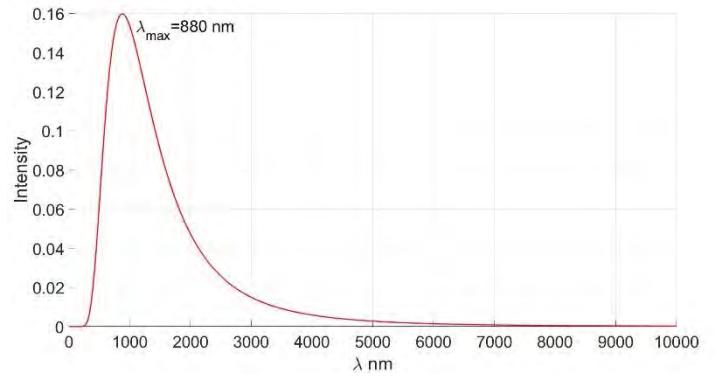

Figure 8. Radiation spectrum for a blackbody at a temperature of 3300 K.

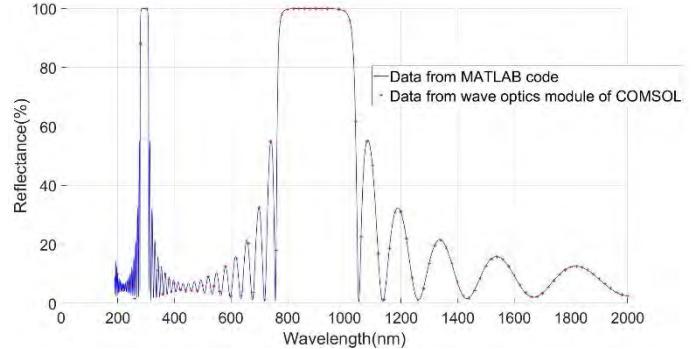

Figure 9. Reflectance spectrum for a quarter-wave stack comprised of alternating layers of TCO and SiO<sub>2</sub> NP films with thicknesses of 110 nm and 169.5 nm, respectively.

#### IV. DOUBLE BRAGG REFLECTOR DESIGN AND CORRESPONDING RESULTS

The reflectance spectra shown in Figure 9 can be extended to wavelengths greater than 1030 nm by stacking the initial dielectric mirror, which has a peak reflection wavelength of 880 nm, with a second dielectric mirror that has a different reflection peak position. The stacked dielectric mirrors, shown in Figure 10 and referred to as a ‘double stack’, can be designed with a layered configuration denoted as [hLh]<sup>10</sup>[HLH]<sup>10</sup>. In this notation [HLH]<sup>10</sup> represents the initial quarter-wave stack comprising 10 bilayers with L= 169.5 nm thick SiO<sub>2</sub> NP films and H = 55 nm thick TCO films. The second dielectric stack, denoted as [hLh]<sup>10</sup>, is also comprised of TCO and SiO<sub>2</sub> films, although the thickness of the TCO films

have been increased to 169.5 nm (with  $h = 84.75$  nm) to move the reflection peak position further into the infrared spectral region. The maximum Bragg-peak reflectance wavelength for the  $[hLh]^{10}$  stack is  $\lambda_p=2.(t_L \cdot n_L + t_H \cdot n_H) \approx 2 \times (169.5\text{nm} \cdot 2 + 169.5\text{nm} \cdot 1.3) \approx 1119$  nm.

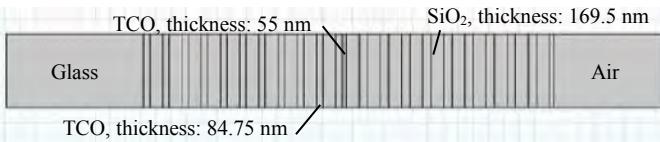

Figure 10. The one-dimensional multilayer film used for the single Bragg reflector design

The reflectance spectra calculated using our MATLAB code for the single and double-stacked dielectric mirrors are shown in Figure 11. The double-stacked dielectric mirror is strongly reflecting over a broad spectral region extending beyond 800 to 1200 nm. We determine the amount of radiant power emitted from the incandescent light by multiplying the blackbody radiation spectra from the light filament with the transmission spectra of the glass bulb for the cases in which it is bare, coated with a single dielectric mirror and coated with the stacked dielectric mirror, and the results are shown in Figure 12.

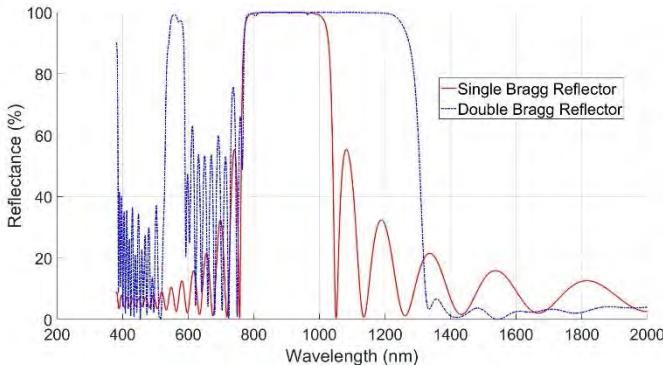

Figure 11. Reflectance spectrum for the “double stack” comprised of alternating layers of TCO and  $\text{SiO}_2$  NP films with a  $[\text{hLh}]^{10}[\text{HLH}]^{10}$  stacking sequence

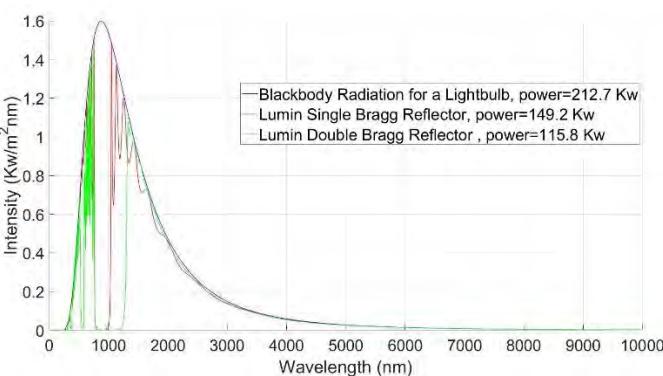

Figure 12. The radiation spectra for a blackbody at a temperature of 3300 K (blue curve) and the intensity of radiation emitted from a blackbody that is transmitted through the  $[\text{HLH}]^{10}$  Bragg reflector and the “double-stack” with a  $[\text{hLh}]^{10}[\text{HLH}]^{10}$  stacking sequence.

## V. LIGHT BULB EFFICIENCY

The lumens emitted from a light bulb with a filament at a temperature of 3300 K for the case in which the glass bulb is: bare, coated with the  $[\text{HLH}]^{10}$  quarter wave stack, or coated with the “double-stack” with a  $[\text{hLh}]^{10}[\text{HLH}]^{10}$  stacking sequence, are shown in Figure 13. For each of these cases, the transmitted irradiance of the light bulb was multiplied by the CIE 1978 eye sensitivity function<sup>17</sup> to determine the transmitted lumens<sup>18</sup>. The lumens transmitted for the case of the stacked dielectric mirror is a lot less than the lumens transmitted for the case of the bare glass bulb or single dielectric mirror coating. The corresponding values are equal to 9.51, 8.785 and 3.44  $\text{Klm}/\text{m}^2$  for the case the bare lightbulb, the single dielectric mirror and the stacked mirror, respectively.

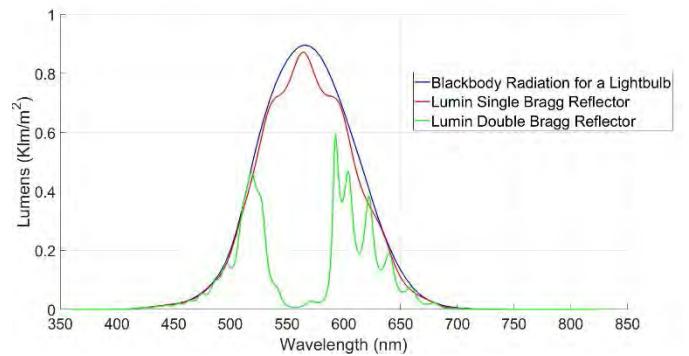

Figure 13. The lumens emitted from a light bulb with a filament at a temperature of 3300 K for the case in which the glass bulb is: bare (blue curve), coated with the  $[\text{HLH}]^{10}$  quarter wave stack (red curve), or coated with the “double-stack” with a  $[\text{hLh}]^{10}[\text{HLH}]^{10}$  stacking sequence.

In this work we assume the temperature of the filament in the incandescent light is 3300 K, regardless of what coating is applied to the bulb. However, the power consumed by the filament to reach a temperature of 3300 K depends on the optical coating applied to the glass bulb. The efficiency of the bulb can be estimated using Equation 5.

$$\eta = \frac{\Phi}{\text{power}} \quad (5)$$

Where the power in the denominator is the total radiant power emitted by the light over all spectral regions, and  $\Phi$  is the power of light emitted in the visible spectral region. It follows that the efficiency of the incandescent light bulb for the case in which the glass bulb is bare is 4.47%. Moreover, this efficiency can be increased to 5.89% by coating the glass bulb with the dielectric mirror comprised of TCO and  $\text{SiO}_2$  NP films with a  $[\text{HLH}]^{10}$  stacking sequence and a Bragg-reflectance peak position of 880 nm. However, the efficiency decreases to 2.97% if the glass bulb is coated with the “double-stack” with the  $[\text{hLh}]^{10}[\text{HLH}]^{10}$  stacking sequence.

## VI. CONCLUSION

In this work we presented the design of a dielectric mirror coating that improves the efficiency of incandescent light bulbs. The dielectric mirror is comprised of alternating layers of TCO and  $\text{SiO}_2$  NP films with indices of refraction of 2 and 1.3, respectively. The thicknesses of these TCO and  $\text{SiO}_2$  are

set such that the dielectric mirror has a peak reflectance value at the same wavelength as the maximum of the radiation spectrum of the filament within the incandescent bulb. For example, we considered a filament operating temperature of 3300 K, which has a radiation spectrum peak value of 880 nm, and the dielectric mirror was designed such that its peak reflectance value is also at 880 nm. Our results show that the dielectric mirror coating increases the efficiency of the incandescent light by ~32 %.

# Composite heat Sink LED Cooling

M. J. Gibbons, C. Feng, S. Chandra

Department of Mechanical and Industrial Engineering, University of Toronto, Toronto, ON, Canada

**Abstract** — Metal coating of 3D printed polymers is an attractive proposition for thermal dissipation of light emitting diodes, due to its high efficiency and markedly lower material costs than conventional aluminum heat sinks. Efficient thermal cooling of light emitting diodes is essential in maintaining electronic and optical performance. The thermal performance of three heat sink designs were experimentally investigated for three applied heat fluxes ( $0.5\text{--}1.5 \text{ W cm}^{-2}$ ). The results show that metal coating of the polymer heat sinks enables significant heat transfer enhancement of 37% over the uncoated case. The inclusion of an aluminum insert into the base of the composite heat sink design, in tandem with the zinc coating reduced on chip temperatures by 27% over the zinc coated case for the greatest applied heat flux.

**Keywords:** Light emitting diode; Heat transfer; Metal spray coating; Composite heat sink

## I. INTRODUCTION

Light emitting diodes (LEDs) are a fast developing technology due to their high energy efficiency, long lifecycle, environmental benefits and optical performance [1-5]. LED lighting uses 75% less energy than incandescent or fluorescent counterparts [6]. 70% of the total energy consumed by an LED light is emitted as heat. Effective thermal dissipation of LED devices is crucial in maintaining luminous performance and extending a LEDs lifespan [6, 9-12]. Numerous authors have investigated the thermal dissipation of LED devices both experimentally [3, 10, 13-15] and numerically [16-21].

Conventional aluminum heat sinks that are used to passively cool LED chips are thermally inefficient. A thermal resistance bottleneck exists at the gas-solid interface ( $R_2$ ) (Figure 1) which

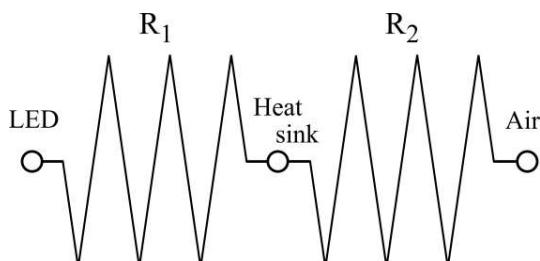

Figure 1. LED cooling thermal resistance diagram.

is significantly larger than the thermal resistance from the LED through the aluminium solid ( $R_1$ ). Metal coating of 3D printed polymers enables the matching of thermal resistances ( $R_1 = R_2$ ) by controlling the thickness of the coated metal, with the polymer substrate acting as a structural component. 3D printing also enables innovative heat sink design, which is not limited by the manufacturing processes of traditional heat sinks.

This research endeavours to be the first to experimentally investigate low power LED cooling using composite heat sinks. This was achieved using three heat sink designs tested across three applied heat fluxes ( $q''_{gen}$ ). This methodology was employed to characterise the thermal dissipation enhancement due to the zinc coating and to demonstrate the technology viability for future adaptation in cooling low power LED devices.

## II. EXPERIMENTAL APPARATUS AND DATA REDUCTION

The experimental apparatus consists of three primary components; the composite heat sink, pseudo LED heater pad and the data acquisition system. A schematic of the apparatus is shown in Figure 2.

### A. Composite heat sink

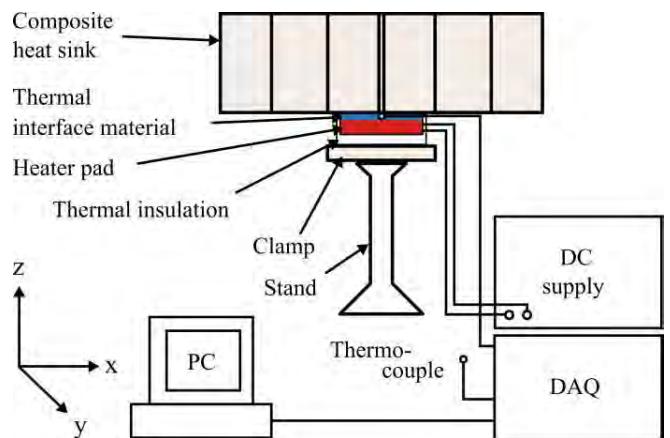

Figure 2. Schematic of the experimental facility.

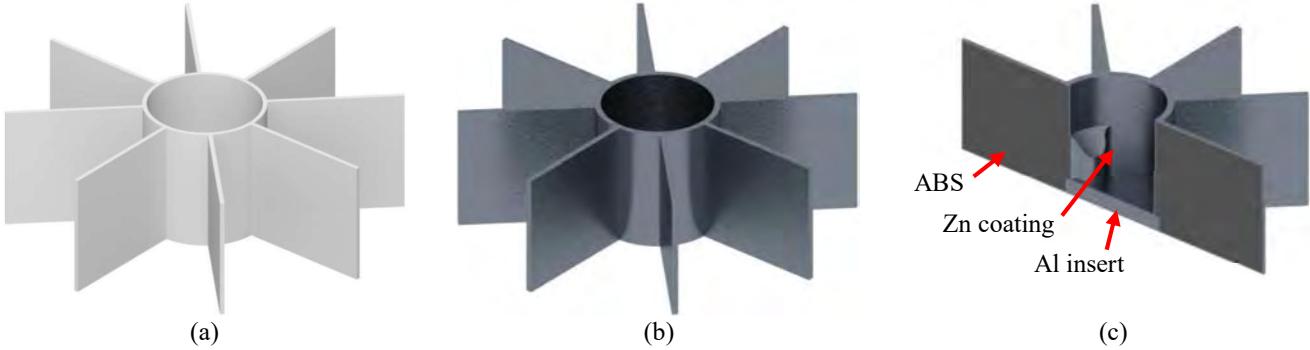

Figure 3. Heat sink design. (a) ABS heat sink, (b) zinc coated heat sink and (c) zinc coated heat sink with aluminum insert.

The three heat sink designs are shown in Figure 3. The design is based on a commercial LED heat sink (Aavid, P/N: NX300159) and they were fabricated using a Stratasys uPrint 3D printer (P/N: 680-50105-D). The heat sinks have a maximum diameter of 132 mm and a height of 42 mm. An eight fins design was implemented to optimize the uniformity of the zinc coating thickness. Each fin measures 41.4 x 42 x 1.5 mm<sup>3</sup> before the zinc coating is applied. The first heat sink (Figure 3a) is an uncoated Acrylonitrile Butadiene Styrene (ABS,  $k = 0.25 \text{ W m}^{-1} \text{ K}^{-1}$ ,  $\rho = 1040 \text{ kg m}^{-3}$ , T P/N: P430) design. The second (Figure 3b) heat sink consists of ABS coated in zinc. The final design is zinc coated ABS with an aluminum insert (5 mm thick, 41.3 mm in diameter) incorporated into the base of the heat sink (Figure 3c).

A Wire-arc spraying system (ValuArc, Sulzer Metro Inc.) was employed in coating the 3D printed heat sink designs with zinc (Sulzer Metro Inc.,  $k = 116 \text{ W m}^{-1} \text{ K}^{-1}$ ,  $\rho = 7140 \text{ kg m}^{-3}$ , P/N: 1031592). In wire-arc spraying an electric arc is struck between the tips of two continuously fed wires to melt them. A high velocity air jet strips the molten metal from the wires and creates a spray of droplets that impact on the substrate. Zinc was chosen due to its high thermal conductivity and its relatively low melting point (420°C). This ensured that the polymer heat sinks were not damaged during the coating process. A list of the relevant heat sink properties are outlined in Table 1.

Table 1. Heat sink properties

Heat sink design	ABS	ABS-Zn	ABS-Al-Zn
Initial mass [g]	32.4	32.5	50.3
Coated mass [g]	32.4	117.1	140.9
Average coating thickness [μm]	0	268	271

### B. Experimental facility

The applied heat flux was generated using a thermal heating pad (Mcmaster-Carr, 25.4 x 25.4 x 5 mm<sup>3</sup>, P/N: 35765K14) (See Figure 1). The thermal pad is attached to the base of each heat sink using thermally conductive tape (3M, P/N: 1-5-8810)

and is clamped to a fixed pressure of 265 kPa using a torque screwdriver (Mcmaster-Carr, P/N: 5716A21). The thermal pad is insulated from the clamp using 10 mm thick Cryogel z (Aspen aerogel, 25.4 x 25.4 x 5 mm<sup>3</sup>,  $k = 0.014 \text{ W m}^{-1} \text{ K}^{-1}$ ) as shown in Figure 1. The heat sink assembly is mounted 150 mm from the ground using a 3D printed stand to ensure unobstructed air flow during testing. A 1.6 mm hole is drilled in the center of the base of each heat sink, to facilitate measurement of the heat sink base temperature ( $T_b$ ) during testing. T-type thermocouples (Omega, P/N: FF-TI-20) are used to measure the base temperature and the ambient surrounding temperature ( $T_\infty$ ). Temperature measurement are acquired using an Omega DAQ (P/N: OMB-DAQ-56).

### C. Experimental testing and analysis

Experiments were conducted at atmospheric pressure and room temperature after steady state conditions were reached. The applied heat flux ranged between 0.5-1.5 W cm<sup>-2</sup> in increments of 0.5 W cm<sup>-2</sup>. It is assumed that all of the generated thermal energy is dissipated by the composite heat sink. Temperature data was averaged over a 15 minute period once steady state conditions had been achieved.

### D. Experimental uncertainty

The experimental uncertainty for all parameters was implemented using the methodology outlined by Kirkup and Frenkel [22]. A list of the relevant parameter and their associated percentage uncertainty (PU) is outlined in Table 2. All listed values are to a 95% confidence level.

Table 2. Experimental uncertainty

Parameter		PU [%]
$q''_{\text{gen}}$	+/-	6
$T_b$	+/-	2.6
$T_\infty$	+/-	4.4

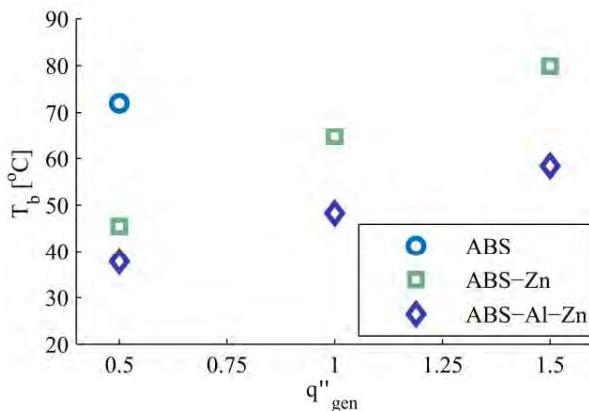

Figure 4. Heat sink base temperature for varied applied heat flux.

### III. RESULTS

Figure 4. shows how the base temperature of each heat sink design varies with the applied heat flux. For the lowest  $q''_{gen}$  the uncoated ABS heat sink reached a steady state temperature of 72°C. As  $q''_{gen}$  is increased to 1  $\text{W cm}^{-2}$  the base temperature exceeded the glass transition temperature of the ABS (105°C). The zinc coating on the second heat sink (ABS-Zn) reduces the base temperature by 37% over the uncoated case to 45.4°C. As  $q''_{gen}$  increases the base temperature increases linearly up to 79.9°C at the maximum applied heat flux.

The final heat sink (ABS-Al-Zn) incorporates an aluminium insert into its base, this enables a much lower thermal resistance path between the circumferential fins and the thermal pad. The thermal resistance between the inner surface of the inner cylinder and the thermal pad is also significantly decreased by the insert. This results in a greater cooling than the ABS-Zn heat sink. A 48% and 17% decrease in the base temperature is observed over the ABS and ABS-Zn heat sinks respectively, at the lowest applied heat flux. For the largest  $q''_{gen}$  a base temperature of 58.4°C was noted, this corresponds to a 27% decrease in comparison with the ABS-Zn heat sink.

### IV. CONCLUSIONS

The thermal performance of three low power LED heat sinks have been characterized. Optimum cooling was achieved by the zinc coated ABS heat sink which incorporated an aluminum insert into its base. The zinc coating was shown to significantly increase cooling performance over the uncoated case. Most importantly this research has demonstrated the potential of metal coated polymer heat sinks in cooling low power LED devices. Future work will focus on varying the coating material, numerical simulation to investigate optimum geometry and coating thickness, and direct comparison with an aluminum heat sink of a similar design.

**Abstract**—This work serves as a design tool for the development of integrated terahertz time-domain spectroscopy systems with microfluidic platforms. The emission of terahertz radiation from a GaAs THz antenna is simulated. This simulation involves a semi-classical computational model with white noise effects used to control the dynamic range of the system. The maximum measurable frequency for the overall integrated system is strongly influenced by the sample thickness of the microfluidic platform and the dynamic range of the terahertz time-domain spectroscopy system.

**Keywords**-biosensing; microfluidics; terahertz

## I. INTRODUCTION

Ultrafast science and measurement of terahertz (THz) electromagnetic radiation is a rapidly-growing research area with many applications [1-7]. Terahertz electromagnetic radiation occupies a unique section of the electromagnetic spectrum, being 0.1-10 THz. This THz electromagnetic radiation has important applications in the fields of security [8], communications [9], quality control [10], and biomedical spectroscopy [11].

One of the most important tools that has been enabled through THz electromagnetic radiation is THz time-domain spectroscopy (THz-TDS). Terahertz time-domain spectroscopy [12] has been applied to various biomedical applications, including genome analysis [13], oncology [14], and proteomics [11]. In THz-TDS, absorptive and refractive material properties are detected in pulses of THz radiation with extremely short duration ( $< 1$  ps) through changes to amplitude and phase, respectively. Measurements are performed with and without a sample and compared. For analyses of vibrational and rotational modes, THz-TDS performance is at or beyond that of traditional methods such as Fourier transform spectroscopy [15]. Additionally, THz electromagnetic radiation is non-ionizing, making THz-TDS an appealing option compared to X-ray and other spectra [16].

Despite the above advantages, THz-TDS systems have critical design parameters which should be taken into account for use in modern biomedical devices. This is especially true for integration with microfluidic devices [17-20]. These limitations

come from the strong absorption of liquids at THz frequencies. With this strong absorption in liquids, THz-TDS microfluidic systems must be made with sufficiently small microfluidic platform thickness and sufficiently high dynamic range, to ensure that spectroscopy is properly performed over the full bandwidth of the THz-TDS system [21].

This paper addressed the knowledge gap between microfluidic platforms and THz-TDS systems. We present a comprehensive investigation of microfluidic platform thickness and dynamic range for a THz-TDS microfluidic system. Data analysis is implemented through a semi-classical computational method [22] with white noise incorporated into the simulation. An increasing noise amplitude is used to examine the effects of THz-TDS dynamic range. The maximum measurable frequency,  $f_{\max}$ , of the system is found for numerous combinations of input parameters, being dynamic range and microfluidic platform thickness.

## II. THEORY

A THz-TDS microfluidic system is shown in Fig. 1. Here, an ultrafast laser pulse pumps a THz emitter to generate a reference THz pulse. Upon passing through the microfluidic platform, the reference THz pulse,  $E_R(t)$  becomes the THz sample pulse,  $E_S(t)$ .

The electric field of the THz pulse in the far-field can be expressed [23] as

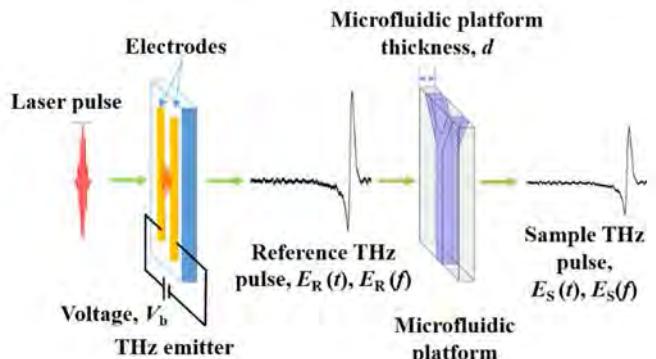

Figure 1. Microfluidic-based THz-TDS system

$$E(z, t) = \frac{L_y}{8\pi\epsilon_0 c^2 z} \frac{d}{dt} \int_0^{L_x} k_n(x, t) dx \quad (1)$$

where  $L_y$  is the gap width in the  $y$ -direction,  $L_x$  is the gap width in the  $x$ -direction,  $\epsilon_0$  is the permittivity of free space,  $c$  is the speed of light, and  $k_n(x, t)$  is the surface current of electrons. (The electric field is simulated according to the semi-classical computational method of Rodriguez and Taylor [22].)

The semiconductor electromagnetic equations for the THz emitter accomplishes a noise free radiation, the white noise (which is dominant over other noise sources at high THz frequencies) is added and defines the noise floor of the THz emitter measurements [24]. The equation of the reference THz pulse is

$$E_R(t) = E(z, t) + A_n n(t) \quad (2)$$

where  $A_n$  is the noise amplitude, and  $n(t)$  is the uniform random noise signal (centered about zero, peak-to-peak spread made the same as THz pulse amplitude). A Fourier transform of the generated pulse can be used to find the dynamic range for different noise conditions. The maximum absorption coefficient for a THz-TDS system is

$$\alpha = \frac{1}{d} \ln[DR \frac{4n}{(n+1)^2}] \quad (3)$$

for refractive index of  $n$  [25].

### III. RESULTS

The simulation is run with standard operation conditions of 50 mW average power in the laser pulse and external bias of 0.17 V/ $\mu$ m. The effect of noise amplitude,  $A_n$ , on the reference THz-TDS pulse is investigated by increasing the noise amplitude from zero to 1E-3, 1E-2, 1E-1, 1E0, and 1E1. The resulting reference THz pulses in the time domain are shown in Fig. 2 for progressively increasing  $A_n$  values. The same THz pulses in the frequency domain are shown in Fig. 3 for progressively decreasing dynamic range values of DR = 5.8E3, 5.7E3, 2.4E3, 3.0E2, 2.8E1, and 2.8E0. It is clear that as noise amplitude increases, dynamic range decreases.

By finding the intersection of the maximum absorption coefficient with a known water absorption coefficient curve,  $\alpha_w$ , the maximum measurable frequency can be found. This is shown in Fig. 4(a) for  $d = 120 \mu$ m and DR = 2.4E3. For decreased DR or increased  $d$ , the  $\alpha$  curve will shift down, forcing maximum measurable frequency to a lower value. For increased DR or decreased  $d$ , the  $\alpha$  curve will shift up, forcing maximum measurable frequency to a higher value. Given this behaviour, the various dynamic ranges shown in Fig. 3 can be used in conjunction with the absorption coefficient of water, being  $\alpha_w = 61f + 54 \text{ cm}^{-1}$ , to find the corresponding maximum measurable frequency.

Ultimately, the maximum measurable frequencies can be collected for a variety of simulated conditions for microfluidic platform thickness and dynamic range. This is shown in Fig. 4(b) which displays a three-dimensional surface plot that shows the maximum measurable frequency versus dynamic range and microfluidic platform thickness. As described previously, one

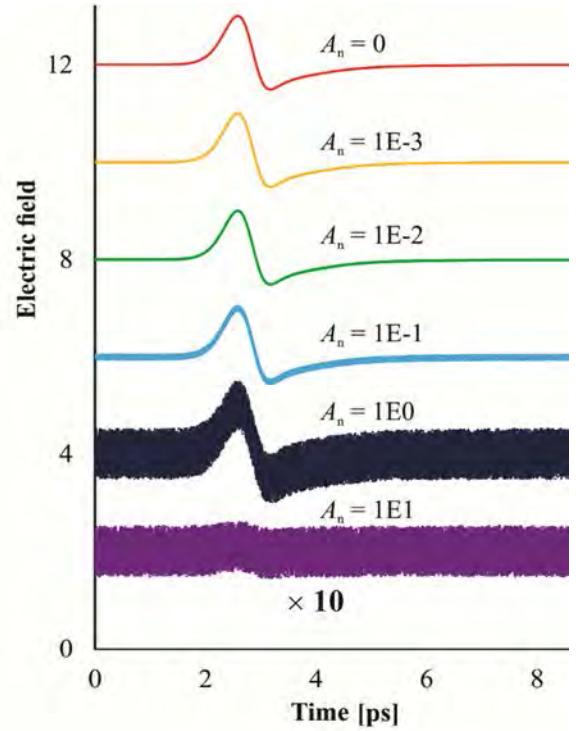

Figure 2. Simulated THz pulses in the time domain with different noise amplitudes.

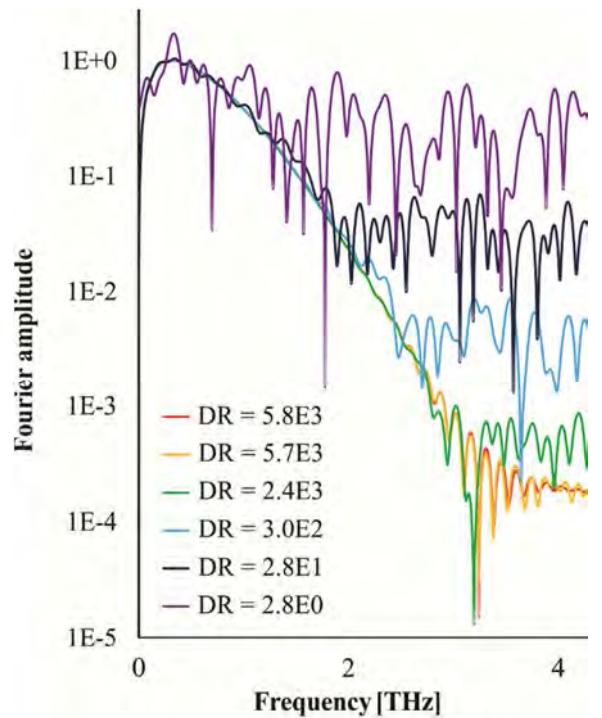

Figure 3. Simulated THz pulses in the frequency domain with different dynamic ranges (corresponding to the noise amplitudes from Fig. 2).

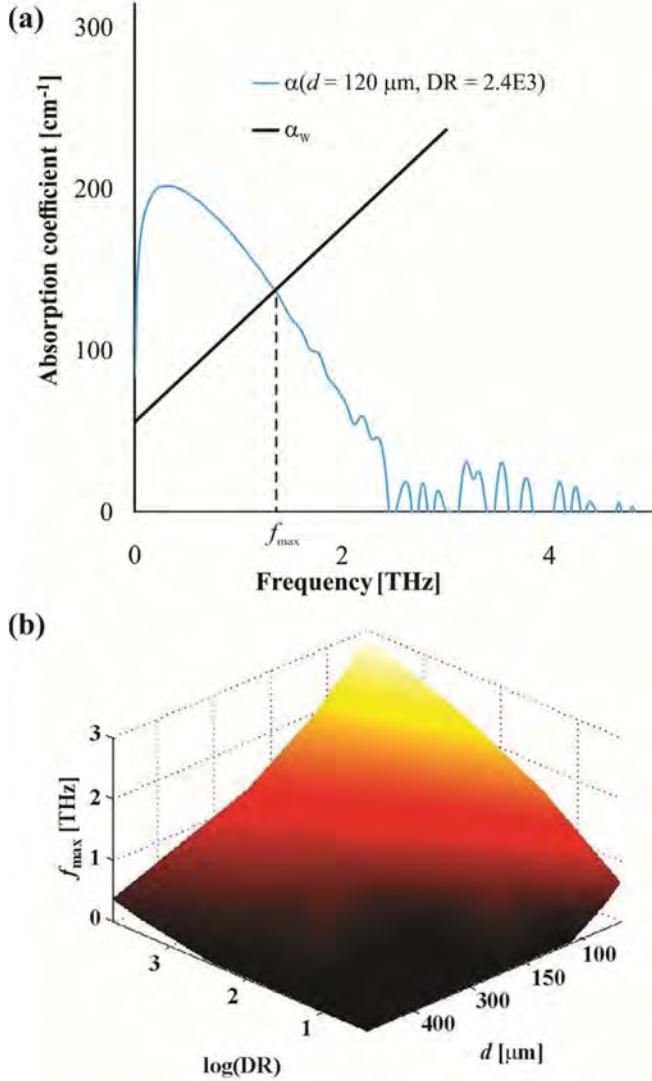

Figure 4. (a) The absorption coefficient versus frequency is shown for a representative case of 120  $\mu\text{m}$  microfluidic platform thickness and 2.4E3 dynamic range. (b) The maximum measurable frequency is plotted against the log of the dynamic range and the microfluidic platform thickness. The maximum measurable frequency has a maximum value of approximately 3 THz and decreases with decreasing dynamic range and increasing microfluidic platform thickness.

can observe an increase of the maximum measurable frequency with decreased  $d$  and increased DR. These results can be used to inform future designs.

#### IV. CONCLUSIONS

In conclusion, for THz-TDS microfluidic systems, the microfluidic platform thickness and dynamic range of the THz-TDS system play a critical role in defining the maximum measurable frequency. It was found that the maximum measurable frequency decrease with decreasing the dynamic range and increasing sample thickness. These fundamental results can be used in the design of future microfluidic THz-TDS systems for biomedical applications.

**Abstract**—In the last two decades, majority of the newly developed dental caries detection techniques have been optics-based, relying either on enhancement of light scattering in early carious lesion (e.g. optical coherence tomography or OCT) or enhancement of light absorption in early caries (e.g. thermophotonic lock-in imaging or TPLI). This paper aims to explore the detection threshold capabilities between light scattering and light absorption based dental caries detection methods. With this intention, the experiments will be conducted through examination of controlled artificially-induced early caries. It is anticipated that the molecular-contrast TPLI imaging technology outperforms OCT due to the more specific nature of light absorption contrast mechanism.

**Keywords-component;** *early dental caries; thermophotonic lock-in imaging; spectral-domain optical coherence tomography; artificial demineralization.*

## I. INTRODUCTION

Dental caries continues to be a major public health challenge in both children and adults [1]. Over the past years, the state of the art in preventive dentistry has provided promising therapeutic techniques for preventing the progression of early dental caries to cavities and complete tooth decay [2]. However, the effectiveness of these preventive provisions rely on detection of caries at very early stages. But, unfortunately, clinical detection methods such as x-ray radiography and visual-tactile inspection lack sufficient sensitivity for detection of early stages of carious lesions due to morphology of tooth structure and large surface area of healthy enamel around the carious lesion [3]. In this paper, a quantification of detection threshold for mainstream optical imaging modalities, optical coherence tomography (OCT) and thermophotonic lock-in imaging (TPLI) (as representative techniques based on light scattering and absorption, respectively), is performed in early detection of dental caries. Optical coherence tomography (OCT) is a promising modality capable of imaging samples based on back reflection of light, and is capable of providing 3-dimensional sub-surface morphology of biological tissue microstructure with micron-scale resolution [4]. The ability of OCT in providing high-

resolution 3-dimensional images has led to its popularity in dentistry especially in diagnosis and screening of dental diseases [5][6].

While OCT provides three dimensional maps of light-reflecting interfaces in biological tissues, such as void interfaces introduced by demineralization in tooth, light absorption-based technologies, such as TPLI, produce maps of subsurface features absorbing the specific incident laser radiation (e.g., Calcium and phosphate as the byproducts of demineralization). The working principle of lock-in thermography involves an incorporation of active thermography along with lock-in demodulation signal processing in turbid samples to detect thermal waves emitted back from subsurface molecular absorption sites (e.g. early dental caries) by focusing the infrared camera on the sample [7]. As such, lock-in thermography is a very advantageous tool in electronic device testing and failure analysis of materials [8], but it also has important applications in early pre-clinical diagnosis and control during treatment in medical fields such as imaging of early caries [9]. Therefore, the motivation behind this study is to evaluate the detection threshold of two emerging medical imaging technologies, spectral domain-OCT (OCT) and TPLI, in diagnosis of early dental caries.

## II. MATERIALS AND METHODS

### A. Thermophotonic Lock-in Imaging

The experimental setup of TPLI (Fig. 1(a)) [10] consists of a continuous wave 808 nm near-infrared laser diode (808nm; Jenoptik, Jena, Germany) which is regulated by a laser controller unit (Ostech, Berlin, Germany) in order to allow for modulation of laser intensity. Samples are put on LEGO blocks and positioned at the focal plane of the camera. The LWIR camera (Gobi 640; Xenics, Leuven, Belgium) used has a spectral range of (8-14  $\mu$ m) and maximum frame rate of 50 frames per second. The detector of the camera consists of 640 $\times$ 480 elements with pixel pitch of 25  $\mu$ m. A custom made extension tube and an 18 mm focal-length objective lens are used to obtain a magnification of one from the interrogated surface of the sample.

The multifunctional data acquisition board synchronously generates three signals: reference pulse train, in-phase, and

quadrature reference signals. The reference pulse train finds the beginning of each modulation cycle for averaging. The in-phase reference signal is also sent to the laser controller to modulate the intensity of the laser beam. The in-phase reference signal is in-phase with the laser modulation while there is a  $90^\circ$  phase lead between the in-phase and quadrature reference signals. The images are then taken with a long-wave infrared camera and then weighed and averaged using the instantaneous readings of the two reference signals to yield in-phase ( $S^0$ ) and quadrature ( $S^{90}$ ) images [10]. The amplitude and phase for each pixel are then calculated by applying equation 1:

$$A = [(S^0)^2 + (S^{90})^2]^{0.5} \text{ and } \varphi = \arctan(S^{90}/S^0) \quad (1)$$

In this paper, we only present and discuss the phase images as they are known to be of superior sensitivity due to the emissivity normalized nature of phase channel [11].

### B. Spectral Domain Optical Coherence Tomography

Fig. 1(b) depicts a schematic of the developed OCT system. OCT laser is a broadband source of 30 mW superluminiscent diode (SLD; Exalos) centered at wavelength of 1315 nm and bandwidth of approximately 110 nm. Spectrometer is a 2048-pixel high speed camera with line scan/acquisition rate of 147 kHz. The theoretical axial resolution of the system is approximately 4.5  $\mu\text{m}$  in tooth and the theoretical lateral resolution is 10  $\mu\text{m}$ . The experimental axial resolution in air and tissue were measured as 12 and 8.6  $\mu\text{m}$ , respectively. Optical power at sample is  $\sim$ 7mW and the signal-to-noise (SNR) of the built OCT system is  $>100$  dB. The measured imaging depth of the system is 5 mm in air. The OCT beam is scanned along the smooth surface of the tooth using the two galvo scanners (GS) and performs the inverse Fourier transform operation on the Fourier-domain signals registered by the spectrometer, thus creating a 3D tomographic image of early caries. For OCT, the backscattered light in a form of integrated *en-face* images are measured and displayed.

### C. Controlled Demineralization Protocol

Following the bio- and laser safety regulations at York University, anonymous extracted human teeth were collected from local oral surgeons and teeth with no visible stains or white spot lesions were selected for the study. In controlled demineralization of dental samples, a lactic acid-based solution is prepared. The solution is an acidified gel, consisting of 0.1 M lactic acid and 0.1 M NaOH which is gelled with addition of 6% w/v hydroxyethylcellulose [10][11]. As such, teeth with no visible defect are selected and the surface of the tooth is covered by nail polish except for a rectangular treatment window. Sample is then submerged upside down in the acidic gel for certain number of days. Finally, sample is removed from the gel, and the nail polish is removed for imaging.

### D. Data Processing and Analysis

To quantify the detection threshold of TPLI and OCT in progression of early caries, the thermophotonic phase images at

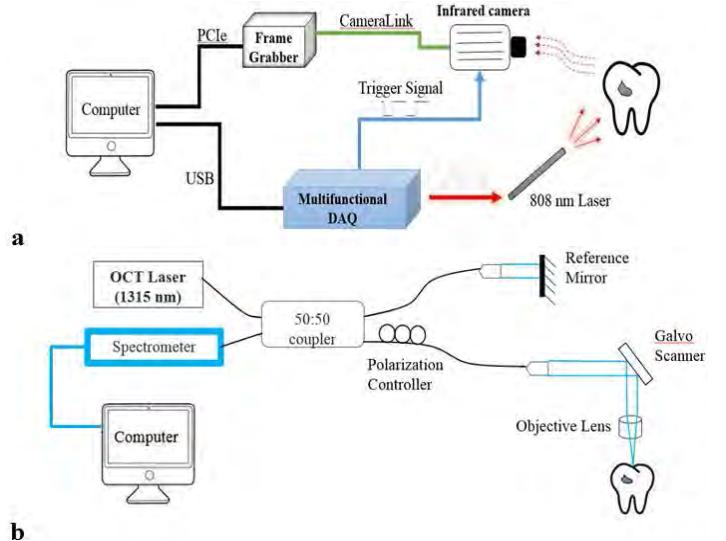

Figure 1. Schematic representation of (a) TPLI system and (b) spectral-domain OCT system.

2Hz and integrated *en-face* images derived from OCT were normalized [11]. For TPLI phase images, the pixel values were normalized by subtracting the phase value of pixels by the average pixel value of an intact reference area from the same image. For integrated *en-face* images, normalization was performed by dividing the amplitude values of pixels by the average amplitude values of an intact reference area from the same image. To compare and monitor the progression of artificial tooth demineralization in OCT and TPLI, the normalized phase and integrated *en-face* images were averaged in the regions of interest and the standard deviation of pixel values was calculated.

## III. RESULTS AND DISCUSSION

Detection threshold is an important parameter of a diagnostic modality, i.e. how early the diagnostic system can detect caries.

### A. Detection Threshold of OCT and TPLI

To this end, a time-dependent controlled demineralization procedure was followed on smooth surface of a tooth sample. Fig. 2(a) shows the visual photograph of the sample and the dashed rectangle shows the location of the treatment window.

In integrated *en-face* OCT (Fig. 2(b)-(l)), it can be observed that as the treatment time increases, the contrast between the treatment window and the intact region gradually increases as a result of progression of artificially-induced early caries which results in enhancement of light scattering. The maximum contrast occurs at day 15 of demineralization. Similarly, visual inspection of TPLI phase images (Fig. 3(a)-(k)) shows that TPLI starts to show very small change in contrast with progression of early caries starting from day 1 of demineralization. This change becomes fully visible at day 2 of demineralization. While the contrast from day 2 to day 10

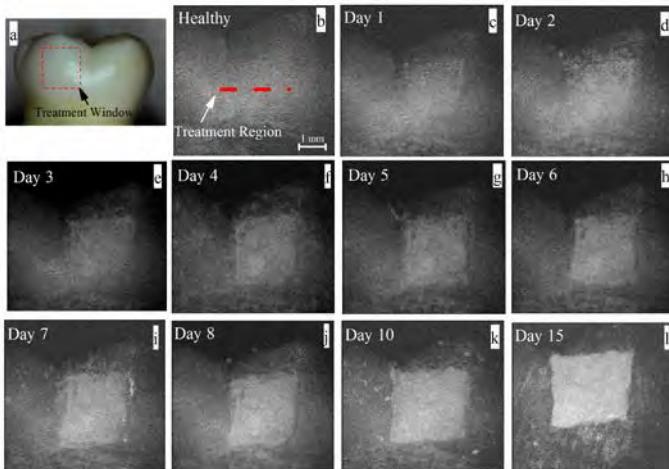

Figure 2. Image of the sample (a) before demineralization and after (b) 0 days, (c) 1 day, (d) 2 days, (e) 3 days (f) 4 days (g) 5 days (h) 6 days (i) 7 days (j) 8 days (k) 10 days, and (h) 15 days of demineralization

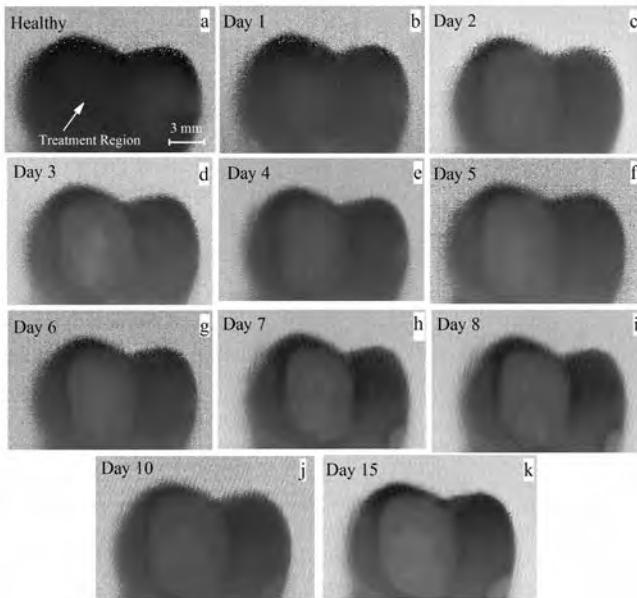

Figure 3. TPLI phase images at 2-Hz modulation frequency at (a) 0 days, (b) 1 day, (c) 2 days, (d) 3 days (e) 4 days (f) 5 days (g) 6 days (h) 7 days (i) 8 days (j) 10 days, and (k) 15 days of demineralization

increases gradually, at day 15 of demineralization the maximum contrast occurs. In addition to visual observations, statistical analysis was conducted on images of Fig. 2 and Fig. 3. The bar plots of Fig. 4 confirm the superiority of detection threshold of TPLI over OCT. In integrated *en-face* OCT bar plots, it can be seen that in each demineralization step, the system tends to show higher standard deviation compared to the bar plots of TPLI. The relatively large standard deviation present in OCT is due to its non-specific nature of light scattering mechanism. It is observed that with progression of artificially-induced early caries, there are gradual enhancements in average integrated intensities. However, there also exists some instability in the average integrated intensity values between the demineralization steps of day 4 to 10. Consequently, it can be concluded that after application of demineralization for 15 days or more, OCT could differentiate

between healthy and early carious lesions as the standard deviation of treatment steps up to day 10 contain intensity values which lie within the standard deviation of the healthy region. Thus, at 15-day of treatment step the detection threshold of the system can be defined. Bar plots of TPLI show an increase in the average phase values between each treatment interval. Due to smaller standard deviation of average phase value obtained from the healthy region of the sample, the detection threshold of TPLI can be distinguished at day 2 of demineralization. More comprehensive comparison between TPLI and OCT is tabulated in Table 1. From these comparison parameters it can be concluded that TPLI is an optimal choice for detection of early dental caries.

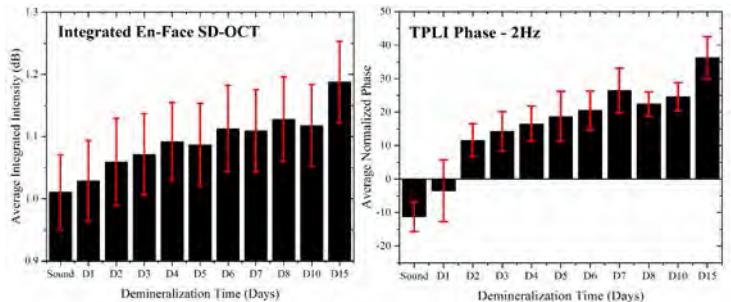

Figure 4. Bar plots of (left) spectral-domain optical coherence tomography (OCT) and thermophotonic lock-in imaging (TPLI) (right) with their standard deviations.

TABLE 1. SUMMARY OF COMPARISON BETWEEN TPLI AND OCT

Parameters	TPLI	OCT
Source of Contrast	Absorption	Scattering
Imaging Depth	few mm-cm	1- 2 mm
Resolution	Low (~100μm)	High(~10μm)
Field of view	Wide (whole tooth)	Small
Detection Sensitivity	Very High	Low
Detection Threshold	2 Days of Demin	15 Days of Demin
3D Imaging	No	Yes
Clinical Translation	Difficult	Straight Forward
Cost (\$)	\$	\$\$

#### IV. CONCLUSION

In this study, we present a study that quantifies the detection threshold between spectral domain optical coherence tomography and thermophotonic lock-in imaging in detection of early dental caries. These systems used for diagnosis of early caries and their progression would significantly improve caries management decisions with respect to preventive care. Results suggest that the detection threshold for detection of early dental caries were found to be better in TPLI images compared to OCT due to its light absorption contrast mechanism compared to light scattering contrast mechanism in OCT.

**Abstract**— Flexible endoscopes require reliable advancement and steerability of the device tip. Helical spring design is critical to both endoscopic steerability and cable function. To characterize the impact of geometric and material factors on endoscopic function, a parametric helical spring and a cable assembly was modelled using the finite element method and analyzed using a design-of-experiments approach. Individual input parameters (height, modulus ( $E$ ), force, and width) and two interactions (pitch/width and pitch/height/ $E$ /width) were found to significantly impact the radius of curvature (a measure of steerability). The force and pitch/width interaction had negative effects, in contrast to positive effects from height,  $E$ , width and the pitch/height/ $E$ /width interaction. This information provides critical geometric and material information to guide helical spring design for optimized endoscopic steerability.

**Keywords:** *Endoscope, Helical Spring, Finite Element Analysis, Design-of-Experiments, Geometry and Material Parameters, Radius of Curvature*

## I. INTRODUCTION

Endoscopes are long thin tubular devices for non-invasive visualization of the interior of cavities, canals and vessels. The flexibility of articulated endoscopes is important in many clinical applications. Articulated endoscopes are generally controlled by cables and levers which bend the distal extremity of the device to enable route selection or to change the field of view.

Challenges associated with flexible endoscope design include reliable advancement and steerability of the device tip [1]. Reliable advancement can be addressed by utilization of relatively rigid helical springs within the device shaft. The

helical geometry provides bending flexibility at the expense of some reduction in axial stiffness and tensile strength [2]. However, the device tip must be flexible for steerability to accommodate different bend radii. The device tip can be steered via a cable attached to a control mechanism within the endoscopic handle.

In order to achieve tight bends while preventing cable malfunctions [3] a thorough understanding of the helical spring stress distribution under specific load conditions is necessary. Multiple studies have developed analytical and numerical models to characterize stress distribution in helical springs under axial and pure bending loads [4]. However, to date studies have not considered the optimization of bend radii representative of helical spring and cable assemblies in traditional endoscopes. As such, the aim of this study is to understand the impact of endoscopic tip design (geometry and material properties) on the radius of curvature governing steerability in traditional endoscopes.

## II. METHODS

### A. Experimental Design

A two-level five-factor design-of-experiments methodology was utilized to understand the main geometric and material effects and their interactions on the attainable radius of curvature of an endoscopic device (outcome). The effects of width, height, pitch, Young's modulus ( $E$ ) and applied force were assessed at combination of high and low factor levels, resulting in 32 experimental groups (Table 1). The range for width, height and pitch were based on commercially available endoscopic designs, with  $E$  representing metals from Aluminum (~70GPa) to Steel (~200GPa). Force ranged from 0.5 N (to allow the device tip in the most rigid configuration to

displace at least 0.1 mm) to 2N (representing the maximum tensile force a 0.1 mm diameter steel cable can withstand before plastic deformation).

Factor Level	Width (mm)	Height (mm)	Pitch (mm)	E (GPa)	Force (N)
Low	0.1	1	3	70	0.5
High	1	2.5	4	200	2

TABLE I. HIGH AND LOW FACTOR LEVELS ARE PRESENTED FOR WIDTH, HEIGHT, PITCH, E AND FORCE USED TO INVESTIGATE THE ENDOSCOPIC GEOMETRIC AND MATERIAL EFFECTS AND THEIR INTERACTIONS ON THE ACHIEVABLE RADIUS OF CURVATURE

### B. Finite Element (FE) Model Generation

An FE model of a traditional endoscope was generated that enabled parametric geometric and material property assignments (Table 1). The helical spring (rectangular cross section) was modelled using linear brick elements. The cable was modelled using linear 3-D truss elements. Once assembled the cable proximal end was connected to the helical spring proximal outer circumference (Fig. 1a) and the cable distal end was placed inside the helical spring (Fig. 1b). Interactions were modelled using a general contact algorithm. An ENCASTRE boundary condition was used to fix the distal end of the helical spring. The cable was connected to the helical spring tip using a tie constraint. A concentrated force was then applied to the cable distal end to simulate the pulling force from the controller unit and analysed in ABAQUS dynamic/explicit.

The radius of curvature was calculated based on spatial displacement outputs identified between a node defined at the cable attachment site on the helical spring tip and the most

distal node with greater than zero displacement at the base of the helical spring. Mesh convergence analysis was performed by refining the mesh size and calculating the radius of curvature and maximum deformation in each iteration (to within 5%). The final model contained 3692 nodes, 2135 elements and 10920 degrees of freedom.

An automated procedure through the ABAQUS Scripting Interface (ASI) was utilized to create parts, assign material properties, assemble parts, apply boundary conditions and force, and solve each generated model. The generated nodal displacement outputs and deformed geometry image data sets were analysed by a python script to calculate the radius of curvature, annotate images with their corresponding configuration parameters and organize the raw data to be used for design-of-experiments analysis (Fig. 1).

### C. Design-Of-Experiments

Thirty-two configurations were analyzed in the two-level factorial design-of-experiments analysis (Design-Ease). Based on the Box-Cox plot, a base 10 Log transformation of the output response (radius of curvature) was used to stabilize the variance. A Sum-of-Squares chart with a 2% weighted contribution threshold was utilized to determine the model inclusion criteria. A Shapiro-Wilk test was also conducted to confirm data normality. An Analysis of Variance (ANOVA) with a Bonferroni correction was conducted to determine the significance of the model, effects and interactions.

## III. RESULTS

All thirty-two models were solved successfully. The model, four of the input parameters (width, height, E, force) and two interactions (between pitch/width and pitch/height/E/width)

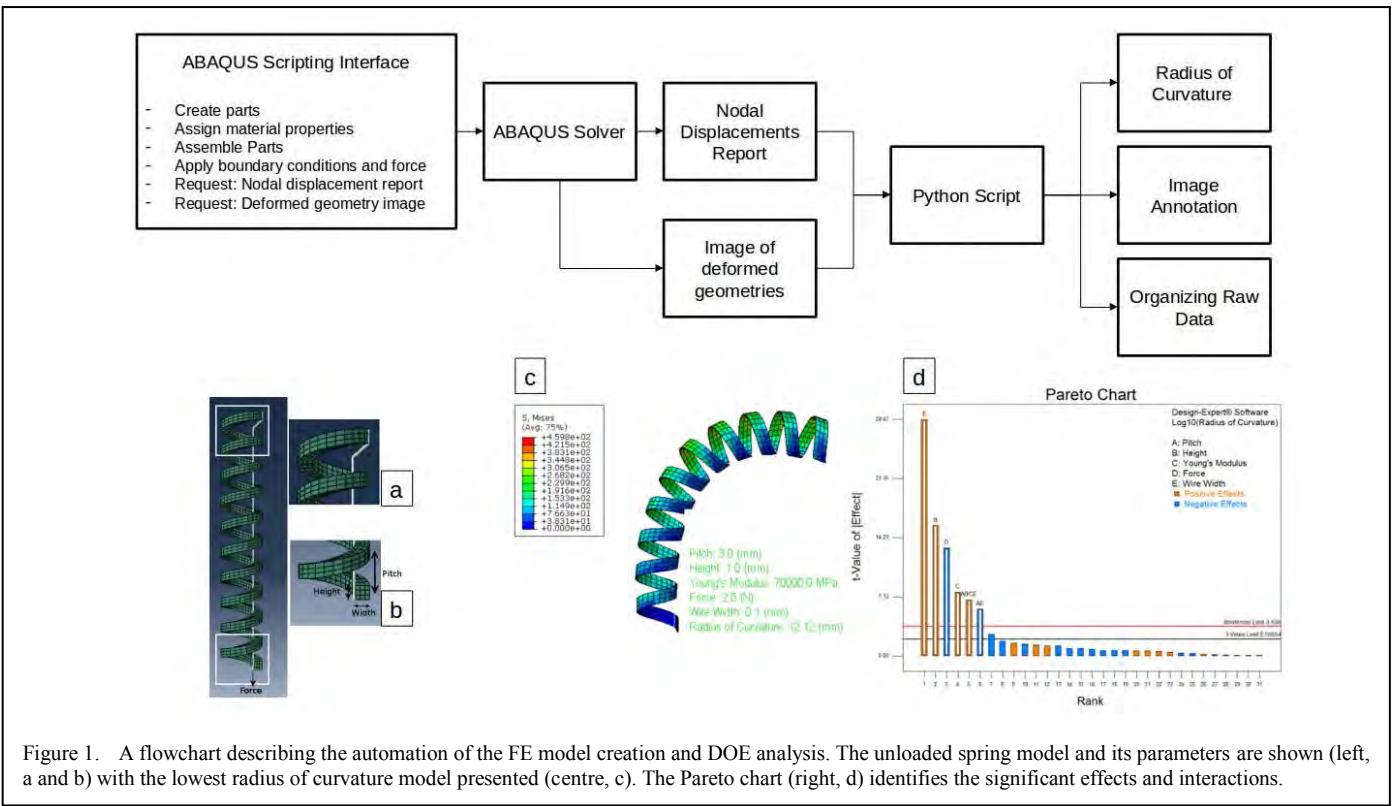

Figure 1. A flowchart describing the automation of the FE model creation and DOE analysis. The unloaded spring model and its parameters are shown (left, a and b) with the lowest radius of curvature model presented (centre, c). The Pareto chart (right, d) identifies the significant effects and interactions.

were found to be statistically significant ( $P<0.0001$ ). The lowest radius of curvature achieved was 12.12mm (Fig. 1c). A Pareto chart summarizing the main effects and model errors is shown in Fig. 1d.

The largest contribution to the model was the width of the spring (effect=1.39, 58.33% contribution). The force and pitch/width interaction each had a negative influence, whereas the height, E, width and pitch/height/E/width interaction showed a positive influence. A negative effect in which higher forces reduce the radius of curvature allows for tighter bends. The negative AE effect shows that pitch and width work in opposition with respect to their impact on radius of curvature, as evident in the response shown in Fig. 2. Pitch and all other interaction effects below the 2% contribution threshold were applied as model error. A summary of the statistical data as well as the final equation in terms of coded factors are presented in Table 2.

#### IV. DISCUSSION AND CONCLUSION

A robust computational model was developed using a design-of-experiments approach that allows parametric optimization of endoscopic tip design parameters for radius of curvature minimization. Based on this model some of the identified disadvantages of traditional endoscopes can be addressed by altering design parameters for different applications. A small pitch and width yield a radius of curvature optimal for acute bending radii. If due to design restrictions a larger width is necessary, an increase in pitch may be employed to maintain a sufficiently small bending radius.

The challenges associated with endoscopic device advancement have been reported in multiple studies [5,6,7]. A study of FDA reports from 1985 to 2009 (Chen et al. 2010) reported that 21% of endoscopic mechanism failures are due to cable malfunctions. Based on our models, if advancement of

the device requires high pushing forces, the device axial stiffness must be increased by increasing the cable width and/or modulus of elasticity and the acute bend radius can still be achieved by increasing the pitch, and/or lowering the height without increasing the force applied to the cables.

This study demonstrates the potential of a combined FE modelling DOE approach for optimization in biomedical instrumentation design. Through optimization of geometric and material properties, endoscopes can be optimized to meet specific tip design criteria and function safely and effectively within varied environmental conditions.

**Abstract**—Focused ultrasound surgery (FUS) is a new energy-based therapeutic technique which has been recognized as a truly non-invasive surgical method. Since the ultrasonic energy is applied from an external transducer, FUS has the potential to improve both oncologic and cosmetic outcomes for breast cancer treatment. In the present study, we conducted a computational analysis on a realistic patient model to investigate the mechanism and the applicability of FUS in breast cancer treatment. Magnetic Resonance Imaging (MRI) data of a patient with breast tumor were used to provide a clinical model for finite element analysis (FEA) using COMSOL. Results from computational analysis clarify the acoustic and thermal mechanisms of FUS and suggest the way how this technique can be carried out during the breast cancer treatment.

**Keywords**-focused ultrasound surgery; breast cancer; finite element analysis;wave propagation; heat transfer.

## I. INTRODUCTION

After the cardiovascular and cerebrovascular diseases, cancer is considered as the second leading cause of death in the world, with nearly 8.8 million deaths (15.7% of total) each year. Breast cancer is the most common cancer among women, with an estimated 1.7 million new cases diagnosed each year in the world [1]. This represents about 25% of all cancer in women. The Canadian Cancer Society statistics show that about 26,300 new cases of breast cancer have been diagnosed in Canadian women in 2017, and about 5,000 of the cases will be developed to death [2]. The high mortality rate substantiates the importance of early detection and treatment of breast cancers.

Determinant factors in the treatment of a breast tumor are highly dependent on the type, size and location of the tumor [3]. For both benign and malignant cases, surgical techniques such as mastectomy and breast-conserving therapy (BCT) have been considered as the main methods of treatment. Mastectomy, which is the surgical removal of the entire breast, was first introduced by William Halstedt in 1894, and remained as the cornerstone of therapy for about 80 years [4]. Whereas BCT is achieved just by removing a discrete portion of breast

tissue containing the cancer, and can practically be followed by adjuvant treatment modalities such as chemotherapy and radiotherapy to get more efficient results. Despite the widespread use of surgery as a main treatment for cancer, it is invasive and unable to preserve the structure of the breast postoperatively.

The sensitivity of the human body to the temperature change has caused the development of new therapeutic methods for cancer. Thermal ablation therapy can be achieved by increasing the tissue temperature above a standard level to change the properties of targeted tissue [5]. Some of the energy-based methods used to achieve the thermal ablation of tumors are radiofrequency ablation, laser thermotherapy, and ultrasound therapy. Among them, ultrasound surgery is truly a non-invasive technique, since acoustic waves are emitted by an external transducer [6].

Ultrasound therapies can be split into two major categories, namely “ultrasound hyperthermia” and “high intensity focused ultrasound (HIFU) surgery”. During the hyperthermia treatment, the targeted tissue is exposed to the acoustic energy at a low intensity level for a long period of time (10-60 minutes), such that the tumor temperature is evaluated and maintained at 41-45°C. In contrast, HIFU uses the ultrasonic energy at a high intensity field to increase the temperature of focused area up to 56°C with a short ablation time (from 0.1 to 30 seconds) [7].

FUS is a truly non-invasive therapeutic technique which has been recognized for enormous medical applications ranging from cancer treatment to thrombolysis [6]. In principle, FUS allows the local treatment of a tumor by focusing acoustic energies to a targeted area from an extracorporeal source of ultrasound. This process induces tissue heating and corresponding temperature rise in the focal region that would be associated with irreversible biological effects such as necrosis and cell apoptosis.

FUS has been considered as a promising option for the thermal therapy of breast tumors due to its non-invasive mechanism. Since this technique is applied from an external source remotely, it does not cause any significant changes in patients' mammary shape, and has the potential to upgrade both oncologic and cosmetic outcomes for breast cancer

treatment [8]. In response to the potential benefits of HIFU to patients with breast cancer, many researches have been carried out on the different aspects of HIFU including acoustic-heating characteristics of ultrasound transducer, effects of blood perfusion, and physiological effects of HIFU ablation. During the current decade, the clinical researches on the HIFU treatment of breast cancer were promoted by development of monitoring techniques [8].

In the present paper, we conducted a computational analysis to simulate the wave propagation and heat transfer mechanisms in the FUS of the breast cancer. Finite element model of breast tissue including a tumor was constructed from MRI images of a patient. Using COMSOL software, thermal mechanical results are presented in graphical form to investigate the performance of FUS in the treatment of breast cancer.

## II. MATERIALS AND METHOD

### A. FUS Mechanism

Figure 1 shows a schematic drawing of the FUS system to treat breast cancer. When the acoustic waves propagate through the tissue, the medium particles start to vibrate, resulting in alternating cycles of compression and rarefaction pressure inside the tissue [9]. The ultrasound beams then converge into the focal area where the resulting acoustic pressure reaches the highest amplitude. This process leads to temperature rise in the focal region that would be associated with biological ablation and therapeutic results[7].

A single HIFU exposure ablates a small volume of the tumor, so in order to achieve the complete necrosis, the ablating treatment should be applied to the entire volume of tumor [10]. In practice, many of ablated regions must be placed side by side to paint out the entire tumor. The size of each lesion depends on many factors such as the characteristics of transducer and the acoustic properties of targeted tissue, but typically a single insonation covers a cigar shape region with approximate dimensions in the order of 8-15 mm (along beam axis)  $\times$  1-3 mm (transverse direction). The postoperative imaging data show that two weeks following FUS, the periphery of the ablated regions would be replaced by proliferative repair tissue [10].

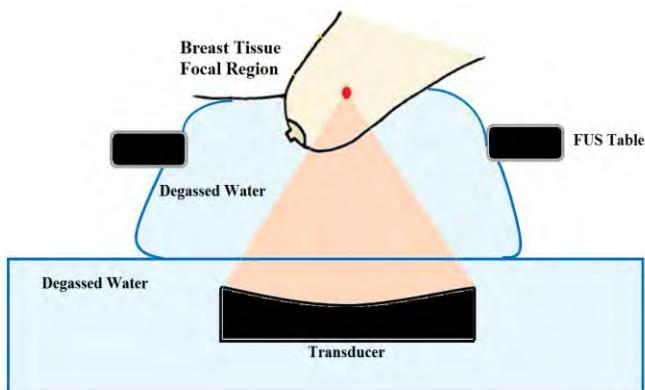

Figure 1. schematic drawing of FUS system used to treat breast cancer

### B. Physics and Mathematics

The main operation of FUS, is the ablation of a targeted region inside the body by focusing ultrasound beams to that area. [7]. The two predominant factors of FUS, which lead to the therapeutic results, are the conversion of acoustic energy to heat (thermal effect), and the cavitation (mechanical effect). In principle, the role of each effect depends on the dosage parameters, i.e. the intensity at the focal area and the exposure time. If the targeted tissue is exposed to an ultrasound field at a low intensity level for a long period of time, the thermal effect will be the only mechanism of action. However, for applying mechanical effects, a focused energy at a high intensity level for a short time is required [9].

For the mathematical modeling of the focused ultrasound induced heating, the mathematical theories of continuum physics can be used to model the thermal effects of FUS at a relatively low intensity level and before the cavitation threshold [11]. To this end, a set of mathematical equations that describes the wave propagation, absorption and heat transfer mechanisms should be combined together. Accordingly, the ultrasound wave propagation can be characterized with Helmholtz equation, which represents the time independent form of wave equation [12]:

$$\nabla^2 P + \left(\frac{\omega}{C_c}\right)^2 P = 0, \quad (1)$$

where  $P$  is the acoustic pressure,  $\omega$  is the angular frequency, and  $C_c$  is the local speed of sound. To model the heat transfer during FUS, the absorbed acoustic energy can be considered as a heat source for the Pennes bioheat transfer equation [12]:

$$\rho C_p \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) - \rho_b C_b w_b (T - T_b) + 2\alpha_{ABS} I, \quad (2)$$

where  $T$ ,  $\rho$ ,  $C_p$  and  $k$  denote the temperature distribution, density, specific heat and thermal conductivity of breast tissue, respectively.  $\rho_b$  refers to the density of blood,  $C_b$  is the specific heat of blood,  $w_b$  is the blood perfusion rate, and  $T_b$  is the temperature of the blood.  $\alpha$  is the acoustic absorption coefficient, and  $I$  is the local acoustic intensity which can be determined as a function of the acoustic pressure.

### C. Finite element analysis

In order to simulate the heating mechanism induced by ultrasound energy and to calculate the acoustic pressure and consequent temperature rise during the FUS process, a FEA using COMSOL software was performed on a realistic patient model. In order to obtain the precise information on the breast tissue and tumor geometries, MRI of a patient with breast tumor was utilized. According to the Helsinki agreement, the whole study was thoroughly explained to the patient. Bilateral MR mammography was performed on a 42 years old lady in the “Erfan imaging center” in Tehran, Iran. The patient was a known case of recently diagnosed breast cancer in the right breast. The images show that there is a 26 $\times$ 17 mm ill-defined low signal intensity mass in T1W in the right LIQ middle zone. Figure 2 displays the MRI images and consequent 3D solid model of the breast tissue and tumors.

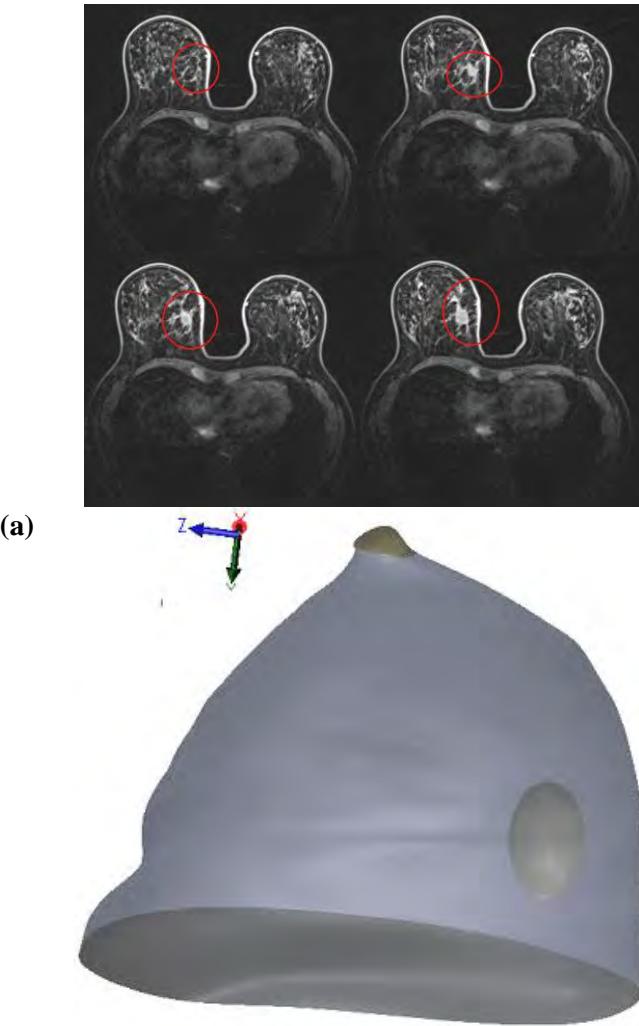

Figure 2. Geometrical features of breast and tumor location: (a) MRI data; (b) Solidworks Model

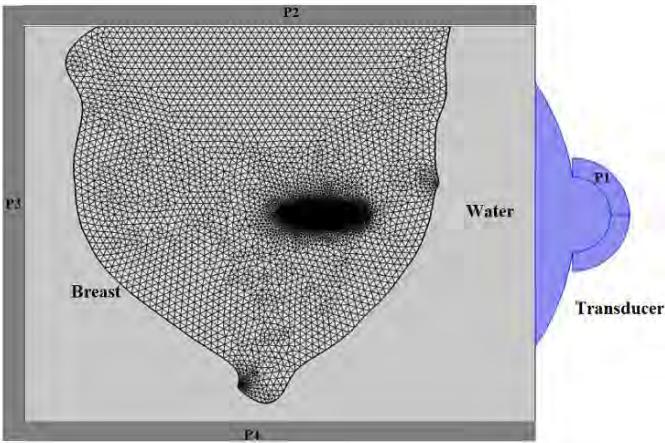

Figure 3. Breast and transducer model for FEA or FUS

A FUS simulation model composed of breast tissue, water and a transducer was developed, as shown in Figure 3. The transducer was bowl-shaped having a focal length of 62.64 mm, an aperture of 35 mm in radius, and a hole of 10 mm in radius in the center [9]. A medium of water was considered

between the breast tissue and the transducer to act as a coupling material. Four perfectly matched layers (P1-P4) were defined to absorb the outgoing waves. The pressure acoustics simulation was applied to all domains while the thermal analysis was performed only in the breast tissue domain.

The transducer was driven at the frequency,  $f$ , turned on for 15 seconds, and then turned off to let the breast tissue cool down. For meshing procedure, quadratic (2nd order) elements were used to discretize the temperature in the breast domain and quartic (4th order) elements were used to discretize the acoustic pressure in all domains including breast tissue, water, transducer and PMLs. The acoustic and thermal properties of the water and breast phantom used in the model simulation were derived from Ref [9].

### III. RESULTS AND DISCUSSION

#### A. Validation of numerical results

First, the numerical analysis was developed for a simplified model of water domain to validate the numerical results with those achieved from the experiments [9]. In Figure 4, the normalized pressure profiles in the focal plane are presented, where the results from FEA are compared with those from experiments acquired in water at 30 °C and at source frequency of 1 MHz. The pressure profile from FEA in the present study shows good agreement with the experimental result, particularly in the focal region.

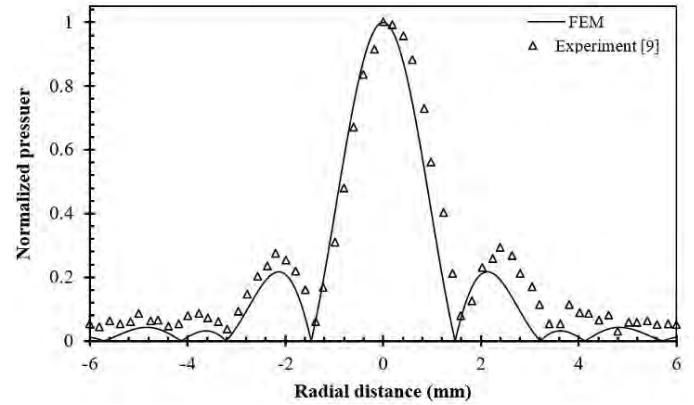

Figure 4. Validation of numerical data with experimental model

#### B. Acoustic effect

In this section, the results of wave propagation analysis in the water and the breast domains are presented when the transducer was driven at the frequency of 1 MHz. Figure 5 shows the acoustic pressure profile generated by the ultrasound waves propagated through the domains. The figure shows compression and rarefaction regions insides the breast tissue caused by the wave propagation. Here, the waves are focused into the tumor area which lead to a region with high acoustic pressures. A focal region with approximate size of  $10 \times 2$  mm is noticeable in the parts of breast which contains cancerous cells.

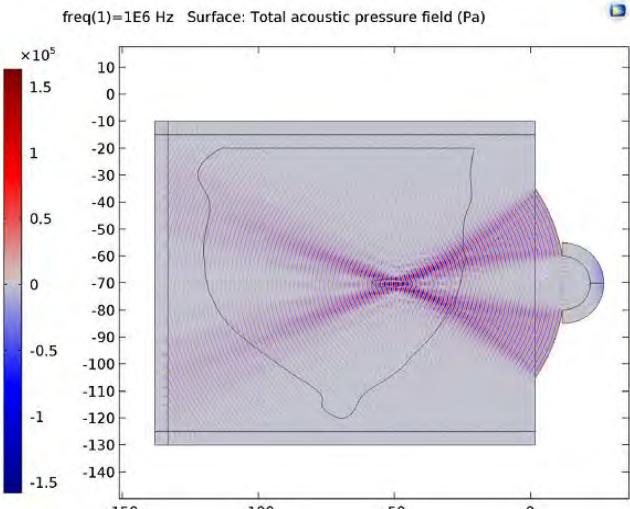

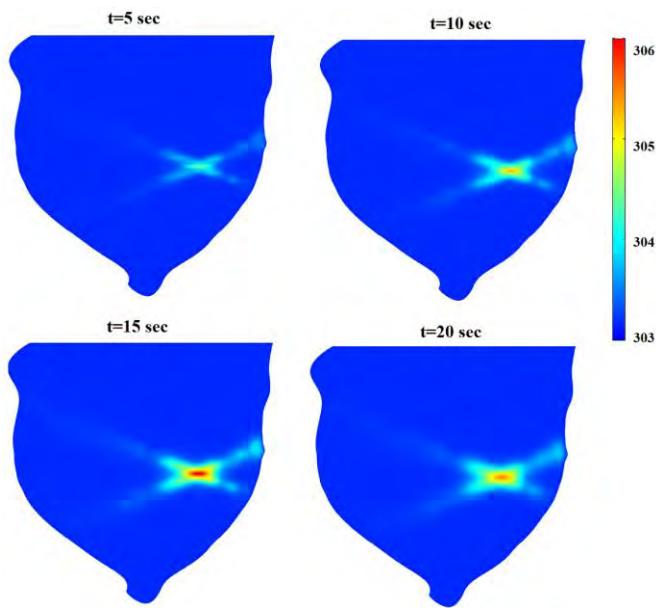

Figure 5. Total acoustic pressure field in breast and water domains.

### C. Thermal effect

After presenting the acoustic pressure distribution in the breast tissue and water domains, the heat transfer mechanism generated by the absorption of acoustic energy in the breast tissue was determined. Figure 6 shows the temperature distribution in the breast tissue at the different moments of time during the thermal ablation treatment. The figure shows how the temperature rises in the tumor area that needs to be treated. According to the temperature distribution, the maximum temperature rise happened in the cigar-shaped focal region with an approximate length of 10 mm and a width of 2 mm.

## IV. CONCLUSION

In the present study, a computational study on a realistic patient model was performed to examine the mechanism and the applicability of FUS in the treatment of breast cancer. To this end, the MRI data of a patient with breast tumor were used to mimic the breast tissue and tumor geometry for the finite element analysis of acoustic wave propagation and heat transfer. The results form acoustic and thermal analyses enabled us to understand the mechanism of wave propagation and heat transfer in the breast tissue during the FUS of breast cancer.

**Abstract**—We present a microfluidic platform that is capable of controlled diamagnetic droplet displacement. In this method, monodisperse aqueous droplets are produced in a continuous phase of hydrophobic ferrofluid. Both phases are exposed to magnetic field. Precise deflection of the aqueous droplets is then achieved in a single step by adjusting the flow-rate of the disperse phase.

**Microfluidics, diamagnetics, droplet control, biocompatible.**

## I. INTRODUCTION

Microfluidically generated droplets are readily used for the storing of biomaterials and biological analysis [1]. Control of these droplets using magnetophoresis has emerged as a key technology in microbiology. Currently, the leading methods of droplet control by magnetophoresis require the synthesis of biocompatible fluids and magnetic labeling, which is often time-intensive and costly [2].

Here, we present a fast, low-cost, and label-free alternative for the precise control of biocompatible droplets using negative magnetophoresis. We describe a ferro-hydrodynamic microfluidic system requiring only microchannels and a permanent magnet.

## II. EXPERIMENTAL AND RESULTS

### A. Device fabrication

We fabricated microfluidic polydimethylsiloxane (PDMS) channels based on a standard soft-lithography method. Then we introduced a permanent magnet parallel to the main channel of the device.

A magnetic fluid phase and a water phase were introduced to the system through the device inlets. Syringe pumps were used to control flow-rates of the fluids.

### B. Fluid properties

The magnetic phase consists of oil-based ferrofluid, mineral oil, and a surfactant. The ferrofluid used contains magnetite nanoparticles with a 10 nm diameter [3].

### C. Droplet Production and Control

A monodispersed stream of aqueous water droplets is achieved in the magnetic phase using a jetting regime. The external magnetic field attracts the magnetic medium of ferrofluid in the continuous phase. The attraction of this phase preferentially deflects the water droplets from their laminar flow. By simply adjusting the flow-rate of the dispersed aqueous phase, the degree of droplet deflection is precisely controlled.

# Characterization of the Electrodes of DEP-based Micro-separator

Arash Dalili, Erfan Taatizadeh, Mina Hoofar

School of Engineering  
University of British Columbia  
Kelowna, Canada  
mina.hoofar@ubc.ca

**Abstract**—In recent years, advances in lab-on-a-chip (LOC) devices has led to separation, sorting and manipulation of cells and particles on miniaturized devices. Among the different mechanisms that have been used in this regard, dielectrophoresis (DEP) offers high controllability on the particles, provides high throughput, and is tunable. Due to these advantages, DEP is used in this paper for the design of a micro-separator. To optimize the geometry of such a separator, COMSOL Multiphysics® is used to simulate the electric field with the goal of achieving the highest performance in cell separation. For a DEP-based micro-separator, two inclined rectangle planar electrodes are considered. The effect of the width of each one of these electrodes as well as the gap between them on the DEP force is investigated to find the optimum design.

**Keywords**— *DEP; COMSOL modeling; Optimization, Microfluidics*

## I. INTRODUCTION

The separation of cells and particles in a micro scale has attracted the attention of researchers in the fields of microfluidics, bio-engineering, biology, chemistry, etc. The researchers are using different methods, which can be categorized into passive and active. The passive methods include micro-filters, micro-devices based on inertial forces, deterministic lateral displacement and the pinched flow fractionation. While the passive operate on their own, the active methods rely on an external force to manipulate the cells or particles, which can lead to more accurate and specific separation. Acoustic, magnetic, optical and electrical forces are among the forces that are used for cell/particle manipulation. The electric force can manipulate charged particles, which is called electrophoresis, or it can manipulate uncharged particles, which is called dielectrophoresis (DEP). DEP has been used by researchers for different applications such as cell patterning [1], trapping [2, 3], focusing [4], enrichment [5], separation [6] and isolation [7, 8]. DEP can separate the cells based on their electrical properties (electrical conductivity and permittivity) and size. Although some studies have used biomarkers to change the electrical properties of the cells [9], in general, DEP is a marker-free method depending on the intrinsic properties of the cells. Eliminating the labeling of the cells and biomarkers makes the preparation for DEP-based separation much faster

and cheaper than some other methods such as fluorescence-activated cell sorter (FACS) and magnetic-activated cell sorter (MACS). Another advantage of DEP over other marker-free techniques is its relative ease of fabrication compared to other techniques such as those based on acoustic forces.

Different configurations of electrodes such as interdigitated [10], castellated [11], top-bottom patterned [12] and sidewall patterned [13] have been used for DEP-based devices. Among these configurations, planar slanted electrodes are easy to fabricate and operate, and are suitable for continuous cell separation. The slanted electrodes can continuously move the cells laterally toward the target outlet.

To apply an effective DEP force for cell/particle separation, the design needs to be optimized. This optimized design can lead to higher throughput and lower voltage (which means lower joule heating and higher cell viability). In this study, slanted electrodes are chosen and simulation is used to find the optimum width of the electrodes and the gap between them for achieving a maximum DEP force and hence effective cell separation.

## II. THEORY OF DIELECTROPHORETIC FORCE

When a particle is in a non-uniform electric field, it is polarized and experiences a force from the electric field. This phenomenon is referred to as DEP. The DEP force can be calculated as:

$$F_{DEP} = 2\pi\epsilon_m R^3 CM \nabla E^2 \quad (1)$$

where  $\epsilon_m$  is the absolute permittivity of the medium,  $R$  is the radius of the particle,  $CM$  is the Clausius Mossotti factor and  $E$  is the electric field. The  $CM$  factor depends on the relative permittivity of the particle and medium, and it is the factor that determines the sign of the DEP force as described below:

$$CM = \frac{\epsilon_p - \epsilon_m}{\epsilon_p + 2\epsilon_m} \quad (2)$$

Based on the sign of the  $CM$  factor, there are two categories of DEP: negative dielectrophoresis (nDEP) and positive dielectrophoresis (pDEP). The pDEP happens when the particles are more polarizable than the medium and the DEP force on the particles is towards the highest intensity of the electric field regions. On the other hand, the higher polarizability of the medium in comparison to the particle generates an nDEP effect,

pushing the particles towards the regions with the lowest intensity of gradient of the electric field square.

### III. COMPUTATIONAL MODELING

The electric current module of COMSOL Multiphysics software have been used for the simulation of our design.

Figure 1 shows the geometry (the cross section along width of the channel) which has been used for studying the effect of DEP on cell separation. The geometry consists of two rectangular electrodes, which are positioned at the bottom of the microfluidics channel. The channel is  $1\text{ mm} \times 75\text{ }\mu\text{m}$  and height of the electrodes are  $100\text{ nm}$ . The width of the electrodes varies from  $10$  to  $200\text{ }\mu\text{m}$  during simulation to investigate the effect of the electrode size on the DEP force.

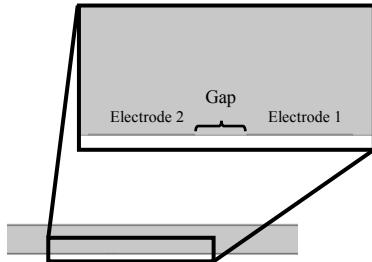

Figure 1. The geometry used for simulation

The minimum feature size that we can fabricate in our clean room is  $5\text{ }\mu\text{m}$ . Therefore, this is the minimum gap (see Fig 1) that is used in this study. The simulation has been done for gaps ranging from  $5$  to  $85\text{ }\mu\text{m}$  and electrode width ranging from  $10$  to  $300\text{ }\mu\text{m}$ .  $1$  volt AC electric current with a frequency of  $100\text{ kHz}$  is applied to the electrodes and the other boundaries of the channel is assumed to be isolated.

Electrical potential of  $1$  and  $-1$  voltage were used as boundary conditions for electrode  $1$  and  $2$ , respectively. In addition, at the interface of the electrodes and fluid, continuity boundary condition was assumed. Furthermore, water and copper are used as the materials for the fluid and electrodes, respectively.

In order to evaluate the changes in DEP force exerted on particles, one cut line across the top of the channel is drawn. As can be seen in Figure 2 and Figure 3, the variation of the forces across this line have been evaluated.

The electric current, electrical potential, and electrical field can be evaluated by solving the Ohm's law. Fundamental equations from Ohm's law are shown from equation (3) to equation (5).

$$E = -\nabla V \quad (3)$$

$$J = \sigma E + j\omega D \quad (4)$$

$$D = \epsilon_0 \epsilon_r E \quad (5)$$

$J, \sigma, E, \omega$  and  $V$  are electric current density, electrical conductivity, electrical filed, angular frequency, and electrical voltage, respectively.  $D$  is the corrected electrical field in different mediums,  $\epsilon_0$  is the relative permittivity of air and  $\epsilon_r$  is the relative permittivity of the used medium. AC voltage is applied as an input, both real and imaginary terms are created in the electrical flux  $J$  and will be changed by the input frequency.

In this study, only the variable  $E$  is important as it has a direct influence on amount of DEP force, as demonstrated in equation (1). Furthermore, all other terms of equation (1) are constant for this specific study, except  $\nabla E^2$  term. Consequently, we focus on this term as it has a direct impact on the DEP force. The widths of electrode  $1$  and electrode  $2$  and also the width of the gap between the two electrodes, play a vital role on the magnitude and direction of the  $\nabla E^2$  term and the DEP force. Therefore, these parameters were used in this study.

### IV. RESULTS AND DISCUSSION

As mentioned before, the parameter that affects the DEP force in Equation (1) is  $\nabla E^2$ , which depends on the geometry of the device. The other parameters in this equation rely on the particle, medium, and frequency of the applied electric field. As for  $\nabla E^2$ , only its horizontal component affects the lateral displacement of the particles. Thus, the horizontal component of  $\nabla E^2$  is used to optimize the electrodes geometry. As shown in Figure 2, the value of  $\nabla E^2$  is minimum on the top of the channel, resulting in the minimum DEP force. To make sure that all the particles are affected by DEP, the  $\nabla E^2$  term must be maximized on the top of the channel.

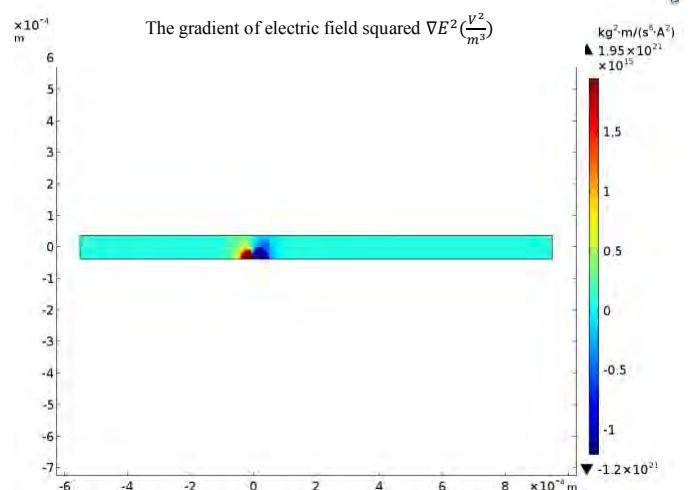

Figure 2. The contour of  $\nabla E^2$  inside a channel with the width of the electrodes of bot  $W_1 = W_2 = 300\text{ }\mu\text{m}$  and  $G = 5\text{ }\mu\text{m}$ .

First, the effect of the gap between the electrodes is studied. For this, the electrodes are assumed to have the same size. Then, the gap is changed to find the optimum gap size resulting in the maximum value of  $\nabla E^2$  on the top of the channel. The curves in

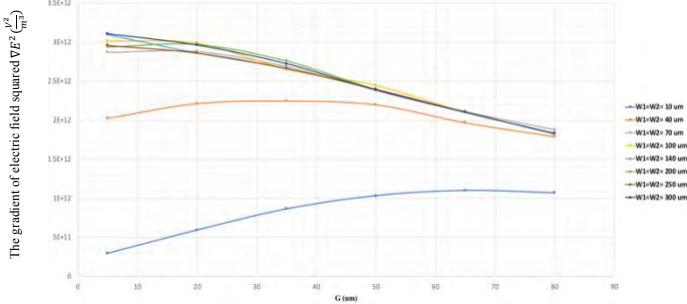

Figure 3. Maximum value of  $\nabla E^2$  along the top of the channel as a function of the gap size.

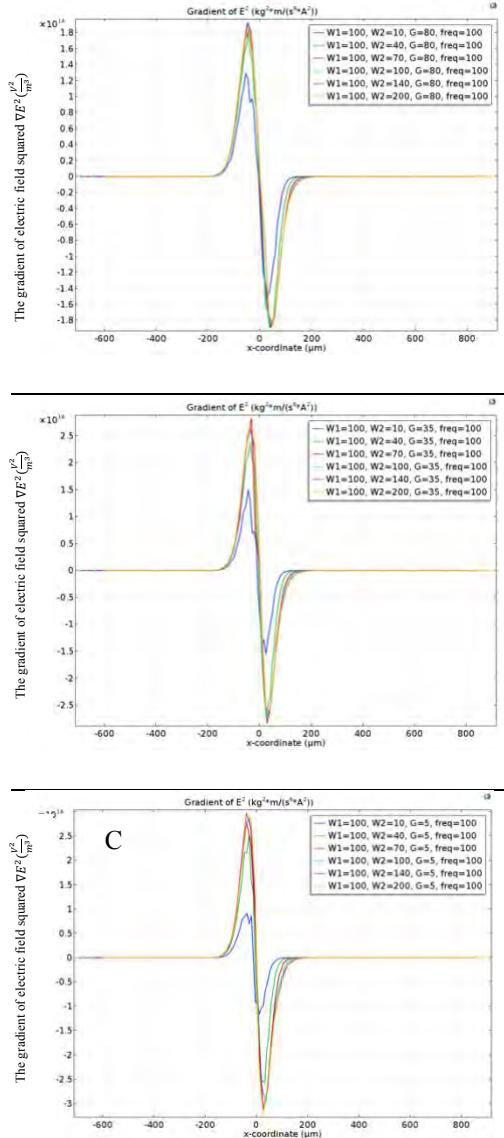

Figure 4. Variations of the exerted force on the particles as a function of the distance across the cut line.  $W_1$  (the width of electrode 1) is considered as 10  $\mu\text{m}$  while  $W_2$  (the width of electrode 2) is varied from 10 to 200  $\mu\text{m}$ .  $G$  (gap between two electrodes) is (A) 80  $\mu\text{m}$ , (B) 35  $\mu\text{m}$  and (C) 5  $\mu\text{m}$ .

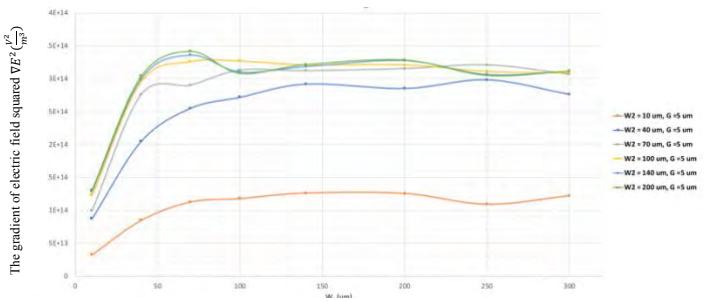

Figure 5. Maximum value of  $\nabla E^2$  on the top of the channel for the case that the gap is 5  $\mu\text{m}$  and different combinations of the electrodes

Figure 3 are each associated with a certain value of the electrode width. The results show that all the curves have a similar trend (as the gap is reduced the value of  $\nabla E^2$  increases), except for the electrode widths of 10 and 40  $\mu\text{m}$ . In order to make sure that this result is not just for the case of the same size electrodes, assuming that the first electrode is 100  $\mu\text{m}$  wide, the second electrode's size is changed for three different gaps, and the results are provided in Figure 4. Comparing Figure 4 (A), (B) and (C) shows that even if the electrodes' sizes are not the same, as the gap decreases the DEP force increases. Hence, the optimum gap size is 5  $\mu\text{m}$ .

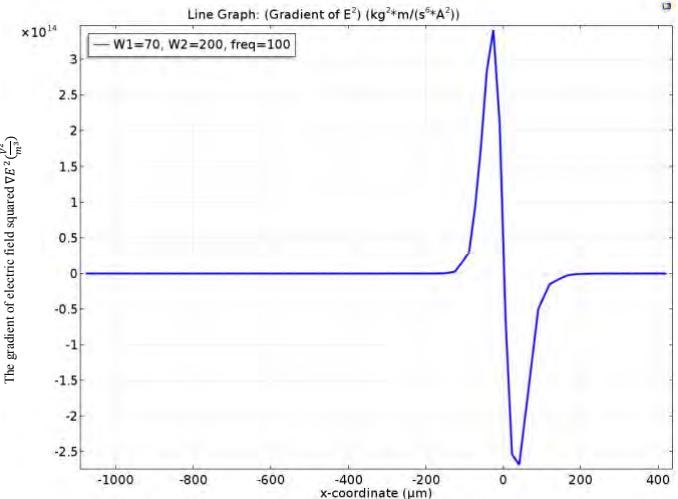

Figure 6. Variation of  $\nabla E^2$  along the top of the channel for a width of  $W_1 = 70 \mu\text{m}$  and  $W_2 = 200 \mu\text{m}$  and gap size of 5  $\mu\text{m}$ .

To find the optimum electrode width, the simulation was run with the gap size of 5  $\mu\text{m}$  and the electrode size combination of 10  $\mu\text{m}$ , 40  $\mu\text{m}$ , 70  $\mu\text{m}$ , 100  $\mu\text{m}$ , 140  $\mu\text{m}$ , 200  $\mu\text{m}$ , 250  $\mu\text{m}$  and 300  $\mu\text{m}$ . The results in Figure 5 show that the electrodes smaller than 70  $\mu\text{m}$  wide, lead to significantly lower  $\nabla E^2$ . This means that electrodes smaller than 70  $\mu\text{m}$  wide should be avoided in this design. However, increasing the width after 70  $\mu\text{m}$  does not have a significant effect on  $\nabla E^2$ . A closer look to the results shows that a slightly higher  $\nabla E^2$  (and DEP force) can be generated by using a combination of 70  $\mu\text{m}$  and 200  $\mu\text{m}$  wide electrodes.

With the optimum values of the gap and the electrode widths obtained, the variations in  $\nabla E^2$  are calculated and shown in Figure 6. This graph shows that the maximum value of the  $\nabla E^2$  term occurs on the side of the smaller electrode (blue line). Thus, the particle motion will be from the side of the large to the small electrodes. Based on these optimum values, the design shown in Figure 7 is used for a DEP-based micro-separator.

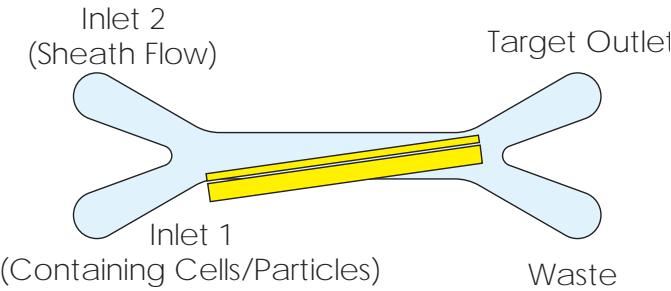

Figure 7. A schematic of the proposed DEP-based micro-separator

## V. CONCLUSIONS

In this study, COMSOL Multiphysics® tool was used to simulate the electric field created by two electrodes for a DEP-based cell/particle micro-separator. Different geometries in terms of the width of the electrodes and the gap between them have been investigated to find an optimum design, which leads to the maximum value of the DEP force on the top of the channel. The results show that in order to get the best outcome, the gap size must be as low as possible (which is 5  $\mu\text{m}$  in our lab) and the width of the electrodes must be larger than 70  $\mu\text{m}$ . Further investigation shows that the best results are obtained when the width of one of the electrodes is 75  $\mu\text{m}$  and the other is 200  $\mu\text{m}$  wide. Based on these results, a DEP-based micro-separator design is optimized.

## **Automation in high throughput/content screening for cancer stem cell drug discovery**

Eleftherios Sachlos

Department of Mechanical Engineering Lassonde

School of Engineering, York University

Mounting evidence suggests that cancer development is due to a rare population of cancer stem cells (CSC) uniquely able to initiate and sustain the disease (Al-Hajj et al., 2003; Bonnet and Dick, 1997; Lapidot et al., 1994; Li and Ren, 2008; Singh et al., 2003; Smalley and Ashworth, 2003). Conventional chemotherapeutics which inhibit cell proliferation are however ineffective against quiescent CSCs capable of re-initiating the disease (Bao et al., 2006; Dean et al., 2005; Diehn et al., 2009; Diehn and Clarke, 2006; Eyler and Rich, 2008; Li et al., 2008; Woodward et al., 2007). Instead, the indiscriminate cytotoxicity of these drugs often affects normal stem cells and progenitor populations, leading to dosage restrictions and necessitating supportive treatment (Smith et al., 2006). This traditional therapy has defined current patient survival rates, but these rates remain largely unchanged during the past 3 decades (Estey and Dohner, 2006; Visvader and Lindeman, 2008) implying that novel approaches are required to fight cancer. Recently, agents that selectively induce CSC apoptosis have been identified (Gupta et al., 2009) but their impact on normal stem cells has yet to be validated.

Stem cells, whether normal or CSC, are defined by an equilibrium between 1) self-renewal and 2) differentiation. In the case of CSCs, this equilibrium shifts towards enhanced self-renewal and limited differentiation capacity. A deviation in equilibrium however leads to eventual stem cell exhaustion (Duncan et al., 2005). One approach to eradicate CSCs is to tilt the equilibrium in favour of terminal differentiation in an effort to exhaust the CSC population. Eliminating cancer by inducing differentiation was first proposed in the 1970s (Fibach et al., 1973; Friend et al., 1971;

Sachs, 1978a; Sachs, 1978b). This led to the identification of all-*trans*-retinoic acid (ATRA) (Breitman et al., 1981; Breitman et al., 1980) and then arsenic trioxide (ATO) (Niu et al., 1999; Raffoux et al., 2003) as differentiation-inducing agents for the treatment of acute promyelocytic leukemia (APL), an acute myeloid leukemia (AML) subtype. If left untreated, APL causes death within weeks. ATRA/ATO treatment of APL currently demonstrates remission rates in excess of 93% with 5-year overall patient survival rates approaching 100% (Sanz, 2006; Sanz et al., 2009; Wang and Chen, 2008) and exemplifies how differentiation therapy can be used to transform a fatal, non-resectable, cancer to one that is essentially curable.

Cancer differentiation therapy has not however been translated to the treatment of other cancer types, let alone other AML subtypes (Burnett et al., 2010; Estey et al., 1999). This failure is, in part, due to the absence of robust *in vitro* assays which can interrogate CSC differentiation.

To address these issues, an overview of the application of automation for cancer stem cell screening will be presented.

**Abstract**—We have used microcontact printing as a means of simulating injury or wounds in a healthy monolayer of LLC PK1 cells to study the expression of Epithelial-to-Mesenchymal Transition (EMT) signature proteins. Cells were patterned on PDMS substrates using stamps that were prepared in the cleanroom using conventional soft lithography techniques. Patterned cells were exposed to an external stimulus of Transformation Growth Factor  $\beta$  (TGF $\beta$ ) and analyzed further for the presence and upregulation of EMT signature proteins that are indicative of the progression of EMT.

## Introduction

Organ fibrosis is considered a failed or dysregulated wound healing process, triggered by prolonged and repetitive injury to epithelium and endothelium. It was first discovered in 1995, that fibroblasts that contribute to fibrosis often originate from the local conversion of epithelium.<sup>1</sup> This discovery set forward a slurry of research activity around the phenomenon of Epithelial-to-Mesenchymal transition or EMT, and its role in organ fibrosis.<sup>2</sup> EMT is a process through which epithelial cells lose their strong intercellular contacts and polarity, and transition to migratory and often invasive mesenchymal cell types.<sup>3</sup> These mesenchymal cells then mediate either physiological functions (e.g. tissue differentiation during embryogenesis or normal wound healing), or participate in pathological processes (fibrosis, cancer).<sup>3</sup>

Our goal is to investigate the concept that epithelial wounding or injury (which can be simulated in vitro by the absence of cell-cell contacts), predisposes the injured cells for various features of EMT, including the expression of EMT signature proteins (such as alpha-Smooth Muscle Actin). We also aim to investigate the proportional secretory response (termed profibrotic epithelial phenotype or PEP) caused by the loss of cell-cell contacts (or injury) which holds true even if EMT is just partial. We hypothesize that the length of free epithelial edges in a monolayer is proportional to the propensity of the epithelium to acquire a profibrotic epithelial phenotype.

To address this hypothesis, we have used microfabrication to establish a model in which the proportionality of the response can be investigated. To establish our gold standard, initially we investigated SMA expression., the hallmark of full-blown EMT. The next step will be the investigation of the secretory phenotype.

## I. EXPERIMENTAL SETUP

### A. Cell Culture and treatment

We use porcine kidney proximal tubule cell line (LLC-PK1) used to conduct all experiments as described in previous studies.<sup>4</sup> Cells are cultured using DMEM supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin. After patterning, cells are treated with 5 ng/ml TGF $\beta$  in serum free medium for 48 hours. Cells are washed with phosphate-buffered saline (PBS) prior to analysis.

\* Co-corresponding authors.

### B. Mold fabrication for Microcontact printing

The stamps used for patterning cells are prepared using conventional soft lithography techniques in a cleanroom.<sup>5</sup> Stamps are incubated with 80ug/ml Fibronectin prior to stamping. Polydimethylsiloxane (PDMS) is used to line 6-well plates to prepare surface for cell patterning.

**Abstract**—Linked-segment models of the head-arms-trunk (HAT) along with an inverse dynamics approach can be used for estimating inter-vertebral moments. Several studies estimated the lumbo-sacral inter-vertebral moment using one-segment HAT models during execution of different functional tasks. However, methods for estimating inter-vertebral moments at different levels of the spinal column have rarely been investigated due to the propagation of the experimental errors. This study quantified multi-segment HAT kinetics during multi-directional trunk-bending after minimizing the experimental errors. Eleven healthy individuals participated in a multi-directional trunk-bending experiment in five directions with self-comfortable pace. We used a reconstructed seven-segment HAT model for each participant along with a bottom-up inverse dynamics approach to estimate intervertebral moments after minimizing the effect of experimental errors. Our results indicate a significant effect of joint level and trunk-bending direction as well as interaction effects. Our results revealed complex patterns for three-dimensional (3D) inter-vertebral moments which can only be obtained via a multi-segment model and error minimization. Inter-vertebral moment patterns along the spinal column after minimizing the errors can play a significant role in objective clinical evaluations and in designing pre- and post-treatment strategies.

## I. INTRODUCTION

Estimation of the inter-vertebral interactions such as motions and loads is useful for clinical evaluation of several pathological conditions such as low-back pain [1] and spinal cord injury [2]. Moreover, injury prevention strategies, as well as the risk of injury assessment, can benefit from the accurate estimation of inter-vertebral loads [3]. As a mathematical technique, linked-segment models of the body have been extensively used for *in-vivo* studying of spine kinematics [4]. Previous studies have

addressed the three-dimensional (3D) kinematics of the upper body using single-segment and multi-segment models of the head-arms-trunk (HAT). Estimating joint moments and forces using a linked-segment model of the HAT along with an inverse dynamics approach requires inter-segmental kinematics, accurate estimation of individual-specific body segment parameters (BSPs), and force plate measurements of the external forces. However, the accuracy of an inverse dynamics approach can be affected by experimental errors such as inaccuracies in (a) kinematics, (b) estimation of BSPs, and (c) force plate measurements. These inaccuracies could cause errors 6% to 232% of the estimated peak moment [5] implying that minimizing the effect of experimental errors is of great importance.

Previous studies addressed the significant effect of the relative motion between the skin-mounted markers and actual bony anatomical landmarks, soft tissue artifacts (STA), on the kinematics and kinetics of the lower limb [6], [7]. The effect of STA on the kinematics of the spinal column has been investigated [8]. However, No study has addressed the effect of STA on the estimating inter-segmental moments of a multi-segment HAT.

In addition, estimating inter-segmental moments using a linked-segment model and an inverse dynamics approach requires accurate estimation of BSPs including mass, the center of mass (COM), moments of inertia, and joint centers of rotation (JCRs). Medical imaging techniques can provide an accurate estimation of BSPs for each individual; however, radiation exposure [9] make them non-practical for routine clinical motion analyses. Some studies reported BSPs for a single cadaver [10], other studies proposed regression equations based on cadaveric data [9] for estimating individual-specific BSPs based on body weight and height. However, estimating BSPs based on cadaveric data may have error larger than 40% [11]. As a different approach, some studies used optimization techniques to minimize the effect of inaccuracies in BSPs on joint moment estimation at lower limb joints with assuming HAT as a single rigid segment [11]. However, there is currently no study that

estimated joint moments in a multi-segment HAT based on optimized individual-specific BSPs.

Several studies have calculated the 3D joint moment at the L5/S1 joint using a single-segment HAT model based on BSPs estimated via regression equations [12], [13] and for clinical evaluation of low-back pain [14] and lower-limb amputation [15]. However, none of these studies obtained 3D joint moments at different levels of the spinal column using a multi-segment model due to several technical challenges such as estimating individual-specific BSPs. Our team has recently proposed (a) a method for compensating the effect of STA on kinematics of a multi-segment HAT, and (b) an optimization-based method for estimating individual-specific BSPs for each HAT segment. Based on our previous studies, this study presents 3D joint moments in a multi-segment HAT model using optimized individual-specific BSPs and STA error compensation during trunk-bending tasks at different directions. The effect of joint levels and trunk-bending directions have also been investigated.

## II. METHODS

### A. Experimental Protocol

The experimental protocol was described in detail in our previous study [4] and thus, are only briefly described here. Eleven non-disabled individuals (4 females; age:  $28.5 \pm 3.3$  years; trunk height:  $0.75 \pm 0.04$  m) with no history of spine-related neuromuscular or musculoskeletal impairments or recurrent back pain take part in this study. All participants provided written consent prior to participating in the experiment. Research Ethics Board approval was received from the local ethics committee.

Participants sat on a rigid force plate in an upright natural posture with no backrest or foot support. The arms were crossed motionless over the chest. Five targets were placed anterior to the participant. The distance and height of each target were adjusted to represent the trunk-bending angle of  $45^\circ$ . Each participant was asked to lean toward the target, touch the target with the head, and return to the initial upright position. Each trunk-bending trial was performed three times at self-comfortable pace. To avoid a counterweight effect of the lower legs during trunk movement, participants were asked to keep their legs vertically downwards throughout the experiment (Figure 1).

### B. Data Acquisition and HAT Model

Twenty-three reflective markers were placed on the spinous processes and around them for each participant to constitute a seven-segment HAT model. The instantaneous position of markers was captured via six motion tracker cameras (Vicon, Oxford, UK) at the sampling rate of 120 Hz. A force-plate (AMTI, Watertown, MA, USA) was used to measure ground reaction forces (GRFs) and center of pressure position (COP) at the frequency of 1000 Hz. The time-series of the marker's trajectory were filtered via an 8<sup>th</sup>-order dual-pass Butterworth low-pass filter with a cut-off frequency of 2 Hz.

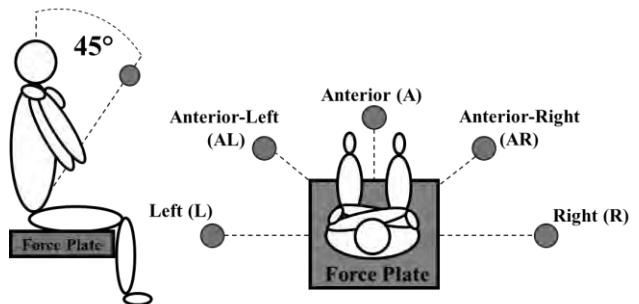

Figure 1. Targets were placed for each participant at the distance and height which represent the trunk-bending angle of  $45^\circ$ . Targets were placed in the transverse plane at  $45^\circ$  intervals, anteriorly and laterally of the participant.

### C. Seven-Segment HAT Modeling

We reconstructed a seven-segment model for each participant consisting of two segments for lumbar spine: upper lumbar (UL: T12-L3), lower lumbar (LL: L3-S1). Four segments for thoracic spine: upper thoracic (UT: C7-T3), mid-upper thoracic (MUT: T3-T6), mid-lower thoracic (MLT: T6-T9), lower thoracic (LT: T9-T12), and one segment for head and neck (HD). The segments were assumed to be rigid and connected to each other by 3D revolute joints located at the center of respective inter-vertebral discs (Figure 2). Each segment was defined by a cluster of three markers: one marker placed centrally on the spinous process of the caudal vertebra of that segment, and two markers placed laterally at 5 cm distance from the spinous process of the rostral vertebra of that segment (Figure 2).

Based on the three markers of each segment, a segment-fixed frame was defined for: The X-axis pointing from left to right, parallel to the two rostral markers, the Z-axis pointing superiorly, parallel to the line between the caudal marker and the mid-point of two rostral markers, and the Y-axis pointing anteriorly, as the cross-product of the Z and X axes. Therefore, the X-, Y-, and Z-axes represented flexion/extension, lateral bending, and axial rotation, respectively. A pelvis-fixed frame was defined based on the markers placed on the left and right anterior superior iliac spine (ASIS) and the midpoint between the posterior superior iliac spines (PSIS).

### D. Inverse Dynamics

A custom-made Newton-Euler iterative algorithm was developed for calculating the inter-segmental moments based on bottom-up and top-down inverse dynamic approaches. Using kinematic data, BSPs for each segment as well as force plate measurements, the bottom-up approach calculates joint moments from the bottom-most joint and proceeds superiorly with applying force plate measurements as the boundary condition of the inferior segment. The top-down approach uses kinematic data and BSPs to calculate joint moments from the top-most joint and proceeds downward with assuming zero loads at the top-most joint.

### E. Minimizing the Effect of Experimental Errors

#### 1) Soft Tissue Artifacts (STA)

STA is defined as the relative displacement between the skin-mounted marker and actual underlying bony anatomical

landmark. The effect of STA induced error on kinematic measurements of the multi-segment HAT was compensated based on the model introduced in our previous study [8]. This model assumed that the relative displacement between the skin-mounted marker and actual bony anatomical landmark is minimum (zero) at initial upright posture and proportionally increases with the trunk-bending angle, and thus, it is maximum at the maximum trunk-bending posture.  $\theta_t$ , instantaneous trunk, was defined as the angle between the line from  $S1$  and  $C7$  markers at each instant of time( $t$ ), and the initial upright posture. Soft tissue artifact of marker  $i$  in segment  $j$  was calculated in the segment's local frame as defined in equation (1):

$$STA_i^j(\theta_t) = STA_i^j(\theta_{max}) \frac{\theta_t}{\theta_{max}} \quad (1)$$

where  $\theta_{max}$  and  $STA_i^j(\theta_{max})$  are the maximum trunk-bending angle, soft tissue artifacts, respectively. The instantaneous position of the markers were then corrected:

$$C_i^j(t) = {}^G R_j(t) [ {}^G R_j^{-1}(t) \cdot P_i^j(t) - STA_i^j(\theta_t) ] \quad (2)$$

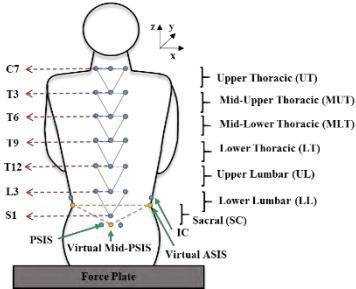

Figure 2. Markers were placed over the spinal column to form a seven-segment trunk model: Head and neck (HD), upper thoracic (UT), mid-upper thoracic (MUT), mid-lower thoracic (MLT), lower thoracic (LT), upper lumbar (UL), lower lumbar (LL), and sacral (SC) segments.

where  $P_i^j(t)$  and  $C_i^j(t)$  are the preliminary and corrected trajectory of marker  $i$  in segment  $j$  at the time index  $t$ , respectively, and  ${}^G R_j(t)$  is the instantaneous rotation matrix from the segment-fixed frame to the lab-fixed frame.

## 2) Optimized Individual-Specific BSPs and COP Offsets

Calculating 3D joint moments requires individual-specific estimation of BSPs for each segment including mass, COM, moments of inertia, and JCRs. Vette et al. [10] calculated upper body BSPs for a 38-year-old white male cadaver (height: 1.80 m and weight: 90 kg). We estimated the initial guess of BSPs for each individual by scaling cadaveric data based on participant's trunk height and body weight. We assumed that the body is symmetric in the frontal plane and, thus, that all COMs and JCRs lie in the body's sagittal plane. However, scaling method based on cadaveric data induces inaccuracies in estimating BSPs when the individual falls outside the originally studied population for which the BSPs were estimated in terms of age, gender, body type, and ethnicity [16]. As a result of induced inaccuracies, the value of the joint moments calculated via bottom-up and top-down approaches differ mostly due to inaccurate estimation of individual-specific BSPs. In our previous study, we developed a nonlinear constrained multi-step optimization-based method to find an optimized set of individual-specific BSPs for each HAT segment as well as compensating the effect of COP offsets that

minimizes the difference between the joint moments calculated via bottom-up and top-down inverse dynamics at all inter-segmental levels. We used the optimized individual-specific BSPs and COP offsets obtained via our optimization-based method to quantify multi-segment trunk kinetics after minimizing the effect of inaccuracies in BSPs, COP offsets, STA to obtain a less erroneous estimation of inter-segmental moments.

## F. Data Analysis

The Kolmogorov-Smirnov test and Levene's test showed that the absolute peak values of the 3D moments came from a normal distribution with equal variances. We conducted a two-way analysis of variance (ANOVA) on the absolute peak moments in the sagittal, coronal, and transverse planes to investigate the effect of joint levels (SC~LL to UT~HD), and trunk-bending directions. Moreover, we investigate the effect of STA compensation on estimating joint moments. We performed a two-way ANOVA on the root-mean-square (RMS) difference between the net joint moments before and after STA error compensation and investigated the effect of joint level and trunk-bending directions for both bottom-up and top-down inverse dynamic approaches. For all statistical analyses, the significance level was set at 0.01 by considering Bonferroni correction. We performed a multi-comparison post hoc test for interpreting the main effects of joint level and trunk-bending direction as well as their interaction effect.

## III. RESULTS

Figure 3 represents the RMS difference between the net joint moments calculated with and without compensating the effect of STA. Results are presented as  $c$  at all inter-segmental levels, for five trunk-bending directions, calculated via both bottom-up and top-down approaches. Statistical analysis revealed significant main effects of joint level and trunk-bending direction and two-way interaction effect on the RMS difference between the joint moments calculated with and without STA error compensation. We also observed a significant difference of inverse dynamic approaches.

Figure 4 represents the absolute peak joint moments in the sagittal, coronal, and transverse planes as well as the plane of movement (net sagittal-coronal) after minimizing the effect of inaccuracies due to COP offsets, BSPs, and STA. Results are presented as a *mean  $\pm$  standard error* at all inter-segmental levels and for five trunk-bending directions. The main effect of the joint level, trunk-bending direction, as well as two-way interaction effect.

The main effect of joint level revealed that the sagittal moments of the lumbar joints were significantly larger ( $p < 0.01$ ) than thoracic and cervical joints. Among the lumbar joints, the LL~UL joint tended to have the largest sagittal moment. Among the thoracic and cervical joints, the sagittal moment at each inferior joint was significantly larger than superior joints implying that the sagittal moment decreased from inferior joints to superior joints. A similar trend was observed for the coronal moment, and it decreased from the inferior joints to the superior joints except for SC~LL joint which was significantly smaller ( $p < 0.01$ ) than the LL~UL joint. The transverse moment at the

most superior joint (UT~HD) was significantly larger than all other joints while no significant difference was observed among all other joints.

The main effect of trunk-bending direction reflected that the sagittal moment across different joint significantly decreased with more lateral directions and it was maximum at the anterior direction ( $p<0.01$ ). No significant bilateral asymmetry effect was observed ( $p=1.00$ ). The opposite pattern was observed for the coronal moment. The coronal moments across different joints increased significantly with more lateral trunk-bending directions ( $p<0.01$ ), and it was maximum for bending towards left and right direction and minimum for the anterior direction. No bilateral asymmetry was observed ( $p=1.00$ ). No effect of direction was observed for the transverse moment.

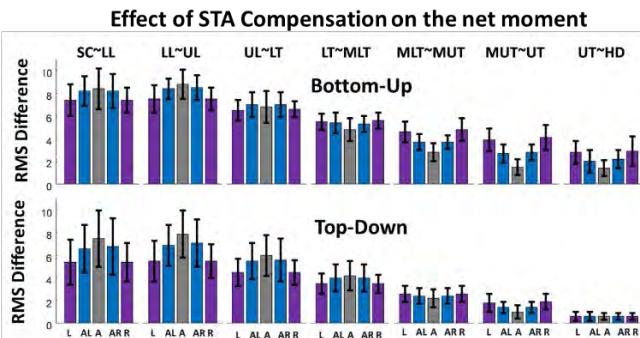

Figure 3. RMS difference between the inter-segmental net joint moments calculated before and after STA error compensation at each joint level of the proposed HAT model (Figure 2) for five trunk-bending directions (Figure 1). Results are expressed as mean  $\pm$  standard deviation among all participants and obtained through both bottom-up and top-down inverse dynamic approaches.

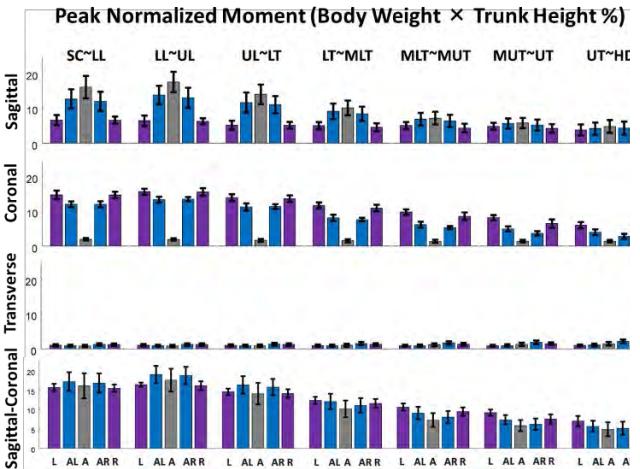

Figure 4. Peak joint moment in sagittal, coronal, and transverse planes and in the plane of movement (net sagittal-coronal) calculated via bottom-up approach using optimized individual-specific BSPs and STA compensation for different joint levels, and trunk-bending directions. Results are presented as bar and error bar plots. Moments (N.m) were normalized by participant's body weight and trunk height. (L: left, AL: anterior-left, A: anterior, AR: anterior-right, R: right).

#### IV. DISCUSSIONS

Estimating inter-vertebral moments requires: (a) the capture of inter-segmental kinematics, (b) accurate measurement of GRFs, and (c) individual-specific estimation of BSPs. Using

regression and scaling equations [12], [13] along with single-segment trunk models, many studies have investigated lumbosacral (L5-S1) joint moments. The accuracy of the estimated joint moments is dependent on the accuracy of the kinematics, BSPs estimation, and force plate measurements. Therefore, methods that compensate for the above-mentioned inaccuracies can result in less erroneous estimation of joint moments. Although previous studies demonstrated the influence of STA on estimating lower limb joint moments, its effect on the joint moment estimation of the multi-segment HAT is yet to be studied. Our team has recently proposed a method to compensate for STA induced error on the kinematics of the multi-segment HAT model. We employed the same approach in the current study to investigate the effect of STA on the multi-segment HAT kinetics. Moreover, Inaccuracy in estimating individual-specific BSPs and its effect on the lower limb kinetics with assuming the trunk as a single rigid body has been addressed by previous studies. In fact, due to the high inter-participant variability of BSPs for HAT segments, multi-segment HAT kinetics have been rarely investigated. We have recently proposed a nonlinear, constrained, multi-step optimization-based method for estimating individual-specific BSPs for each HAT segment in the proposed model (Figure 2). In the current study, we used our STA error compensation method along with the optimized individual-specific BSPs to obtain a less erroneous estimation of inter-segmental moments in the proposed multi-segment HAT model. We subsequently investigated the effect of the joint level, and trunk-bending directions in the sagittal, coronal, and transverse planes.

##### A. Effect of STA on Net Joint Moments

The results (Figure 3) revealed that for both inverse dynamic approaches, the RMS difference between the net joint moments calculated before and after STA error compensation was significantly larger at the two bottom-most joints (SC~LL and LL~UL) compared to all other superior joints. Moreover, The RMS difference significantly decreased from the inferior joints to the superior joints. This implies that kinetics of the inferior joints can be significantly more affected by STA and thus STA compensation is more required for the kinetics of the inferior joints compared to the superior joints.

In addition, The RMS difference between the net moments calculated with and without STA compensation tended to decrease with more later directions at SC~LL and LL~UL joints. The opposite was observed for MLT~MUT and MUT~UT joints where the RMS difference tended to increase with more lateral directions. This is due to the fact that trapezius muscles in this region are involved in bending toward lateral directions which increases STA.

##### B. Effect of Joint Levels and Bending Directions

Both sagittal and coronal components of the 3D moments, decreased from LL~UL joint to UT~HD joint, going superiorly. This is due to the fact that inferior joints bear more weight during the trunk-bending task. Although no significant difference was observed between the sagittal moment at SC~LL and LL~UL joints, this component tended to be larger at the LL~UL joint. However, the coronal component at the LL~UL joint was

significantly larger. This is justified as the maximum curvature of the lumbar spine occurs at this joint when the trunk bends. [12] A. Plamondon, M. Gagnon, and P. Desjardins, "Validation of two 3-D segment models to calculate the net reaction forces and moments at the L5/S1 joint in lifting," *Clin. Biomech.*, vol. 11, no. 2, pp. 101–110, 1996. doi: [https://doi.org/10.1016/0268-0033\(95\)00043-7](https://doi.org/10.1016/0268-0033(95)00043-7)

Moreover, the moment for the weight bearing during trunk-bending task toward the anterior direction is projected into the sagittal plane and during trunk-bending toward the lateral directions is projected into the coronal plane which can be observed in Figure 4. The two-way interaction effect between the joint level and trunk-bending direction revealed no significant difference among the sagittal moments across different joint for the lateral directions. However, the sagittal moment at the mid-lower joints (SC~LL, LL~UL, UL~LT, and LT~MLT) for anterior direction was significantly larger compared to more lateral bending directions while sagittal moment at the mid-upper joints (MLT~MUT, MUT~UT, UT~HD) was not significantly affected by trunk-bending direction. This finding suggests that even though the sagittal moment significantly decreased from inferior joints to the superior joint for anterior direction, this is not valid for bending in lateral directions. No significant difference was observed among the coronal moments across different joints for the anterior direction while for the lateral direction this component significantly decreased from the inferior joints to the superior joints. Results also indicate that the transverse component was significantly smaller and negligible compared to the sagittal and coronal components at each joint level and trunk-bending direction. This is due to the fact that the participants were asked to preserve their spine's torsional direction during bending trials.

We calculated the net sagittal-coronal moment to investigate whether these components reflect the upper body weight bearing moment projected into the sagittal and coronal planes (Figure 4). The effect of the joint level was similar to the sagittal and coronal moments. Net sagittal-coronal moment significantly increased inferiorly from UT~HD to SC~LL except for the LL~UL which was the largest. Interestingly, no significant effect of trunk-bending direction was observed while the contribution of the sagittal and coronal moments to upper body weight bearing increased with more anterior and lateral directions, respectively. No significant two-way interaction effect was observed for the net sagittal-coronal moment. These findings imply that the sagittal and coronal moments are the weight-bearing moments projected into the sagittal and coronal planes during trunk-bending tasks. The results of the joint moments obtained for the multi-segment HAT model reflect the complex, task-specific patterns across joint levels and trunk-bending directions which cannot be observed using a single-segment HAT model or without compensating inaccuracies in input parameters. The bilateral symmetrical moment patterns found in this study could be useful for objective clinical assessments to recognize any asymmetrical patterns at different levels of the spinal column. Note that this study demonstrates the results for a mix-gender relatively small population which can be a general representation of neither male nor female non-disabled populations. Larger datasets could be useful for identifying clinical meaningful moment patterns for clinical evaluations.

In conclusion, this study presented a less erroneous estimation of the 3D inter-segmental moments at different levels of the spinal column during bending toward different directions after minimizing the effect of experimental errors using a multi-segment HAT model. The error minimization was achieved by

using STA error compensation method, optimized individual-specific BSPs and COP offsets from our previous studies. Our results showed complex and task-specific patterns for 3D moments at different levels of the spinal column which could not be captured by a one-segment HAT model. Accurate estimation of the joint moments can be useful for objective clinical evaluation, rehabilitation, as well as designing pre- and post-surgery treatments.

**Abstract** A finger or hand brace may be required to be worn for people who require physical support or ‘controlled motion’ support. Ehlers Danlos Syndrome (EDS) patients have connective tissue disorders, and wear braces to support and limit motion. Manual assembly operators, carpal tunnel sufferers, and the elderly may also benefit from wearing finger or hand braces. Additive manufacturing (AM) solutions provide flexible manufacturing options for customized braces; however, a CAD model must be developed to facilitate a manufacturing solution. The goal of this research is to develop a readily adaptable CAD model for a hand, which would link to a flexible brace model. Rhinoceros® and Grasshopper® modelling tools are employed to develop a solution that can be dynamically manipulated to adjust to a specific hand size, and/or localized finger-hand configurations. The final CAD model (hand or brace) can then be built using an AM process.

**Keywords-human skeletal modeling; dynamic CAD model; finger; hand; additive manufacturing**

## I. INTRODUCTION

The human hand is an incredible tool. It is capable of up to 47 kg grip strength<sup>1</sup> (with a 9.5 – 9.7 kg standard deviation for men aged 20 – 49) [1] as well as controlling extremely fine motor movements. However, ‘tools’ can wear. Complex motions, such as securing a button, require dexterity and precise motor control. Strength and fine motor control may prove to be difficult for people with Ehlers Dowler Syndrome (EDS), a connective tissue disorder, for people who encounter repetitive strain injury when performing tasks that are prone to developing carpal tunnel syndrome (CTS), and the elderly.

For the people who suffer from EDS, everyday activities are problematic [2]. The braces for the fingers and/or hand are required to provide support, the needed limits for motion, and to allow for some precise motion control [3]. CTS is condition that causes pressure on the median nerve in the hand, which results in numbness in the hand, tingling, or itching. In severe cases, there is pain. CTS can occur as a result of repetitive motion activities where the wrist is overextended repeatedly. Other conditions linked with CTS are diabetes, high blood

pressure, or fracture or trauma to the wrist. CTS is the most common nerve compression syndrome, affecting 3 to 6 % of the American public [4]. As shown in Fig. 1, the manufacturing sector typically has 2 – 3 times more injury occurrences compared to most other industries [5]. Well-designed custom braces would allow workers to perform their tasks with the needed dexterity and the required control while keeping the wrists in a neutral position and reducing the pressure on the nerves. People in the older demographic may also have lower dexterity [6] and have trouble with daily tasks such as holding cutlery and opening containers. Proper brace designs can assist with support and motion control, similar to EDS patients, although the physical conditions are different.

Although hand braces may be useful for many situations, ‘general’ sized hand braces may not allow for the needed flexibility or comfort, and customized braces are costly. Localized customization may be required if a person has had broken bones or arthritis. The introduction of additive manufacturing (AM), or 3D printing, processes can lead to a better ‘quality of life’ solution for the various scenarios described here, as complex patient-specific designs can be readily fabricated. However, prior to fabricating a solution, a manifold or ‘watertight’ CAD model must be created. The brace model should be linked to a personalized hand model, which is challenging to create. Reverse engineering techniques may be employed to collect point cloud data, but many scans would have to be performed to collect all the shape data, and then point cloud registration, filtering, mesh development refinement, and the final surface modeling must be performed.

Blending surface patches is time consuming and may require several iterations for representing the base geometry [7-8]. Alternatively, a parametric or reconfigurable model can be created, and then adapted to suit based on selected measurements, which is the goal of this research. Creating an adaptable joint – finger – hand model, which allows for either global or local modifications without executing advanced surface or solid modelling commands manually, will facilitate the development of a buildable model, and any necessary design modifications determined from field testing or usage. Coupling the reconfigurable hand model to a brace model, and leveraging AM processes, will provide a platform for

customizable, yet affordable, hand braces for the general public.

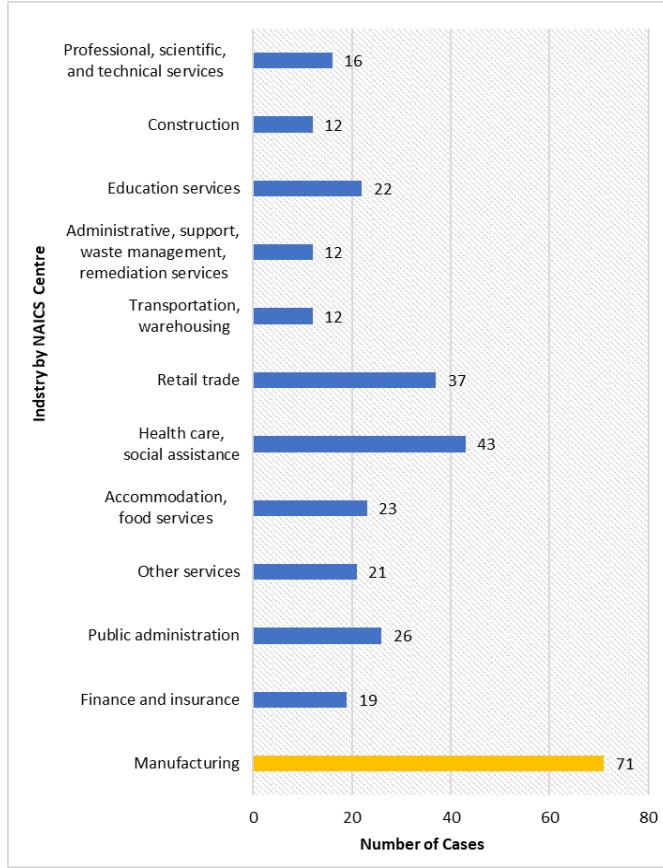

Figure 1. Carpal tunnel cases by North American Industry Classification System (NAICS) [5]

## II. BACKGROUND/LITERATURE

Variations in the human hand/fingers size and shape are due to gender, age, body mass index (BMI), activity levels, and differences in body symmetry (i.e. the left and right hand and fingers will have differences). As illustrated by the anthropological data for the thumb and index finger (Table 1), there are significant variations from person to person (up to 35% for the thumb breadth), and these variations need to be considered when developing a customizable brace solution.

TABLE I. AVERAGE VALUES FOR SELECTED PERCENTILE DATA FOR THE THUMB AND INDEX FINGER, ADAPTED FROM [9]

Dimension	Gender	5th percentile (mm)	50th percentile (mm)	95th percentile (mm)	$\Delta$ 5th - 95th percentile	Var. from mean
Thumb length	Male	44	51	58	14	14%
	Female	40	47	53	13	14%
Thumb breadth	Male	11 - 12	23	26-27	16	35%
	Female	10 - 14	20-21	24	14	34%
Index finger length	Male	64	72	79	15	10%
	Female	60	67	74	14	10%

Presently, the standardized models that have been created to date are constructed for one hand [10], and for the majority of

the population - irregular or damaged hand types are not taken into consideration. However, using advanced reverse engineering techniques, specialized models can be very accurate when modeled to fit a custom hand type [11].

Ideally, a complex and detailed model, which can be easily modified, should be constructed. There are general ‘structural’ relationships that can be exploited linking finger geometry to hand length and width relationships (Fig. 2, Table II and III), and establishing a robust general model that allows for local modifications that could allow for rapid changes, would minimize the reverse engineering data collection.

The goal of this research is to leverage advanced CAD modeling techniques to create a dynamically reconfigurable hand model that can be animated to test finger movement, and how a brace would behave for different positions (ex. A fist or gripping position).

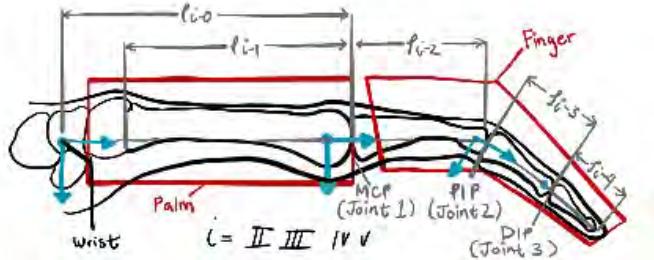

Figure 2. The ‘i’ represents each finger, the thumb being I and pinky V.

TABLE II. TABLE OF METACARPAL RELATIONSHIPS, WHERE HL = HAND LENGTH [12]

Metacarpal Bones	
Thumb	0.251*HL
Index	$((0.374*HL)^2 + (0.126*HB)^2)^{0.5}$
Middle	0.373*HL
Ring	$((0.336*HL)^2 + (0.077*HB)^2)^{0.5}$
Pinky	$((0.295*HL)^2 + (0.179*HB)^2)^{0.5}$

TABLE III. TABLE OF FINGER PARAMETRIC RELATIONSHIPS FOR THE PHALANGEAL BONES[12]

	Proximal	Middle	Distal
Thumb	0.196*HL		0.158*HL
Index	0.265*HL	0.143*HL	0.097*HL
Middle	0.277*HL	0.170*HL	0.108*HL
Ring	0.259*HL	0.165*HL	0.107*HL
Pinky	0.206*HL	0.117*HL	0.093*HL

## III. RESEARCH METHODOLOGY

Initial research has been performed to design, fabricate, and test specialized designs for finger and hand braces [13]. Different parametric modelling approaches are being explored for readily accommodating special conditions. The modelling approach should be flexible, adaptable, easy to use by non-designers, and require a minimal amount of rendering time. For this research, the 64-bit version of Rhinoceros® is employed with the Grasshopper® graphical programming and Bongo® animation add-ons. The Grasshopper® graphical programming tool can leverage known structural relationships and can

<sup>1</sup>Hand strength is measured by the quantity of static force a hand can squeeze around a dynamometer, and is measured in kg or lb.

propagate changes throughout the whole design simultaneously. Local modifications can be performed using the Rhinoceros® CAD tools, and joint / motion relationships for any design can be readily modeled for virtual testing. The general process flow is shown in Fig. 3. The methodology presented is an overview. The details are not included due to space constraints.

The basic finger bone modelling is established for the thumb as it has the simplest structure (Table III). A simple model of the proximal thumb bone with flat ends and a tapered intermediate section was developed using multiple lofted circles. Since every hand is unique, the lengths of the fingers need to be calculated using the parametric relationships shown in Table I and II (i.e., using the hand length as the key input). This static model was updated to include the distal bone.

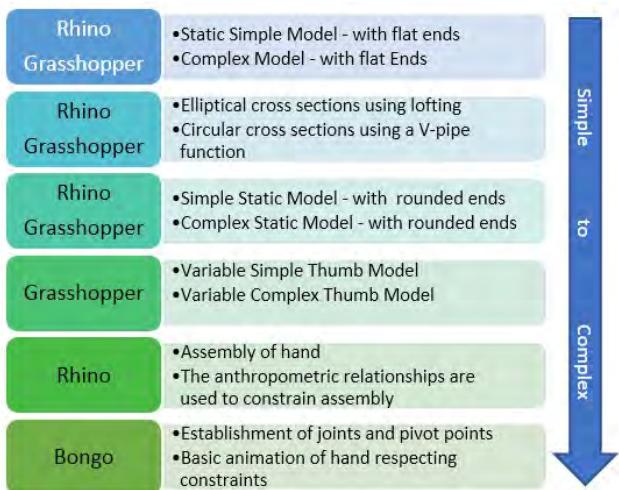

Figure 3. Steps in creating the final adaptable model

Once basic geometric relationships were established, elliptical cross-sections, with specialty Grasshopper® programming commands (V-Pipe or variable pipe), are employed to make this model more realistic. Sets of ellipses, and their control planes, are established. The model with the elliptical cross sections is more customizable as there are variable radii in two directions, and the ellipse positions may be altered using the input to the parametric relationships in the model (Fig. 4). Radii are controlled by a ‘slider bar’ input, as shown in Fig. 8. This modeling approach leverages known relationships yet can accommodate of a wider variety of hands or localized variations, i.e., an arthritic hand, as shown Fig. 5.

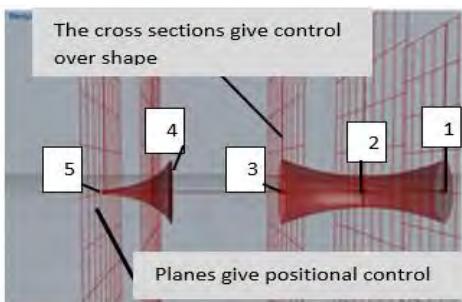

Figure 4. Elliptical cross sections and control planes illustrating the local control of the finger shapes. The 5 cross sections are labelled.

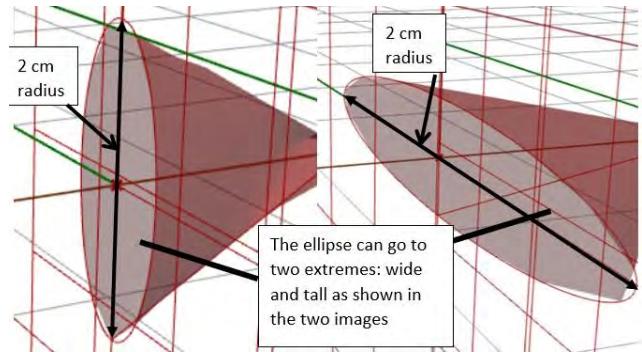

Figure 5. Another angle of the bone cross section and its flexibility

Using the elliptical model as a base line, the rounded ends to the proximal bone are added via ellipsoids, where the control geometry is linked to the bone geometry. The endcaps model can also be personalized, as necessary. The progression from a bone to a finger is shown from right-top counter clockwise to right bottom (labelled 1 – 4) in Fig. 6. The semi-circular ring at the end of the finger is optional for now.

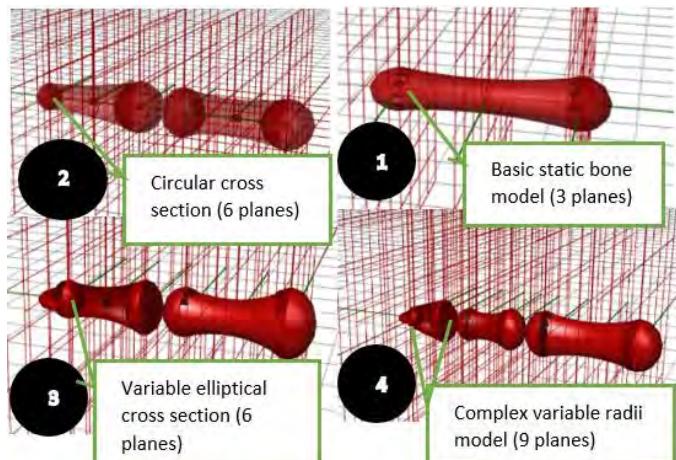

Figure 6. The build of the finger bones ordered from simple to complex (and order of creation)

Using the relationships and design approach, the bone-finger model is updated to become automatically adaptable. Instead of using the fixed numbers with the formulas and parametric relationships, ‘slider bar’ inputs or variables, which are controlled by the user, are utilized. The flexibility provided by the slider bars is shown in Fig. 7, 8 and 9.

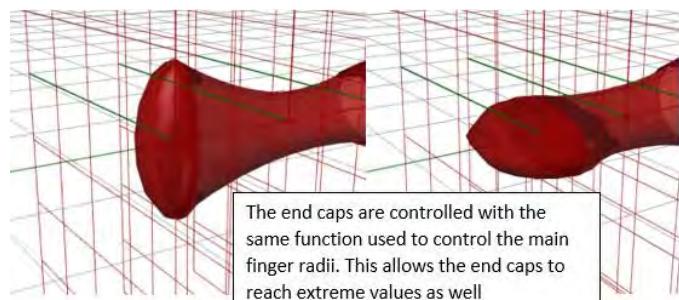

Figure 7. The adaptability of the end caps demonstrated

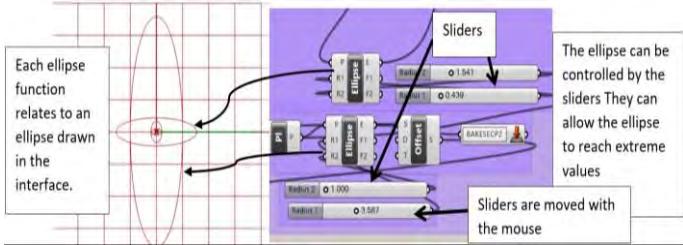

Figure 8. The simplicity of changing the finger radii is shown with the radii if the finger bone

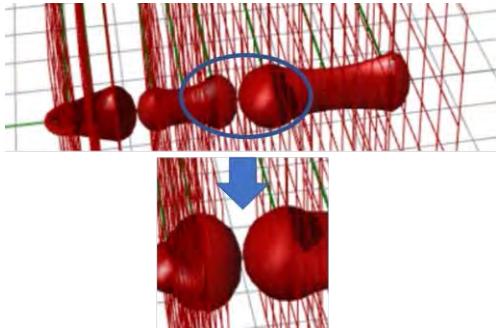

Figure 9. The wide range of the radii is demonstrated through the extreme sizes of the end caps shown.

The interface of the Grasshopper® algorithm is shown in Fig. 10. The parts are connected to each other using ‘wires’ in the program. This feature allows the input data to be transformed using mathematical functions, and the programmable control shapes to create surface, mesh, or solid model geometry in the Rhinoceros® environment.

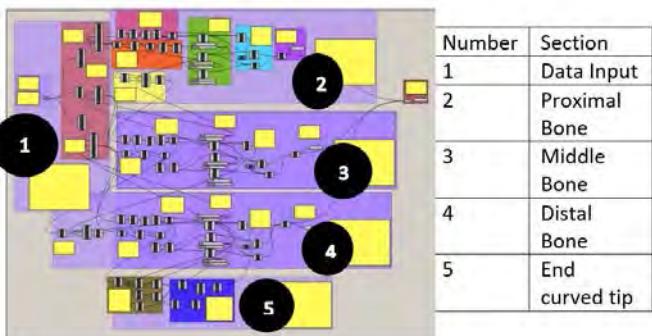

Figure 10. Labelled Grasshopper® interface shown (the behind the scenes of the finger model).

These finger models can easily be assembled into the individuals hand model (in the Rhino® environment) using anthropometric relationships and constraints to link the individual components into a final kinematic assembly. This bone-finger-hand model can then be animated for different situations such as hand gripping using the Bongo® add-on. Once the appropriate relationships are finalized, custom finger braces or hand brace models can be built on top of this.

#### IV. RESULTS AND DISCUSSION

The result of this process is a customizable bone-finger-hand model that can be adaptable for a variety of shapes

instantaneously. The programming elements of this model allows a hand configuration to be programmed using parametric relationships established by other researchers. The hand length and breadth are measured. They are then used as an input to establish the bone lengths for the metacarpal and phalangeal bones each finger. Example solutions are shown in Figure 11 and 12. They are hand of a young female and young male. On the left is the wireframes printout of the model, center the hand, and on the right the 3D shaded model of the hand from Rhinoceros®. The reconfigurable reverse engineered hand models are created.

Both hands shown have different hand lengths, breadths and finger radii, and this model was able to conform to the measurements and create a customized model of the hand.

A preliminary ‘proof of concept’ animation of these reconfigurable models has been completed. Examples of two animations with developed with the Bongo® add-on are shown in the links below (and Fig. 13 and 14).

## V. SUMMARY AND CONCLUSIONS

Reverse engineering a hand to create an editable surface or solid model is a time intensive task and requires highly skilled designers familiar with surface modeling strategies. The goal to develop a dynamically reconfigurable bone-finger-hand model was realized using a set of modeling tools typically used in animation environments. Developing organic parametric models in CATIA is problematic due to linking the many bone-finger-hand constraints [14].

As human anatomy has general known relationships (anthropometric data), but individual variants, the Grasshopper® visual programming language is used to leverage the relationships to create editable models in the Rhinoceros environment. This foundational research allows for the creation a customized hand brace without a significant amount of measurements or data manipulation for developing a personalizing CAD model. This CAD model can then be used as an input for an AM process.

Throughout this process, the main goal was to add enough detail to represent the uniqueness of the individual's hand but not to be overly complex or have the data entry be a time-consuming task. Due to the model's ability to have full control over the shape of the finger, (essentially the thickness), muscles and skin will be added in the future. The overall process for creating specialty braces shown in Fig. 15.

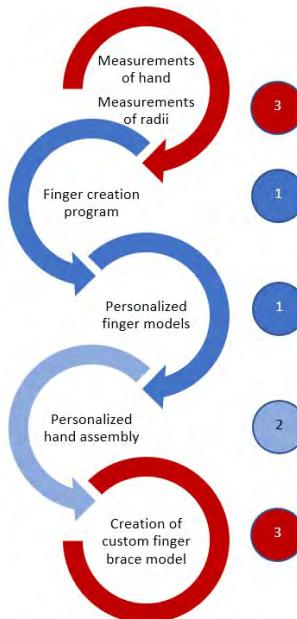

Figure 15. Steps for creating final adaptable hand and braces models (1 – present research, 2 – on-going research, 3 – future work)

## VI. FUTURE STUDIES

Localized 'non-elliptical' geometry solutions will be explored. The animation models will be improved to include anthropometric relationships, as there are unique motion conditions for our hands. For example, all joints in the ring finger cannot be fully rotated inwards without creating motion in the middle or pinky fingers. The Grasshopper® model will be streamlined to add a user interface, data collection strategies determined, and brace design solutions will be designed, fabricated (using an AM process) and tested.

## ACKNOWLEDGMENTS

This research is partially funded by the NSERC Discovery Grant and the University of Windsor Outstanding Scholars programs. Special thanks to hand model Swapnil Patki.

# Development of a Rehabilitation Mobility Assistive Device

Xueqiao Han, Reza Fotouhi\*, Doug Bitner

Department of Mechanical Engineering

University of Saskatchewan

Saskatoon, Canada

\* Corresponding author Reza.fotouhi@usask.ca

**Abstract**—the aim of the overall research presented here was to investigate the motion of a wheeled mobile robot in an indoor (structured) setting while following a pre-set trajectory. An example of an application for this research would be automated maneuvering of a smart power wheelchair in a health care setting, such as a hospital, which would benefit the aging Canadian population. For the specific research reported here, the aim was to investigate the mobility of an assistive device for Sit-to-Stand (STS) operation and walking. A rehab robot was developed and was attached to a wheeled mobile robot to accomplish STS operation and to help walk a patient for rehabilitation. Four major phases of this research are: (i) design of the rehab robot, (ii) development of the control algorithm, (iii) experimentation, and (iv) navigation of the mobile robot and the rehab walker (robot). This research project can be extended to lower limb rehabilitation and design of a smart walker. It intensively studied current research and projects, designed a rehab robot and four control algorithms to help people in both STS and walking processes. Experiments were implemented, and the results indicated the effectiveness of the control algorithms and the prescribed navigation algorithm. According to the results, this project achieved the original goals to assist people in standing up and walking, and to navigate to a pre-set location.

**Keywords:** *mobility assistive device; rehab robot; navigation*

## I. BACKGROUND AND MOTIVATION

As the aging population increases, more and more countries require a larger workforce to take care of the elderly. Meanwhile, the gradually soaring cost and investment in healthcare and nursing have become a global issue. Taking care of people with impaired lower limb functions is one of the trickiest problems. A number of elderly have problems with their knees, hips, and lower limb strength, which affects their mobility. They have difficulties in walking and are not able to cope well at home. People recovering from stroke, lower limb fracture, and some other illnesses suffer similar problems as well. Rehabilitation services and nursing are available, but access is limited due to constrained medical resources and their high cost. As a result, some of these people miss the best time for recovery, and their limited activity

keeps them in their home and hence, they suffer from more health issues caused by lack of movement and being alone. One of the motivations for this research is to provide easy standing and walking assistance for these people and an alternative solution for nursing care as well. This is also expected to help in lower limb rehabilitation and patients' autonomy.

A variety of walkers are available on the market that help in walking, such as the rollator walker and the adjustable standard walker [15]. However, most traditional walkers are designed for people with a high self-care ability level. For people with poor health conditions, such as weakened leg strength, limited hand and finger motion, and hemiplegia sequelae, merely operating the walker would be a huge challenge. Traditional walkers do not provide support for Sit-to-Stand (STS), which is one of the toughest challenges for self-autonomy. Hence, it leads to a second motivation for this research, to design a device that helps a broader range of people.

Motivated by medical needs as stated above, this project is focused on research of lower limb rehabilitation and assistance by devising a machine with the following capabilities:

1. Have basic walker functions.
2. Help in the STS process (the major goal of this design).
3. Provide assistance in standing and walking.
4. Be smart in navigation (this feature will provide care, convenience, and assistance to users, and allow patients for rehabilitation by walking in a pre-defined path).
5. Have a good level of adaptability (it should be able to help a wide range of people having different height, weight and health conditions, and be useful for home/hospital).

### A. Literature Review

Several researchers proposed interesting designs and ideas, and also studied some related topics in this area.

Morbi et al. [1] designed a system called Gait-Enable, which is used in over the ground walking and balance training. This design integrated the Bungee Mobility Trainer, which is a patented elastic passive body weight support system that

consists of a 3-DOF linkage that supports the patients' pelvis from below. The test results show that the Gait-Enable system will reduce pelvis and torso motion constraints. Ahmed et al. [2] designed an assistive device named E-Just Assistive Device (EJAD), a low cost intelligent assistive device to help elders in walking and sit-to-stand activities. This is a mechanical design based on the imitation of the caregivers' motion during the support task, which is mainly composed of back support, a robot arm and an active walker. Bauzel et al. [4, 5] analyzed current research on smart walkers and proposed three required significant features: provide dynamic support, demand little or no effort to use, be user-friendly. Also, a new user interface which allows users to control the walker intuitively was designed and implemented on a ASBGO walker, which is an active robotic walker that assists the elderly and disabled people in walking. Measures have been adopted to assure safety and customer comfort, such as infrared rays gesture detection, force detection of falls, and limit wheels' orientation and speed. Bulea et al. [6] proposed a new design with adapted gas spring actuators to enable auto lifting, utilizing both handles and platforms for arm support. The gas spring provides lifting forces and a steel shaft is designed to help users moving freely. The experimental results from a partially paralyzed male show that the lift walker significantly shortened the transition time of the sit-to-stand process and also resulted in a steadier rise than with a standard walker. Jorge et. al. [7] reviewed all current robotic systems for lower-limb rehabilitation in 2011 and pointed out that research in this field has grown exponentially during the last decade. About 43 robotic systems were mentioned that can be classified into the following five categories: Treadmill Gait Trainers, Foot-Plate-Based Gait Trainers, Overground Gait Trainers, Stationary Gait Trainers and Ankle and Knee Rehabilitations Systems made up of Stationary Systems and Active Foot Orthoses. Of these, more than half of the systems have neither been marketed nor applied for home use. This is due to their bulky size, elevated cost and the lack of high clinical improvement evidence. Research specifically in the STS area has also been investigated and has further contributed to this work. It has helped in developing and designing the motion control algorithms of the walker used in this project.

Other research work has been carried out to help the development of smart robotic walkers. Pasqui et. al. [8] found that the global shape of a patient's trajectory is an "s-like" curve. This was discovered through experiments participated by patients. Wang et al. [9] presented a fuzzy controller design for a lower limb rehabilitation robot, which is more effective than a traditional PID controller. Pasqui et al. [10] proposed a method to assess the efficiency of smart-walkers by measuring the time cost of different walkers when users were required to complete a series of movements. Other types of robotics to assist walking and lower limb rehabilitation have also been studied these include a new design of an exoskeleton system presented by Castro et al. [11], a new robot design for children with cerebral palsy presented by Giergiel et al. [12] and a mechanism model of a lower limb passive rehabilitation

system built by Zhang et al. [13]. In addition, some researchers have also studied the psychological aspects of lower limb rehabilitation. For example, Koenig et al. [14] discussed a psychological measurement method which may help in robotic-assisted gait rehabilitation.

To summarize, some of the work done in this area has been reported here. However, most of the existing rehabilitation systems are not good enough for commercialization. Most of them have issues in cost, safety and portability; and also lack reliable testing. Unfortunately, none of the intelligent devices available can help both STS and the walking process. Hence, a mature, smart, and affordable rehabilitation system for STS and walking has yet to be designed.

### B. Research Objective

The objectives of this research can be summarized as follows:

- 1- Investigate the state-of-the-art for the existence and needs of an assistive device for the sit-to-stand (STS) and walking operation. Develop such a device and its relevant motion control algorithms to help patients with rehabilitation.
- 2- Investigate and test the STS operation and the interaction between the user and the device. Test control algorithms for the rehab robot and evaluate its effectiveness in helping people with lower limbs rehabilitation
- 3- Investigate/examine navigation algorithms in a medical setting that may help in walking for rehabilitation.

### C. Research Methodology

A literature review was performed and a device (rehab robot) was designed based on conclusions and ideas drawn from it. After a prototype of the rehab robot was manufactured, control algorithms for three different means of STS: arm-pad support, handlebar support, and belt support, were developed. Following this, practical tests with different control algorithms were implemented and analyzed. Also, a questionnaire was handed out to participants and the results were analyzed qualitatively. Lastly, the smart walker was attached to an Autonomous Ground Vehicle (AGV) which was used as the driver, and an existing navigation algorithm was tested to assess its feasibility for this project.

## II. DESIGN OF THE REHAB ROBOT

Since this project is an attempt to develop an affordable mature smart walker, the AGV was adopted as a driver in the experiments. A rehab robot was designed to attach to the AGV and complete the major functions of a smart walker. This rehab robot has basic walker functions and adjusts its height according to a control algorithm or a user's commands, hence it helps in the STS process and walking.

There are three main parts in the design process: function analysis, mechanical design, and electrical design. Function analysis was applied first in order to guide both the mechanical and electrical design. Six major functions were determined as follows: help the STS process, be capable of moving, be automatic, be safe, be comfortable to various

users, and be cost effective. Each function was also analyzed in detail [16], which assured that the design met the requirements.

After function analysis, a mechanical prototype was designed since it not only was needed to meet all requirements, but also had to provide sufficient convenience for electrical design and its functions. For example, a battery box was designed for the storage of batteries and other electrical components. There are several parts in the mechanical design section: conceptual design, detailed design, Finite Element Analysis and material selection. The rehab robot prototype is shown in Figure 1.

Figure 1. Prototype of the Rehab Robot

The electrical component design was developed for motion and control. First, the goal and requirements for the electrical design were clarified and then appropriate electrical components were selected (after extensive research). The electrical flowchart of the system is shown in Fig. 2. The basic idea is that microcontrollers (two Arduino Mega 2560) collect data from real-time transducers including, force sensors, position sensors, keypad inputs and as options, a sound detector and voice recognition module. Then the microcontrollers process the data through a programmed control algorithm downloaded to the microcontrollers and output the corresponding signals to a motor controller. Next, the motor controller, that uses a constant power supply from batteries and a voltage regulator, outputs a voltage that governs the motion of the actuators. Transducers collect data at one second intervals. Hence, the closed-loop control algorithm is able to control the motion of the actuators quickly and effectively.

Transducers in the prototype collect position and force data that mainly helps in detecting the users' status, such as sitting, standing, walking and falling. Keypad, screen, voice recognition module, sound detector, and speaker were designed as the user interface. This enabled the rehab robot to take in data that reflects user information and preference, and to react to real-time commands.

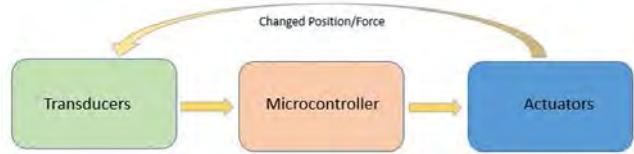

Figure 2. Electronics Connection Schematic Diagram

### III. CONTROL ALGORITHM DESIGN AND RESEARCH

The algorithms developed in this project utilized three different techniques to help in the STS process: 1-arm-pad support, 2-handlebar support, and 3-belt support, as shown in Fig. 3. There are two algorithms (Test 3 and Test 2-1) for arm-pad support, one algorithm (Test 4-2) for handlebar support, and one for belt support (Test 5). More algorithms and corresponding test information can be found in Table 1.

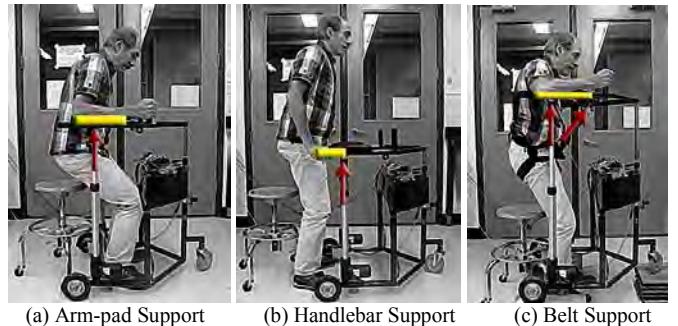

Figure 3. Three Lifting Methods

These algorithms were used to first detect the status of the user and then react appropriately for each status. For the arm-pad support algorithms, once the device detects a user, it triggers the upper frame with the support arm-pad to lift to a theoretical best height, calculated from the applied force on the actuators, user's height and weight. Once it reaches the theoretical height, it enters into a height adjustment phase, where the user will be able to adjust the height automatically or manually. When the adjusting phase is completed, the rehab robot goes into a steady state mode and maintains the same height for the upcoming walking process. When no input is received from the user after a specified period, the actuators will retract to the initial position and wait for the next round of usage. The schematic diagram of the control algorithm is shown in Fig. 4.

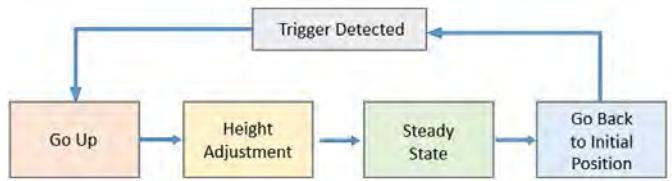

Figure 4. General Control Algorithm Concept Diagram

The belt support algorithm is very similar to the arm-pad support algorithm, except that the actuators are lifted to a higher position first to enable the belt to help lift the user to a fully upright position. It will then be lowered to the theoretical best height before entering into the height adjustment phase.

The handlebar support algorithm is a simple algorithm that controls the height of the rehab robot to follow the trajectory of the desired hand height of the user during the STS process. Abnormal cases have been considered in all algorithms, and voice control is also available. A flowchart for each algorithm and a detailed introduction to these can be found in section 3.1 of [16].

#### IV. RESULTS AND ANALYSIS

This section discusses the test process for the control algorithms, provides results, analysis and comparison with all experiments conducted. Seven experiments were conducted with the help of three participants. Table 1 shows a summary of these experiments. In general, the tests demonstrated in [16, Chapter 4] that they can also be categorized into three classes: arm-pad support lift tests (Test 1-1, Test 1-2, Test 2-1, Test 3), handlebar support lift tests (Test 2-2, Test 4-2), and belt support lift test (Test 5). Also Natural STS is Test 4-1.

TABLE 1. TEST LIST OF REHAB ROBOT (ALL ALGORITHMS USE FORCE AND DISPLACEMENT FEEDBACK)

Test No.	Description	Controller Type	Importance
Test 1-1	Fit the upper frame to preset practical best height for a particular user	Open Loop	Secondary
Test 1-2	Lift the upper frame to highest position	Open Loop	Secondary
Test 2-1	Controlled by Applied Force Based Arm-pad Lifting Method	Closed Loop	Primary
Test 2-2	Controlled by Simple Handlebar Lifting Method	Closed Loop	Secondary
Test 3	Controlled by Body Weight Based Arm-pad Lifting Method	Closed Loop	Primary
Test 4-1	Natural STS process	No Device Required	Secondary
Test 4-2	Lift the handlebar to preset practical best height for a particular user	Open Loop	Secondary
Test 5	Controlled by Belt Support Lifting Method	Closed Loop	Primary

The purpose of discussing the eight tests in this project is to compare the three different support lifting methods, and also compare the effectiveness of the different algorithms for the same lifting method. In general, all three lifting methods provide assistance to the STS process, and require less leg strength, compared with the natural STS process. The belt support lifting method provides the most assistance, which can be concluded from Comparison I: Arm Force Comparison [16, section 4.4]. As the force on arm settles down quicker than other approaches. The other two lifting methods provide a similar amount of support assistance during the STS process. Fig. 5 is a typical result of arm force comparison for different algorithms. For overall lower limb assistance, the arm-pad support lifting method could be the best, because it also carries the upper limb weight during the walking process, and maybe some upper trunk weight as well. The results can be found in detail in Comparison II: Leg Force Comparison [16, section 4.6]. Fig. 6 shows the averaged test results comparison.

In the two control algorithms designed for the arm-pad support lifting method, the Applied Force Based control algorithm was found to be the better algorithm, according to Comparison I: Arm Force Comparison [16, section 4.4]. Perhaps, this is

because this algorithm is more stable, and it takes less time for the participants to find their best arm height.

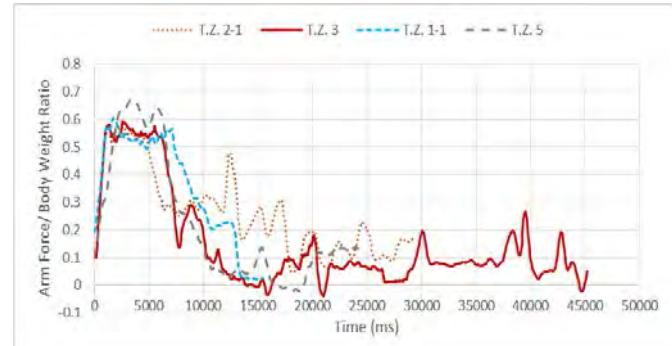

Figure 5. Test Results of the Participant TZ (Force on Arms Comparison), arm-pad support (Tests, 1-1, 2-1, 3), belt support (Test 5).

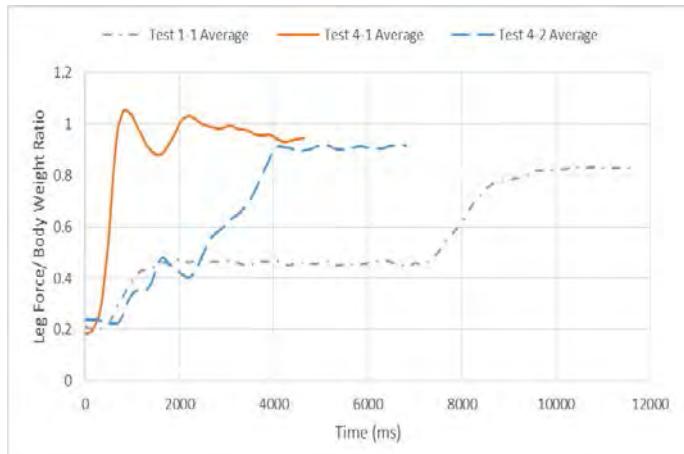

Figure 6. Comparing Different Methods of STS (Leg Force), average results of three participants. Arm-pad support (Test 1-1), Natural STS (Test 4-1), Handlebar support (Test 4-2).

#### V. NAVIGATION ALGORITHM AND TESTS

To demonstrate the walking aspect of the rehab robot, a Fuzzy-Logic-Based (FLB) algorithm [18] was adopted for navigation of the AGV driving the rehab robot in an indoor medical setting. Using this algorithm, the AGV was able to successfully reach several goals while avoiding obstacles during its motion.

Figure 7. Test of rehab-robot Avoiding Obstacles

The rehab robot was attached to the AGV and tested using the FLB algorithm (see Fig. 7). Based on H. Barden's gait speed classification [17], three speed tests were implemented: 0.9 m/s, 0.65 m/s, 0.4 m/s, and one-obstacle and two-obstacle cases were tested for each speed. During the tests, the device successfully reached preassigned goals and avoided obstacles, however, it made sharp turns, and the user experience was not ideal for practical applications. Fig. 8 shows a typical example of navigation of the rehab robot while avoiding a two-obstacle situation. Detailed test results and findings can be found in [16, section 5.3].

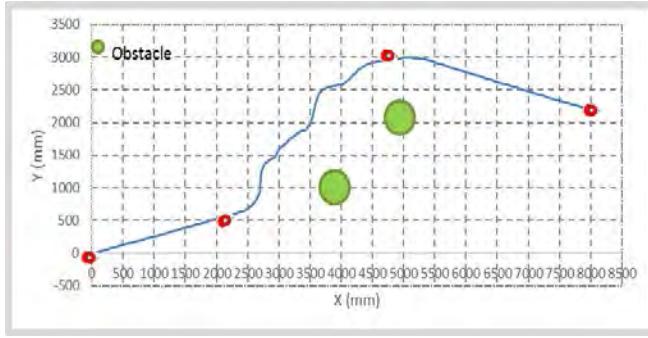

Figure 8. Typical Test Results of Avoiding Two Obstacles (Path). (X: Horizontal Displacement, Y: Vertical Displacement, Goal Position: (8000, 2200))

## VI. CONCLUSIONS

The design of the mechanical and electrical parts, development and comparison of the algorithms, and tests of the navigation algorithm were addressed here. Also, several participants tested the algorithms. The results showed that the designed algorithms helped in the STS process and aided users in finding a comfortable walking position within a reasonable time. According to the results of experiments and questionnaires, the four developed algorithms successfully helped participants to complete the STS process and provided a relatively good user experience at the same time. Hence, it can be concluded that major design goals for the rehab robot have been achieved. However, for future research and possible commercialization, some design details have to be improved and large-scale test data is needed for optimizing the control algorithm. After the rehab robot was fully developed, it was attached to a wheeled mobile robot and went through a set of tests. For navigation, the FLB algorithm adopted in this project, helped in reaching the goal position while avoiding obstacles. However, the user experience was not ideal and hence the navigation aspect of this research needs to be modified for use in any future medical applications.

**Abstract**—According to statistics coronary heart disease is one of the most common causes of death in the world. Heart failure patients with these diseases are the most common one. External assisted Pumps help ventricular thrust can treat this condition. Novel designed pump were developed in this research due to the expensive production techniques prices by using rapid prototyping stereo-lithography .This device were fabricated and experimental flow parameters were tested by artificial blood .The obtained experimental results were compared with software results . Significant collaboration were obtained and the minor discrepancies in the results were indicated because of the lack of impeller surface finishing defects in stereo lithography. Future research could be conducted to evaluate the parameters with other rapid prototyping techniques such as Selective laser sintering.

**Keywords-** ventricular assist device, Pump, Rapid prototyping, Automatic

## I. INTRODUCTION

According to statistics released by coronary heart disease and one of the most common causes of death in the world.[1] Congestive heart failure is one of the most common diseases with Sander recent decades due to the great need for these patients to a heart transplant and a shortage of hearts for transplantation, doctors and engineers together have tried using mechanical pumps; devices help ventricular for this disease and produce. [2,3] . Different pumps for ventricular assist thrust were developed in several researches and several fabrication methods were presented.[4,5,6]

These pumps were divided into different categories, one of the divisions based on fluid flow through the pump into two general types Axial and Centrifugal.[7] Axial pumps have more advantages in comparison to the pumps. Axial flow blood pumps due to the fluid flow during pumping will not redirect any the fluid were pumped in the direction of the axis ;it resulted that these blood pumps has with less damage than others.[8,9] Axial pumps are consist of four important part of the building is (Inducer, Impeller, diffuser, split Straightener) as it illustrated in figure 1. It is an important principle in the design of pumps blood to be pumped with less noise and turbulence Because of turbulence in fluids such as blood can

damage blood components that cause clotting of red blood cells in the blood.[10]

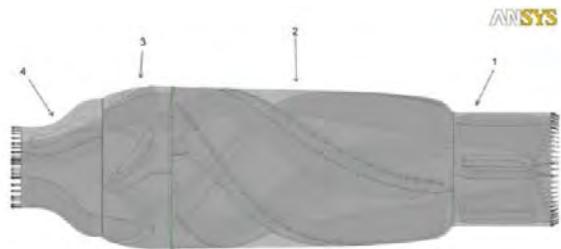

Figure 1: Main components of axial pumps.

Recently, by rapid development of CAD technology in detailed design s, modification forms data in 3D through tranquil. As a result of this data in programming CNC and RP(rapid prototyping), by CAD / CAM, automatic tangible progress is remarkable. Increase the number of common parts and advanced design makes increasing use of CAD design is more complex levels. To reduce the time and costs involved as well as new developments in industrial production, rapid prototyping is known as a great way to prototyping.[11] The purpose of this paper is to present a method of rapid prototyping (RP) used in the development of a of ventricular assist pump. stereo lithography technology was used to create complex impeller blade profiles for testing as part of a this device to optimization fluid convection process.

## II. METHODOLOGY

### *Design and Construction of Vane Pump*

The Ventricular Assist pump and the environment by using software were designed. As mentioned, the pump is composed of four blades, each blade of the specific task they are doing at the pump. The four blades, three blades and other moving Impeller are fixed In order to reduce the time to design and simulate blades of any part of the blade is a blade design and simulation The output of the simulation and analysis for a complete blade. So when output from any part of a pre-existing

ANSYS. The output file that can be acceptable for CATIA software for design and ANSYS for analytical analyzed experiments and the final output file is in IGS format. The output files are in the software CATIA as a shell First it should be map the output and then turned to the other parts and details should be added. Which these output would be used with ANSYS for experimental result simulation. (Figure 2 )

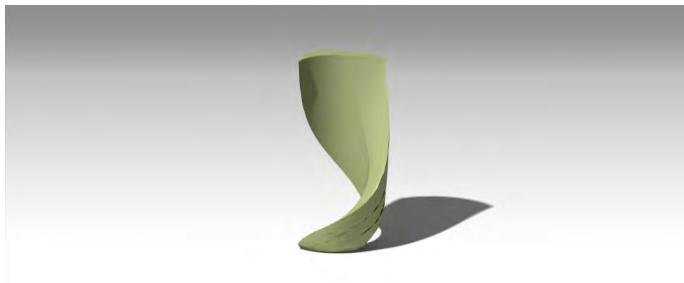

Figure 2: a blade of Impeller

IGS file output from part design were converted using ANSYS software from CATIA environment module, by using the multimedia section. The volume created for the following blade with 4 blades creates. Thus, we repeat the above steps for the other Vane Pump.(Figure 3)

Figure 3: Impeller completed

#### *Design and construction of the pump casing*

After the turn of the pump casing is designed blades. Designed pump casing is designed according to the shape of the blades. As already mentioned, only with rotary vane pump is Impeller. The distance (clearance) Impeller the body of each side is 0.2 mm. The following figure Impeller with pre-Impeller body inside it shows.

The body design Impeller a groove at both ends, for male and female for the purpose of making and assembling other parts of the body are embedded. In real examples of the different parts of the fuselage on both the threads and the O-rings are used to seal off these parts. Due to the method of stereo lithography construction on the project it should be designed housing for threaded connections there. The possibility of making the thickness of less than 0.8 mm is not

possible for us and because of the thickness and depth of less than 0.8 is threaded on the connection. In this project we have used male and female groove. After Impeller body design, body design Inducer we start. Inducer first blades from the inlet pump. The blades rotate and move not because any Within the body and is fixed for any clearance between the blades there Inducer body fluid passes only through the vane pump. In other words, in addition to covering the body Inducer duty blade holder also holds Inducer. (Figure 4)

In the actual case, the pump inlet in parallel with the axis of the blade and shift into the pumped fluid without any In the prototype system driving the pump electrically and fails Impeller pump rotor and a winding around the exterior Impeller, and by passing an electric current through the coil, rotor, which Impeller be induced and began to spin and causes the fluid motion forward.

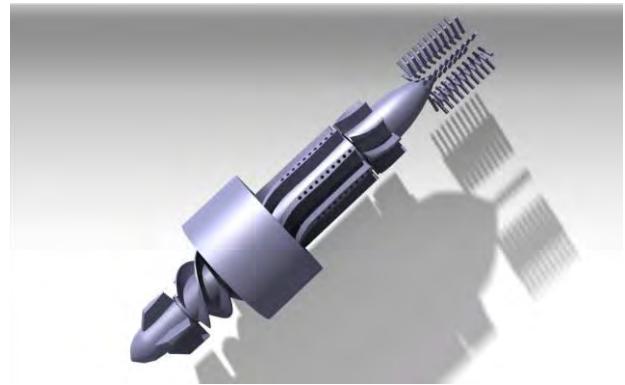

Figure 4: Body Inducer with pre Inducer inside

In these pumps because the steel blades of titanium and titanium as well as magnetism, no holes on the blades Impeller create and sticks very small magnetic inserted up to a coil around it could bars inspire and create spin in Impeller But the project of a power transmission systems outside the pumps have been used. In the following sections we will refer to it because of the design of the pump inlet to discuss the case of 90 degrees. After Inducer body design, body design diffusers have begun. Like Inducer a fixed diffuser blades and chassis in addition to covering the diffuser blades, it also has the duty holder. At the beginning and end of the groove body in order to get on Impeller body and the body is designed Straightener. The last part of the pump body, the body is Straightener. This body should also fully compatible with the external form Straightener blades because the body in addition to covering the blade, blade holder also plays a role. This part of the system, like other parts of the body to the groove of the male and female together. It is located in the pump outlet pipe. Outlet pipe to the inlet pipe diameter is the same.

#### *Transmission*

As mentioned in the previous sections due to laboratory use of the pump system for the external drive. This pump were installed with two mm shaft rotor diameter and the hole on the side of Inducer and pre Inducer and pre Impeller had crossed in front, and inside the bearings inside the body of the diffuser of the bearings packed and in the end Inducer body by bearings inside the bearing are sealed. Because the system driving the

pump externally and by an axis of rotation of the pump to Impeller transmitted, so unlike real examples pump axial inlet hose pump with the pump shaft angle of 90 degrees to find which in turn caused a slight difference in pump efficiency compared to the simulated data. Compliance is centered inside the Impeller for the referendum. Sliding bearings used in the pump within Inducer body and diffuser are asking for compliance and the final fabrication were illustrated in figure5.

The modified impeller blade profiles, relative to the standard radial configuration, were evaluated with the use of computational fluid dynamics (CFD) and experimental testing. Rapid prototype impellers were needed for experimental validation and comparison of results with software (CFD ) results.

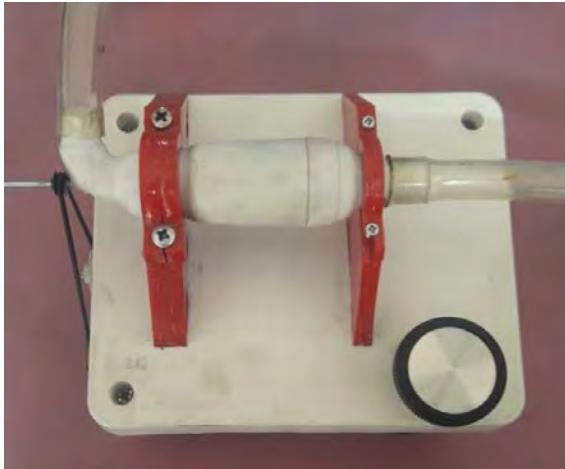

Figure 5: Sample Laboratory pumps

### III. RESULTS

We have chosen. Then the pump inlet pipe placed inside the container. In the direction of the inlet pipe to connect a tap water tested. Pump outlet pipe into an empty container with a capacity of 6 liters made. the path is not output, the pumps are turned on In the direction of the outlet pipe pump, a pressure gauge and a pressure relief valve to measure and control the output pressure placed on the inlet port of the pump and the valve at the outlet is also open to any pressure The path is not output, First, we tested the pump with 4000rpm rotational speed, the speed water pump with flow rate of 3L / min and a pressure of 40 mmHg the pump. Next, set the pump on a rotational speed of 6000rpm and we turn it on. The speed of the fluid pump is proceeding with a flow rate of 5 liters per minute and a pressure of 80mmHg pump. (figue.6) During testing the pressure reducing valve is slowly closed until pressure is 100mmHg. The pump discharge pressure to 4.8L / min reduced. In the final stage pump with ideal rotational speed that simulate the speed of 6250 rpm, the test was conducted At this rate observed at 100 ml mercury pressure, pump flow is equal to 7.5 liters per minute.(table1).

Table 1: Results of testing pumps

Experimen	output fluid	rotationa	(liters
-----------	--------------	-----------	---------

t	pressure (mm Hg)	1 speed (rpm)	per minute)
The first stage	04	0444	3
The second stage	04	0444	5
The third stage	044	0444	0/0
The fourth stage	044	0554	5/7

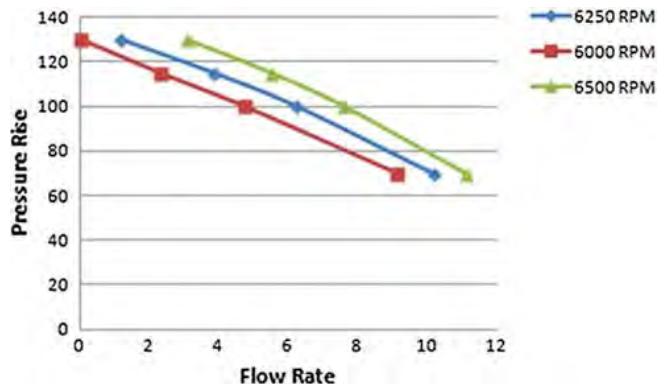

Figure 6: The results of the simulation software

### IV. DISCUSSION AND CONCLUSION

In fabrication of such a complex and sensitive products, the product development process should be done gradually. The product is designed, for example, then the simulation is done, then built and tested prototypes of the product were developed gradually. Actual samples of products were fabricated and the processes were repeated to justify test condition environment. After making quality assurance of product were obtained, the product mass-produced and used. The aim of the project is the construction of a ventricular assist pump test. This pump using actual environment was designed and simulated. In order to ensure the results of the simulation, we decided to build a prototype of the pump. All sizes according to the size of the pump is powered by software. After making the prototype pump were manufactured with rapid prototyping and the experiments were conducted to test it by flowing artificial blood .

The significant results were obtained with slight difference with comparison with the results of the simulation. The reasons for this minor difference between the results of the simulation results were analyzed. The ability to manufacture complex blade profiles that are robust enough for testing, in a rapid and cost effective manner is proving essential in the overall design optimization process for this device.

Finally, the main clues were obtained for the rapid prototyping method of making practices such as, low cost and suitability of accuracy of this method to manufacture prototype

of the pump. Construction of the pump with other rapid prototyping methods such as FDM ,SLS or SLA would be next phase of this research, which at this stage is a real sample of the product will be produced by selective laser sintering with bio metal material such as tantalum..

**Abstract**—The reconstruction process following a mastectomy procedure may require the use of a tissue expander(s) to accommodate an implant. Over several months, the expanders are routinely filled with sterile saline solution to gradually stretch the skin and muscle around the subpectoral pocket. The saline solution is injected manually by the surgeon or nurse into the expander using a syringe, catheter and needle. The injection process is physically demanding and repetitive; it has been reported to pose negative long-term effects on the muscles and joints of the hand, causing repetitive strain injuries for the syringe operator. Thus, the purpose of this study is to analyze the injection process and provide a comprehensive understanding of the factors that can be intervened upon to make this process more ergonomic and safe. To achieve this understanding, a laboratory testing setup is developed to mechanically simulate and analyze the fluid injection process into tissue expanders. Experimental results show that the magnitude of the syringe force required to inject the fluid is significantly correlated to the rate of compression, the size of the syringe and the resistance produced by the stretching of tissue expander. Moreover, the magnitude of forces measured during testing are found to be well above the recommended values to prevent repetitive stress injuries.

**Keywords-** *Breast Tissue Expander, Breast Implant, Biomechanics, Ergonomics, Mastectomy.*

## I. INTRODUCTION

The mastectomy procedure is a common prophylactic management for breast cancer, wherein some or all the breast tissue and overlying skin is removed. The breast implant involves the insertion of a synthetic sac-like prosthesis under the skin and muscle structures of the chest wall to mimic the natural breast mound. In this process, a tissue expander can be utilized prior to implant insertion to reduce discomfort and maximize the aesthetic outcome. The expander is a flexible shell that is inserted into the subpectoral pocket immediately post-mastectomy or later. It is gradually injected with a saline solution, which increases the volume of the expander shell to create a breast mound, and consequently stretch the involved

skin and muscle tissue. Saline solution is introduced through the skin of the patient into the expander through a syringe, catheter and needle, via a fill port located within the expander [1]. Figure 1 shows these elements.

**Figure 1:** Syringe, catheter, needle and breast implant expander

Repetitive hand strain injuries are an occupational hazard that can cause long-term disability and impact quality of life of operators. Actions such as applying force to a syringe plunger for a prolonged period when filling a tissue expander can cause joint pain and even cause cumulative trauma disorders, such as carpal tunnel syndrome [2]. It is believed that the trauma is inflicted by repetitive tension in the flexor tendons of the hand, which over time lead to inflammation and compression of the median nerve within the carpal tunnel [3].

The force applied on a syringe by the operator resembles a chuck pinch, or a pinch implicating the thumb, the second and third digits. A study conducted on eight female and eight male participants found that a thumb in hyperextended position can achieve a maximum pinch force of 49.49 N and 73.7 N, respectively, when the wrist was in a neutral position [4-5]. However, pinch strength appears to decrease significantly, as the wrist is flexed as well as with the use of the non-dominant hand

[6-7]. Moreover, if the thumb is not hyperextended, the resulting force is inferior and pinch force is inversely proportional to the pinch width [8]. Other studies also reported that the maximum acceptable force for tasks completed two times per week at a rate of two repetitions per minute involving repetitive flexion pinch grips is 6.35 N [9], which is considerably less than the maximum pinch force abilities of the human hand. This is comparable to the frequency that a surgeon or nurse operates a syringe during the expansion procedure on a weekly basis.

Through the literature review, no studies have analyzed the mechanical behaviour of the injection process for tissue expanders and its human factor implications. Consequently, it is unclear to what extent different factors germane to the expander expansion process can influence comfort and ergonomics for the operator. Thus, this study aims to achieve a comprehensive understanding of this mechanical procedure and determine the optimal ergonomic method for filling the breast tissue expanders.

## II. METHOD

In this study, the mechanical behavior of tissue expanders during the expansion process is experimentally characterized using an Instron™ universal testing machine. The magnitude of the syringe force required to inject the fluid into the expander is analyzed while altering key variables. Five variables that are believed to have an impact on the syringe injection mechanism and its ergonomics are selected and presented as follow:

### *Syringe size:*

Different operators use distinct syringe sizes to inject fluid. A varying syringe size corresponds to a changing plunger surface area and thus a change in the force required to create the same fluid pressure. In this study, three common syringe sizes are tested to evaluate their impact: 10, 20 and 60 mL.

### *Syringe compression speed:*

The operator can only inject the fluid at a limited speed before feeling a substantial syringe force resistance. It is believed that the injection speed affects the plunger dynamics, fluid resistance through the needle and catheter as well as the resistance caused by the mechanical properties of the tissue expander. For this variable, syringe compression speeds of 20, 25 and 30 mm/min are selected and tested.

### *Expander size:*

The size of the tissue expander varies between patients such to adapt to their needs. A different expander size equates to a different volume and surface and thus alters the resistive behavior of the tissue expander especially when inserted in the subpectoral pocket. For these tests, expanders from Naturelle [10] in common volume sizes of 250, 300, 400, 500, 600, 700, 750 and 850 mL are selected and tested.

### *Expander resistance:*

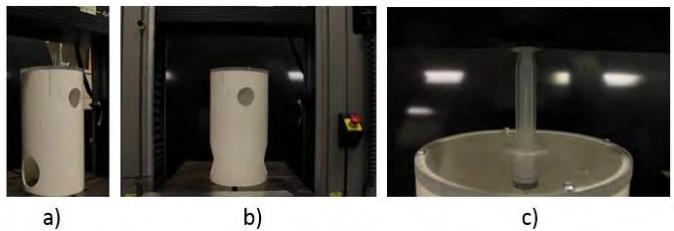

The skin and muscle of the patient creates a resistance against the expansion process. The pressure applied to the tissue expander is hypothesized to restrict the flow of fluid coming from the syringe, thus increasing the required syringe force applied by the operator. Two constant weights of 1 and 2 lbs are placed on the tissue expanders while testing to simulate constant skin resistance load.

### *Injected fluid volume:*

A limited amount of fluid may be injected per visit to minimize discomfort. Expanders with larger volumes tend to have a larger diameter, which may cause an unsymmetrical or incorrect breast shape for patients with smaller chest widths. In these cases, smaller expanders with the correct diameter are overfilled (filling the expander beyond the recommended fluid amount) to further stretch the skin and give a more natural appearance. Consequently, this process amplifies the effort required to inject the saline solution and leads to hand fatigue and discomfort. This scenario is mechanically simulated to analyze the extent of the impact of filling the expander past the rated volume.

To achieve the tests and evaluate the impact of the five selected variables, an experimental apparatus is developed in laboratory to facilitate standardized measurements of the tissue expanders expansion mechanism. As shown in Figure 2, a supporting jig is fabricated using a PVC tube with three openings: one at the top to observe the amount of liquid dispensed, and two at opposite sides of the tube's base to facilitate access to the expanders, catheter and needle. A plexiglass circle with a centered hole was attached to the top of the tube using mechanical fasteners to accommodate the placement of the syringes. The expanders were elevated to help keep the catheter straight and minimize additional resistance.

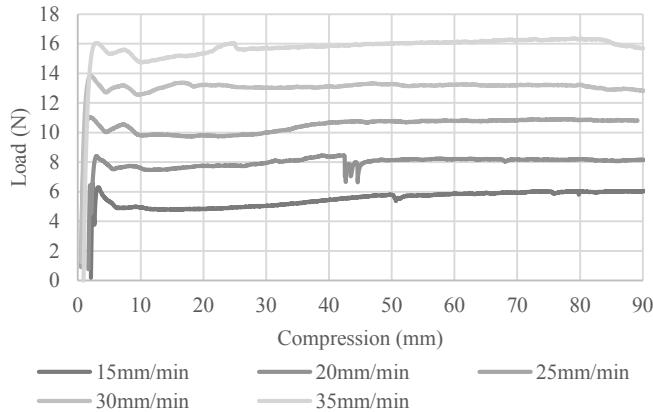

All data is collected using an Instron™ universal testing machine with a 1 kN load cell with an accuracy of +/- 0.25%. Tap water is used as a substitute to saline fluid for simplicity.

**Figure 2:** (a) Front view b) Side view c) Top view of the plastic tube (with 60 mL syringe)

## III. RESULTS

The introduction of the five selected variables throughout testing had shown a substantial impact on the syringe force required to inject the fluid into the tissue expanders. A first test is conducted, without the use of a tissue expander where the fluid is simply injected into an open container. This is achieved to determine the mechanical behaviour attributed to the syringe plunger, catheter and needle mechanisms. The data from this test is presented in Figure 3. This graph also shows a general profile of the curve found in all the achieved tests. The curve displays the transient and steady state response of the syringe force (y-axis, load) when the plunger is moved by the Instron machine with a uniform displacement speed. For clarity and simplicity, only the average of the syringe force will be presented as a bar plot for all subsequent presented results.

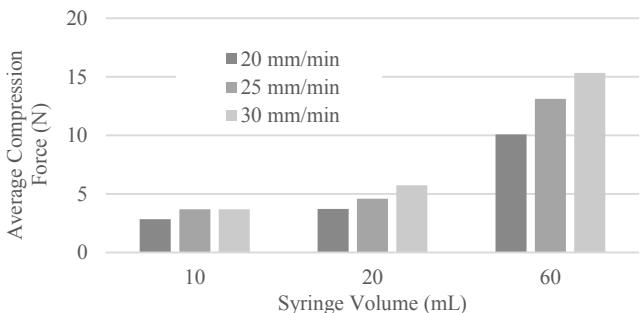

**Figure 3:** Compressive syringe force (Load) vs compression for a 60 mL syringe subjected to compression rates of 15, 20, 25, 30 and 35 mm/min

Preliminary experimental tests showed that the results are relatively consistent as the tissue expander is progressively filled until it reaches its recommended volume (without being overfilled). Thus, the following results and analysis will only consider the overfill scenarios such to demonstrate the effects of this practice on the required syringe force.

#### Syringe size and syringe compression speed rate

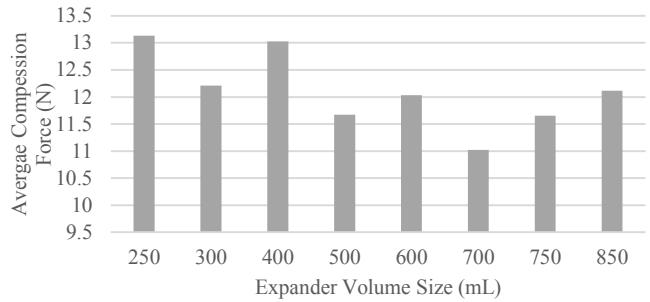

Figure 4 shows the results for the average compression force for three distinct syringe sizes (10, 20 and 60 mL) while varying the compression speed rate (20, 25 and 30 mm/min). The test is achieved using a 250 mL expander and being overfilled with an additional volume of 60 mL.

**Figure 4:** Average compression force of various syringe sizes subjected to a varying compression rate using a 250 mL expander

#### Expander size

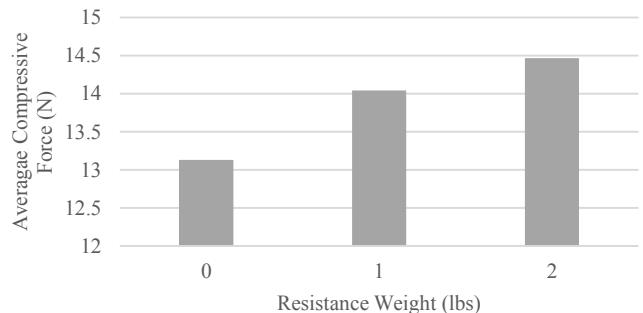

Figure 5 shows the results for the average compression force for eight distinct tissue expanders (250, 300, 400, 500, 600, 700, 750, 850 mL). The tests are conducted at a speed of 25 mm/min while being overfilled with an additional volume of 60 mL using a 60 mL syringe.

**Figure 5:** Average compression force for a 60 mL syringe subjected to various expander sizes at a compression rate of 25 mm/min

#### Expander resistance

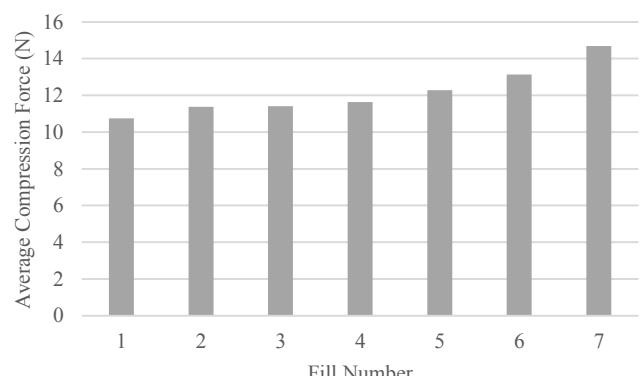

Figure 6 shows the results for the average compression force for three distinct resistance weights (1, 2 and 3 lbs.). The tests are conducted at a speed of 25 mm/min while being overfilled with an additional volume of 60 mL using a 60 mL syringe.

**Figure 6:** Average compression force for a 250 mL expander subjected to various exterior resistance with a compression rate of 25mm/min using a 60 mL syringe

#### Injected fluid volume

Figure 7 shows the average compression force for the seven sequences that are required to fill a 250 mL expander using a 60 mL syringe at a speed rate of 25 mm/min.

**Figure 7:** Average compression force of the seven sequences required to fill a 250mL expander with a 60 mL syringe at a compression rate of 25 mm/min

## IV. DISCUSSION

The first results presented in Figure 3 display the transient and steady state response of the syringe force upon the Instron

machine moving the syringe plunger with a uniform compression speed. Depending on the speed, the measured force varied between 5 and 16 N for a speed range of 15 to 35 mm/min. These represent significant force magnitudes given the absence of the tissue expander and patient skin resistance properties in these tests. Moreover, these results also demonstrate the viscoelastic behaviour of the syringe, catheter and needle mechanism.

#### Syringe size

The impact of syringe size on the compression force is demonstrated in Figure 4. It has been shown that even while varying the speed of compression, the magnitude of force measured remains proportional to the syringe size. Relatively low force magnitudes of 5 N or less were measured for the syringes of 10 and 20 mL while large force magnitudes of about 15 N were measured for the 60 mL syringe. Based on these results, a smaller syringe size would be ideal to achieve smooth and small syringe forces during the injection process. However, a smaller syringe size may be less desirable since it prolongs the expansion process and consequently the overall surgical procedure.

#### Syringe compression speed

Compression speed refers to the rate at which the syringe plunger is compressed (mm/min). Figure 4 shows how the compression speed affects the required compressive force while the rate varies from 20 to 25 to 30 mm/min. On average, a 5 mm/min increase in speeds equates to a force increase of 2.65 N without an expander, and 2.54 N with an expander. The results demonstrate high viscoelastic behaviour and such when the compressive speed is increased; the compression force is also increased. Therefore, the use of a high compressive force to drive the syringe faster is counterproductive as intuitively experienced by operators. A slower and consistent syringe compression speed results in a smaller compression force and a safer process for the operator.

#### Expander size

Figure 5 shows the compression force while filling various expander sizes (250, 300, 400, 500, 600, 700, 750, 850 mL). Given the absence of the skin resistance properties, there is no clear correlation between the compression force and the expander size. However, the two largest forces were found when filling the smaller expanders (13.13 N for the 250 mL expander and 13.03 N for the 400 mL expander). Some limitations of the study may provide an explanation for this phenomenon.

#### Expander resistance

As seen in Figure 6, an increase in the external resistance simulated by the addition of the free weights (1 and 2 lbs.) resulted in an increase in the magnitude of the compression force. The addition of the 1 lbs. weight increased the average compression force by 0.91 N, whereas the 2 lbs. weight caused an increase of 1.34 lbs. Similar but amplified resistance is expected by the skin and over-lying tissues given its non-uniform and increasing stiffness properties throughout deformation. The procedure may be more strenuous on patients with lower tissue elasticities (i.e. patients that have undergone radiation).

#### Injected fluid volume

Figure 7 shows data spanning the entire process of filling one 250 mL expander with a 60 mL syringe, at a compression rate of 25 mm/min. Data is divided into seven sequences, wherein 50 mL of saline was injected per sequence. The first five sequences represented complete filling of a 250 mL expander, whereas the last two sequences recorded the effects of overfilling the expander. The compression force required to push the syringe plunger remains relatively the same as the expander is being filled, with a small gradual increase of 0.39 N on average. However, the force tends to increase more rapidly as it nears full capacity and when the expander is being overfilled. The force increases by 0.85 N between the 5<sup>th</sup> and 6<sup>th</sup> trials, and then by 1.55 N between the 6<sup>th</sup> and 7<sup>th</sup> trials.

#### Limitations

The substitution of tap water for saline may have affected the magnitude of the measured forces since saline solution is denser than tap water and would therefore require larger force. However, the magnitude of the force difference is considered negligible.

Instability of the weights on the expander during the experiment may have caused inconsistencies during data acquisition. The variation in the placement of the weights could also have an impact on the magnitude of the compression force.

The absence of a correlation between the compression force and the expander size during overfill could be explained by the selected overfill amount. The overfill volume was chosen to be a constant 100 mL for all the expanders. This means that during the overfill phase of the experiment, a 250 mL expander was overfilled by 40 % whereas a 500 mL expander was only overfilled by 20 %. Therefore, the smaller the expander, the higher the percentage of overfill. Since a higher percentage of overfill creates more pressure in the expander, it increases the magnitude of the compression force (as seen in the high force observed for the 250 mL and 400 mL expander in Figure. 5).

## V. CONCLUSION

The measured magnitudes of force required to fill a breast tissue expander in a mechanical setup were mostly above the recommended value for preventing repetitive stress injuries given in [9]. The data showed quantifiable trends among most of the selected tested variables. It was observed that a slower compression speed required a smaller compressive force and was a more ergonomic alternative. The magnitude of the compressive force also decreased when the size of the syringe decreased. Therefore, a smaller syringe is more ergonomic as opposed to a larger one. An array of expander sizes was tested; however, the size of the expander did not display any definite effect on the magnitude of the compressive force. External resistance was also applied to the expander using free weights to mimic the resistance applied on the expander by the skin in a real case scenario. As the magnitude of the external resistance was increased, the magnitude of the compressive force also increased. Incorporation of the observed principles from this study (i.e. smaller syringe sizes and a slower rate of compression) into clinical practice may influence the incidence of repetitive strain injuries for surgeons and nursing staff who participate in tissue expansion on a routine basis. Other factors

such as the use of a larger needle could facilitate the task but may cause additional discomfort to the patient. Further clinical research is needed to determine the significance of these adjustments.

**Abstract**— This paper describes the evaluation of the MyoWare Electromyographic (EMG) sensor performance during a typical end-use application to help determine if it could be used for an EMG-based controller of an upper-limb robotic exoskeleton. Tests were conducted to study the signal-to-noise ratio (SNR) and a series of experiments were performed to determine the sensor's capability of capturing key EMG signal features while a subject performed bicep curls. LabVIEW was used for data collection and processing, and Matlab was used for statistical analysis. The results revealed that the SNR was between 10dB and 33dB for the average peak root mean square (RMS) EMG, and between 1dB and 27dB for the average voluntary contraction (AVC) EMG which – except for one case – were all above the acceptable level in the field. The validation of the sensor performance showed a correlation consistent with literature between the force exerted and the RMS EMG signal under both dynamic and static loading. These initial results indicate that the MyoWare EMG sensor could be used in a more advanced robotic exoskeleton EMG-based controller beyond its current popular use as an EMG-level threshold-based ON/OFF switch.

**Keywords-** *electromyography, EMG, muscle, myosignals, upper limb, robotic exoskeleton.*

## I. INTRODUCTION

With the expected surge in the global aging population and the inevitable motor impairment in the elderly, it is anticipated that the already overloaded medical workforce will not be able to keep up with the onset of anticipated rehabilitation demands [1]. To address this issue, the field of Robotic Exoskeletons is growing rapidly, though most of the existing systems are at the research level or are too cost-prohibitive to be widely available. It is pertinent for the technology to be accessible now to educate future researchers and developers in the field. Consequently, Beyond Robotics GmbH released the EduExo Robotic Exoskeleton kit in October of 2017. The kit contains all the major subsystems relevant to a Robotic Exoskeleton including an Electromyography (EMG) sensor – the MyoWare EMG sensor (AT-04-001) from Advancer Technologies. This sensor reads a wearer's EMG signals which are indicative of

muscle activation levels [2]. The controller implemented with this kit activates the exoskeleton elbow joint motor when the measured EMG signal surpasses a set threshold value. In this paper the present authors investigate the performance of the sensor in an application to determine the possibility of using it in a future-build robotic exoskeleton controller to, for example, provide proportional control of the motors to assist the user in achieving the desired motion. A brief background is provided on EMG controllers to justify why studying the sensor's SNR and its degree of linearity are important for the intended application. Factors which influence the fidelity of the signal will also be discussed, followed by a description of the sensor specifications. The experimental setup and procedure will then be presented, the results will be shown and discussed, after which conclusions will be drawn.

## II. BACKGROUND

There are numerous factors that can influence the quality and amplitude of EMG measurements. On the apparatus side, De Luca [3] states that the “main issue of concern that influences the fidelity of the [EMG] signal is the signal to noise ratio.” Additionally, the design of the electrodes, the distance between them, and the placement and the orientation of them along the muscle affect signal fidelity. Furthermore, the quality of the contact between the electrodes and the skin, the wire length to the amplifier, the characteristics between the electrodes [4], the amplifier unit, and the signal processing methods are also important. There are many factors which can influence the EMG signal on the subject side as well, such as the conditions of the muscles. For example, EMG measurements can look very different depending on whether or not a muscle has been warmed up or fatigued. Other factors that could affect the EMG levels are age, sex, quality of the skin, body mass index (BMI) level (which is indicative of the thickness of the fat layer over the muscle), and quality and health of the muscle. EMG readings can also vary from day to day [5] even if the subject is performing the same tests as on the previous day. It is also to be noted that the subject's psychophysiological factors, such as emotions, play a factor in the produced levels of the EMG signal [6].

Numerous existing Robotic Exoskeleton Systems [7,8,9] use these EMG signals as the primary command signal to robot controllers. The EMG signal is typically captured using electrodes on the body that are connected to commercial amplifiers, such as those from Biopack Systems [10]. These controllers incorporate muscle models (myoprocessors) which rely on a correlation between the EMG signal amplitude and dynamic or static exerted force. This information can enable either position control or torque control of the joints with the goal of providing seamless assist-as-needed support to the user. An example of an EMG high-level position controller is shown in Fig. 1 where an EMG sensor is used to determine the desired position of a joint. It is, therefore, critical to identify the correlation between the EMG signal under different loads. Perry [7] points out that a great advantage of EMG controllers is that, due to the “electromechanical delay in the human neuromusculoskeletal physiology, the system can predict the operator’s intention”. The EMG signal changes in magnitude 20-80ms before the actual contraction of the muscle [11]. As a result, the controller can provide smooth motion coordination between the user and the exoskeleton [7] before the muscles have even begun to move.

An EMG controller “needs to provide the correct amount of support to the user with correct timing” [12]. Control systems rely on sensor feedback updates – sometimes hundreds of times per second in motor control applications. When discussing applications that depend on EMG signals, De Luca [2] emphasizes that the EMG signal should be detected and recorded with maximum fidelity as it is an indicator of the initiation of muscle activation and it has a relationship to the force produced by the muscle. If the signal is noisy and not properly filtered, the resulting exoskeleton motion could be unstable and unsafe. High EMG signal SNR is thus crucial.

The question at hand is: Is the MyoWare EMG sensor able to collect EMG data that is high-fidelity and relatable to the amount of effort exerted by the user so that it could be used in a future-build Robotic Exoskeleton EMG controller for more sophisticated control strategies than just ON/OFF?

### III. EMG SENSOR AND SYSTEM DESCRIPTION

Table I summarizes the MyoWare EMG sensor characteristics that will be studied in this paper, along with what they indicate, their relevance, how they will be characterized, and the location from where they are calculated as shown on a sample EMG signal (Fig. 2).

The MyoWare EMG sensor, shown in Fig. 3, measures electrical signals which are detected on the skin just before and during muscle contraction. These signals are usually on the order of  $\mu$ Volts to low mVolts [5] and need to be amplified so that they can be digitized, recorded, analyzed and utilized. The MyoWare EMG sensor is an all-in-one device which amplifies, rectifies and filters the raw EMG signal, and provides the RMS EMG envelope as an output with an amplitude between 0 and the supply voltage (2.9-5.7V). Some of the advantages of the sensor are that it is inexpensive, the raw signal is also available, and the electrode connectors, which are placed 3 cm apart, are embedded on the sensor board to minimize noise.

Fig. 3 The MyoWare EMG Muscle Sensor (shown at full scale)

TABLE I  
SENSOR BEHAVIOUR CHARACTERISTICS PERTINENT TO EMG CONTROLLERS

Characteristic to be measured	Indicator	Relevance to Robotic Exoskeleton EMG Controllers	Characterization	Location in Fig. 2
SNR	Fidelity of the signal	High-fidelity data is crucial for timely and appropriate motor commands	Compare the EMG signal amplitude between rest and Max EMG signal, and rest and static loading EMG signal	1 vs 2 (dyn. loading) and 1 vs 3 (static loading)
Linearity Max RMS EMG (dynamic loading)	Indication of the intended exerted force	The EMG signal is used as control input to the EMG controller to prepare the assist-as-needed routine before the muscles have even moved	Compare the Max EMG signals from 200 tests performed with different weights	2
Linearity AVC RMS EMG (static loading)	Indication of the sustained force	The EMG signal is used as control input to the EMG controller to command required torque or position command to the low-level controller	Compare the Average EMG signals during static loading from 200 tests performed with different weights	3

#### IV. TESTING METHODOLOGY

The evaluation process consisted of initial tests to verify the sensor's SNR after which a series of extensive tests were performed by a subject to validate the linearity between exerted force and the EMG signal.

##### A. SNR Tests

To measure the baseline noise level of the sensor and verify the SNR of the MyoWare EMG sensor, the EMG signal from the sensor was collected while the two parallel electrodes were connected to the reference potential and when the electrodes were connected to the subject's arm and the bicep muscle was relaxed. The data was captured using the National Instruments USB-6361 Analog/Digital Converter (A/DC) and a LabVIEW program which sampled the data for 500ms at a sampling frequency of 2000Hz.

##### B. Linearity Tests

A series of tests were then carried out to observe the performance of the sensor and to determine the degree of linearity during a typical end-goal application scenario, such as those performed during upper-limb robotic exoskeleton assisted rehabilitation sessions.

The tests were performed on a healthy female with no history of bicep pathology, neuromuscular conditions or cardiac disorder. As the SNR is determined almost "exclusively by the electrodes, and more specifically, the properties of the electrode-electrolyte-skin contact" [6, 13], great effort was taken to ensure optimum contact. In particular, the subject's skin at the contact site was exfoliated, cleaned and dried. Next, tape was applied and swiftly pulled from the skin to remove any remnant dry skin at the site. Two 3M RedDot bi-polar surface Ag/AgCl monitoring electrodes with soft cloth tape and solid gel were placed parallel on the subject's dominant (left) belly of the bicep branchii in accordance with the sensor manufacturer's instructions.

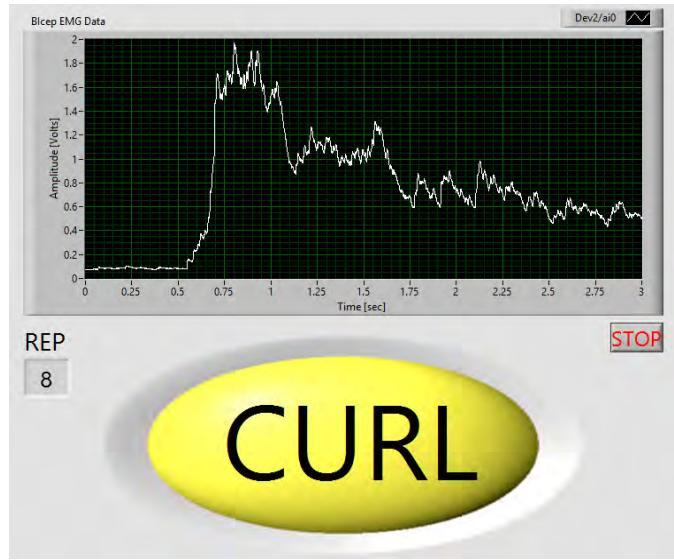

Fig. 4 LabVIEW User Interface for Curling Tests.

Furthermore, as suggested by De Luca [3], the subject flexed her bicep to find the optimum placement of the electrodes to minimize cross-talk noise from neighbouring muscles and increase SNR. A third electrode was placed as far as possible from the bicep branchii, which in this case was limited by an 8 cm length of wire which connected the reference electrode snap to the sensor board. During the tests, the subject sat on a chair and watched the LabVIEW User Interface shown in Fig. 4. Each test lasted 3 seconds.

At the beginning of the test, the subject had her arm down holding the weight at full extension ( $0^\circ$ ) with the bicep muscle relaxed. When the 'CURL' indicator on the LabVIEW User Interface turned yellow, the subject lifted the current weight to full elbow flexion ( $90^\circ$ ). The subject then maintained a static hold at  $90^\circ$  for the remainder of the 3 seconds. Then there was a 3 second rest period after which the next repetition started. This procedure was carried out 40 times for a specific weight. When completed, the subject was given a 5-minute rest period. The set of 40 repetitions were performed consecutively with 5 different weights: 0lbs, 3lbs, 5lbs, 10lbs, and 15lbs. A total of 200 tests were, therefore, performed by the subject. Note that the maximum weight was limited to the 15lbs dumbbell since the amplifier sometimes saturated during tests with heavier weights and the subject could also not perform 40 tests in a row using the larger weights. The data was collected using the National Instruments USB-6361 A/DC and a LabVIEW program with a sampling rate of 2000 Hz which was consistent or faster than tests in the literature [6, 10]. The experimental setup diagram in Fig. 5 shows the computer running the LabVIEW program, the Arduino Uno microprocessor which was used in this case to power the EMG sensor, the EMG sensor placed on the bicep, and the EMG sensor's connection to the NI A/DC which digitized the data that was then collected by the LabVIEW program running on the computer.

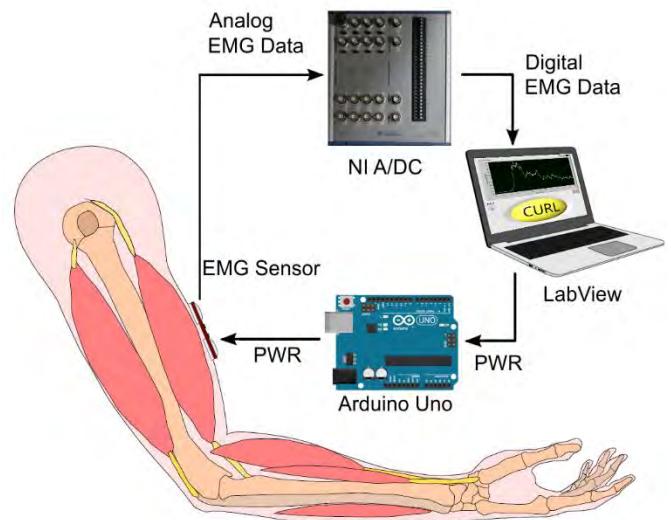

Fig.5 Experimental Setup Diagram for the Curl Tests (modified and used with permission from [12])

## V. RESULTS AND DISCUSSION

LabVIEW was used to process the EMG data and Matlab was used to perform statistical analysis and plot the results.

### A. SNR Tests

The measured (amplified and processed) baseline noise  $V_{rms,noise}$  was 65mV (for both when the electrodes were connected to the reference electrode and when the muscle was relaxed). The SNR was then calculated as follows [14,15]:

$$SNR = 20 \log_{10}(V_{rms,signal}/V_{rms,noise})$$

Table II shows the calculated average maximum RMS EMG (dynamic loading) values for the groups of tests performed with each weight, while Table III shows the Average Voluntary Contraction (AVC) RMS EMG (static loading) values for the groups of tests performed with each weight. As can be seen in these tables, as the amount of effort increased, the EMG signal amplitude also increased – resulting in a greater SNR. Delysis Inc [16], an industry leader in wearable sensors, states that SNR values above 1.2 are acceptable. Except for the SNR of the AVC averages at 0lbs, the SNR for the MyoWare EMG sensor is very good.

One important value to note in the noise baseline of the EMG signal when the muscle is relaxed. Florimond [5] has pointed out that it is generally accepted that the surface EMG of a muscle at rest should be below  $5\mu V$ , while De Luca [2] indicated that it should be less than  $2\mu V$ . The voltages measured during the tests carried out in this paper are amplified. Thus, to determine the relaxed muscle (noise) voltage, it was necessary to divide the measured EMG voltage at the skin by the amplification factor of 9,306.3 [17] resulting in  $65mV/9,306.3=7\mu V$  which is consistent with the literature. This value is satisfactory.

TABLE II  
SNR: AVERAGE MAX RMS EMG (DYNAMIC LOADING)

Weight (lbs)	Avg Max RMS EMG at this weight [mV]	SNR	SNR (dB)
0	0.2150	3.26	10
3	0.5599	8.48	19
5	0.8816	13.36	23
10	1.5280	23.15	27
15	2.7970	42.38	33

TABLE III  
SNR: AVC RMS EMG (STATIC LOADING)

Weight (lbs)	AVC RMS EMG at this weight [mV]	SNR	SNR (dB)
0	0.0748	1.13	1
3	0.1693	2.57	8
5	0.3299	5.00	14
10	0.6328	9.59	20
15	1.4142	21.43	27

### B. Linearity Tests for Dynamic Loading

Fig. 6 plots the maximum RMS EMG signal for all 200 tests (40 tests at each of the 5 weights). As can be seen in the figure, the Max RMS EMG signal became progressively larger as the exerted force increased. Fig. 7 plots the average maximum RMS EMG signal as a function of the weights lifted along with the corresponding 95% confidence intervals. A straight line and a second-order polynomial were fit to the data, with  $R^2$  values of 0.9728 and 0.9949 (shown), respectively.

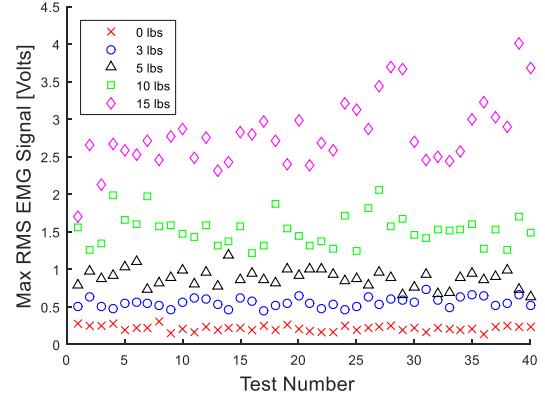

Fig. 6 Maximum RMS EMG Signal for Tests with Different Weights (Dynamic Loading)

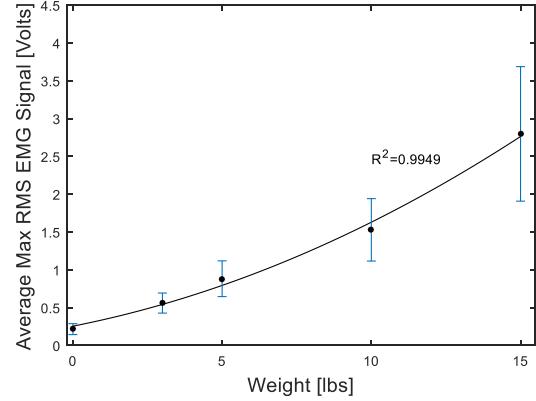

Fig. 7 Average Max. RMS EMG for Different Weights with 95% Confidence Interval (Dynamic Loading)

### C. Linearity Tests for Static Loading

Fig. 8 plots the Average Voluntary Contraction RMS EMG (Static Loading) signal for the last 500 ms of each of the 200 tests (40 tests for each of the 5 weights). Similar to the Max RMS EMG signal, the AVC RMS EMG signal also became progressively larger as the exerted muscle force increased, but with roughly half of the amplitude. Fig. 9 plots the average AVC RMS EMG signal as a function of the weights lifted along with the corresponding 95% confidence intervals. A straight line and a second-order polynomial (shown) were fit for the static loading as was done with the dynamic loading plots.  $R^2$  values of 0.9311 and 0.9921, were calculated for the straight line and the second-order polynomial fits,

respectively. Like with the dynamic loading, a correlation between the exerted force and the measured AVC RMS EMG signal was observed and are both consistent with the curves attained in literature [18, 19] for 61 subjects and 10 subjects respectively. Since the results show a characterizable relationship, the sensor would likely be suitable for a future-build robotic exoskeleton EMG-based controller.

A correlation was also observed between the variability of the EMG signal and the applied force for both types of loading – up to 50% for the 15lbs dynamic loading tests. Similar observations were presented in [20]. Some possible solutions to minimize variability could be to apply sensor-side or controller-side processing or limit the number of repetitions in each test and the payload to 5lbs or less - where the spread is significantly smaller.

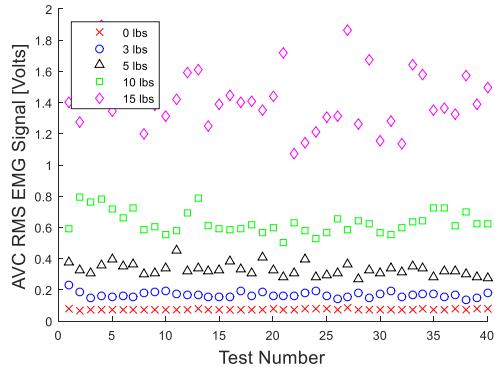

Fig. 8 Average AVC RMS EMGS for Different Weights with 95% Confidence Interval (Static Loading)

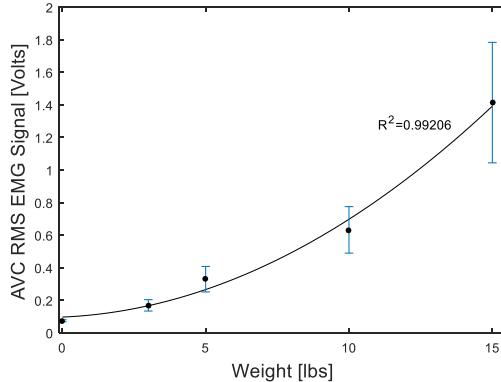

Fig. 9 Average AVC RMS EMGS for Different Weights with 95% Confidence Interval (Static Loading)

## VI. CONCLUSION

Experimental tests were performed on a subject using the MyoWare EMG sensor to evaluate its use for future robotic exoskeleton applications. Verification test showed acceptable SNR values. The degree of linearity of the sensor was studied while it was utilized in a typical end-use application and the results showed expected correlation between the exerted force and both the dynamic and static load EMG signals. Although these results look promising and suggest that the sensor would be a good candidate for a proportional robotic exoskeleton EMG controller, further investigation would be beneficial to

verify the linearity of the sensor itself without the human in the loop. It would also be interesting to perform the same tests on more subjects, and with other EMG sensors. Additionally, it would be beneficial to examine the sensor's raw EMG signal and explore its performance in the frequency domain.

## ACKNOWLEDGMENT

We would like to thank Dr. Bartenbach, Dr. Kesner, and Mr. Kaminski for their help.

## Abstract

Detection of volatile organic compounds (VOCs) in the exhaled breath is found to be a promising method to diagnose different diseases. The amount of alcohol or drugs absorbed/inhaled in the body can also be measured using gas sensors. Oral habits can affect the composition and also concentration of VOCs produced as a result of cellular metabolic reactions inside our body. Recognition of exhaled breath patterns including composition and concentration of VOCs provides useful information regarding how the breath affects the artificial olfaction systems. This can provide a powerful tool to calibrate gas sensors and detect VOCs associated with different diseases.

In the following study, the breath signatures are extracted after different activities including fasting, brushing teeth, and drinking coffee. The results are normalized and implemented into a feature extraction model that extracts principal features for each regime. This will determine the breath signature of each regime. The results show that the effect of these activities on the breath is consistent between different subjects. This study provides the base signature of the exhaled breath which can be used in a clinical setting to identify other target VOCs that are considered the biomarkers of diseases.

**Keywords—** breath analyzer, gas sensor, microfluidic artificial olfaction

## I. INTRODUCTION

Breath analyzers have been considered as a non-invasive method for detection of chemicals or mixtures of chemicals that are either produced as part of biological metabolism or are absorbed from exogenous sources [1]. The exhaled breath can contain volatile organic compounds (VOCs) (e.g., acetone, ethanol, and isoprene), inorganic compounds (e.g., carbon dioxide and nitrogen), and non-volatile substances (e.g., isoprostanes and peroxy nitrite) [2]. The “smell-print” can be used as an indicator of the patient physical condition and lifestyle. Despite its great potential, breath analysis still has

several practical challenges. A mixture of inorganic gases (e.g. CO<sub>2</sub>, ethanol, and N<sub>2</sub>) and VOCs in the exhaled breath of a normal healthy person can be identified (many of these chemicals are absorbed from environment such as smoking, food consumption, bacterial microflora, work environments and medication [3]). However, The exact composition is influenced by diet, age, body mass index (BMI), and gender, and hence, varies between individuals [4]. Although the majority of VOCs in exhaled breath have external sources, they still should be distinguished from the endogenous species.

Another challenge associate with breath analysis is calibration of the sensor based on standard samples. For example, for detection of the cannabis use, it is necessary to control temperature and humidity, and breath samples must be collected from the lower airways (alveolar air). Also, in order to quantify impairment, one must discriminate between THC (the psychoactive component) and CBD.

Finally, identifying a particular health condition is not achievable by detection of a single target gas and instead requires detection of a pattern of compounds [5]. For example, monitoring the level of methane and hydrogen is a promising technique for diagnosis of Small intestinal bacterial overgrowth (SIBO), Irritable bowel syndrome (IBS), and diabetes [6]. However, these gases could be produced as a result of normal digestion and respiration. Therefore, the rate and concentration of these species in exhaled breath should be determined base on each metabolic reaction [7]. Also, malabsorption of lactose and glucose causes huge production of hydrogen and methane in breath [8]. Discovery of the breath pattern as a result of this process will prevent mixing up this malfunction of metabolic system with another disease like diabetes at first stages [9].

The technology presented here has high sensitivity and selectivity, and it uses a single sensor embedded in a microfluidic channel [10]. The latter adds several benefits (such as less calibration complexity, smaller size, and lower cost) compared to traditional e-noses [11]. This technology is used to detect VOCs in the exhaled breath of several subjects after different activities. The purpose of this study is to develop base

signatures of the breath that can be considered while it is used for detection of a certain biomarker for a disease.

## II. EXPERIMENTAL

### A. Device description

This technology is portable and easy to assemble, making it ideal for a hand-held device (see Fig. 1). The air chamber is built into the main cartridge, eliminating the need for a separate chamber to be filled with the sample. Both humidity filters (i.e., potassium hydroxide and zeolite) can be easily installed/replaced simply by sliding each piece into the cartridge. A total of three pieces are needed to complete the two filters. The last piece of the filter design includes slots for three springs to be inserted. These are used to make a one-way valve. A rubber stopper is attached to the end of the three springs to prevent a backflow of the air sample. When the breath is blown into the device, the force of the air will compress the springs allowing the air to flow pass the filters and into the sensing chamber. The one way valve housing is bolted to the cartridge to ensure an air tight seal and easy assembly. The opening at the end of the one way valve housing allows a disposable mouthpiece to be attached for each new sample.

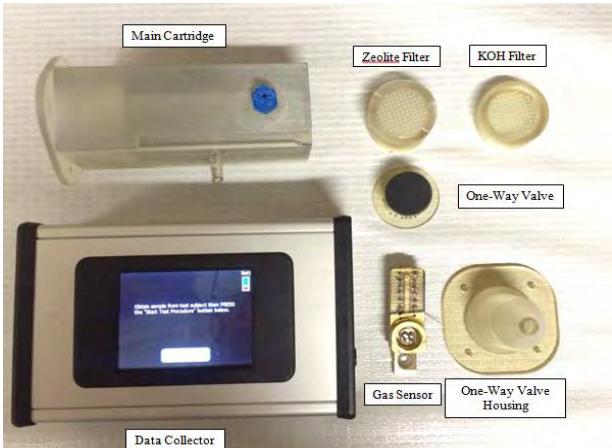

Fig. 1 - Layout of the breathalyzer including each component

A box containing the sensor and electronics is connected to the cartridge and sensing chamber with a push valve. A large bracket will then slide into place following guides imbedded into the cartridge. It can hold the sensing device firmly in place. A schematic of the device including all components and also the test setup is shown in Fig. 2.

### B. Materials

The entire device is 3D printed to reduce machining costs. The cartridge, filters, a one-way valve housing are made of veroclear (UBCO Star 3D printing facility) to allow intricate geometries. Before testing, the cartridge and all of the parts are coated with Parylene C to prevent diffusion of the gases into the plastic.

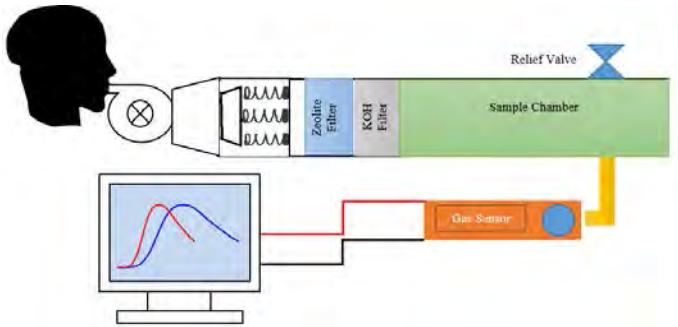

Fig. 2 - Schematic of the device and test setup

### C. Testing procedure

Over the period of testing, the subjects started the experiment by fasting for 12 hours. Following the collection of the breath after fasting, the experiment was carried out by collecting the breath samples after certain activities including drinking black coffee, brushing the teeth (Colgate cavity protection winter fresh), and washing using a mouthwash (Listerine original). After performing each activity, the subject blows into the device twice, giving two samples to ensure the results reproducibility.

## III. RESULTS

Fig. 3 shows the sensor response (referred to as the “smell print”) after each activity for each subject. For every subject, the response was the strongest after using mouthwash. The second strongest response curve is after fasting for 12 hours, which is followed by the signal of the breath sample collected after drinking coffee and finally brushing the teeth. The sensor’s strong response after the use of mouthwash is due to the presence of various alcohols (26.9%) and also organic compounds (e.g. Thymol and Menthol) in the mouthwash solution. Also, since the concentration of ethanol and acetone in the exhaled breath of a person after fasting for 12 hours increases [12], the sensor’s second largest response is for the samples collected after fasting. It is worth to mention that regardless of the subject the trend of the response curves associated with each activity is similar. This proves that the “smell print” of each activity is unique in the breath.

The pattern of breath signature across different activities looks similar for that particular activity between different subjects. This similarity can be observed in the slopes of the curve during the rising period (i.e., for the exposure process) and decaying part (i.e., for the recovery stage).

Fig. shows the results of the feature extraction method (performed based on three features including: the area under each curve, the maximum response, and response at  $t=200s$  for the breath samples collected after using the mouthwash. The results show that each subject has a unique breath signature after rinsing the mouthwash. Also, the two replications conducted for the breath of each subject are in agreement in 3-dimensional space, showing reproducibility of the results.

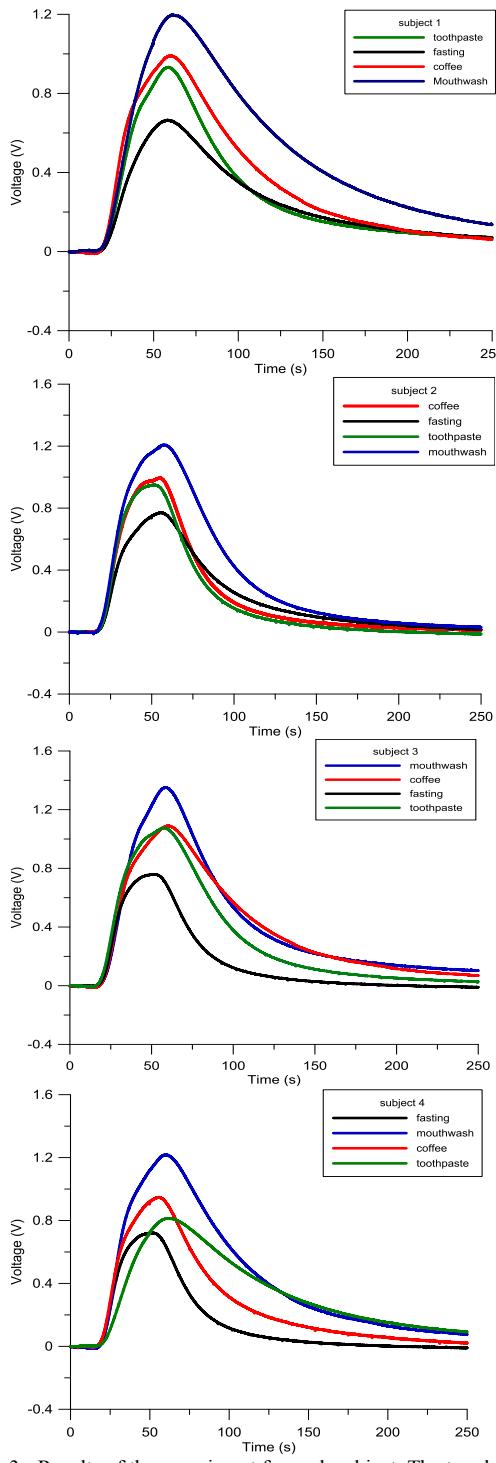

Fig. 3 - Results of the experiment for each subject. The trend in each graph for each activity is similar for different subjects.

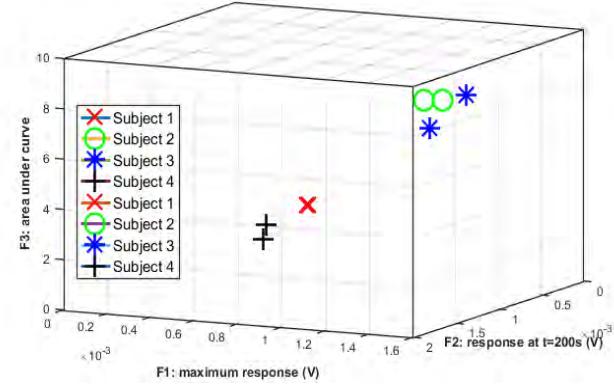

Fig. 4- Feature extraction of results for the breath samples collected after using the mouthwash. These features are based on the area underneath the curve, the maximum response, and response at  $t=200s$ .

#### IV. CONCLUSION

The response of the microfluidic olfaction breath analyzer showed that the trend for the breath samples collected after different activities is consistent regardless of the subject. The response of the sensor ("smell print") is much stronger after the use of mouthwash and fasting due to high amount of alcohol existing in exhaled breath in both of these activities. The experimental results were reproducible for each subject as the signal magnitude trend between different activities was the same in all cases. For the future study, a diverse range of subjects will be tested to observe and extract biomarker patterns in a wide variety of cases.

**Abstract**—Heart valve replacement is still the optimal solution in young patients with severe symptomatic heart valve disease. In those patients, bileaflet mechanical heart valves (BMHV) are preferred to biological valves because of their higher durability. However, thrombus formation has been reported as a common complication following BMHV implantation despite a permanent anticoagulation therapy. Thrombus formation can lead to valve leaflet dysfunction, a life-threatening event that requires immediate surgical intervention. This study aims to investigate the fluid dynamics downstream of a dysfunctional bileaflet mechanical aortic valve. A bileaflet ON-X mechanical aortic valve is used with different dysfunctional configurations. In this study, partially and totally blocked configurations of one of the leaflets is investigated relative to its orientation with the sinus of Valsalva. Time-resolved two-dimensional particle image velocimetry measurements are performed to investigate flow field characteristics in the ascending aorta in terms of velocity and vorticity fields and circulation. Vorticity and circulation in the aorta are significantly affected by the valve orientation with respect to the sinus of Valsalva.

**Bileaflet Mechanical Heart Valve; Particle Image Velocimetry; Hemodynamics.**

## I. INTRODUCTION

Heart valve failure is a known cardiovascular disease where valves fail to open or close properly. A report from the American Heart Association mentioned that the prevalence of heart valve diseases in the United States is 2.5% in 2013[1].

Treatment of valvular diseases ranges from adopting healthy lifestyle up to valve replacement [2] which is recommended for severe symptomatic cases.

Bileaflet Mechanical Heart Valve (BMHV) is a preferable choice for valve replacement in young patients because of its

reported longer durability compared to prosthetic biological heart valves (BHV) [3], [4]. However, BMHV can be affected by thrombus or pannus formation [5]–[7]. Thrombosis formation has been shown to be related to non-physiological flow characteristics at the vicinity of the valve leaflets [5], where the shear stress levels may cause blood cell damage that would lead to platelet activation and clot formation [5], [8], [9]. Thrombus formation is more anticipated in BMHV than in BHV [6]. The incidence rate of prosthetic valve thrombus ranges between 0.03%- 5.7% per year [7]. Moreover, its occurrence is as high as 24% within the first year of the valve replacement [7]. This highly anticipated thrombus formation is expected to cause a dysfunction of one or both BMHV leaflets which will inevitably affect the fluid dynamics and hemodynamics in the ascending aorta [5].

Few previous studies investigated the flow past a dysfunctional BMHV. They considered the fluid dynamics and hemodynamics changes induced by the dysfunctional valve. In addition, they investigated the ability of current diagnostic tools to detect BMHV dysfunction.

Smadi et al. [10] first investigated numerically the steady flow through a defective BMHV at different flow and pathological conditions. They reported that Doppler echocardiography assessment of the dysfunctional valve is suboptimal mostly in the evaluation of transvalvular pressure gradients. The same authors [11] further investigated experimentally and *in vivo* the flow downstream of a dysfunctional BMHV. They showed that current clinical guidelines cannot accurately detect the presence of a dysfunctional BMHV and suggested new clinical parameters. Finally, Shahriari et al. [12] investigated numerically the shear stress accumulation on blood components in a dysfunctional BMHV by using smoothed particle hemodynamics. Their study was the first using a fully mesh-free method to cardiovascular flows. They reported that a dysfunctional BMHV leads to significantly more damage to blood components compared to a normal valve.

In the previous studies, the orientation of the dysfunctional leaflet with respect to the sinus of Valsalva (SV) was not investigated. Despite the fact that bileaflet valves are usually installed with one leaflet facing one sinus and the other leaflet being shared by the other two sinuses [13]–[16]. This is an important issue since the development of the sinus vortex (washout vortex) and the coronary flow are both linked to the leaflet position relative to the sinus [5], [17]–[19]. Therefore, it is important to investigate the direct impact of BMHV dysfunction on flow characteristics downstream of the valve but also in the sinus region. This study aims to investigate experimentally using time-resolved two-dimensional (2D) particle image velocimetry the effect of a dysfunctional BMHV on flow characteristics in the ascending aorta.

## I. METHODOLOGY

### A. Silicone molding

An anatomically accurate aorta, left atrium and a simplified symmetric left ventricle are constructed using silicone molding. The molding process is done by adding a silicone rubber base to a curing catalyst (XIAMETER RTV-4234-T4 Base and XIAMETER T4/T4 O Curing Agent), with a ratio of 10:1 by mass respectively. The cured silicone has a Young modulus of 1.675 MPa. The silicone is coated on a three-dimensional printed core mold of the parts. Four layers are coated, then, the parts are mounted to a rotating arrangement (speed of rotation=10 rpm) to ensure a homogenous distribution of silicone over the core mold surface. The final thickness of the silicone layers ranges between 2-3 mm.

### B. In vitro left heart simulator

The left heart is assembled and mounted to a custom-made double activation *in vitro* heart simulator which is shown in Fig.1. The heart simulator has an activation box where the left ventricle is placed. The activation box is made of plexiglass (with index of reflection = 1.49) which is filled with blood mimicking fluid and is connected to a cylinder which contains a compliance chamber to adjust the left ventricle compliance. A piston is sliding inside the cylinder to transfer the stroke from a linear motor to the left ventricle. Above the activation box, both aorta and left atrium are connected to the left ventricle. The aorta is placed inside a plexiglass box and is connected to the top of the open reservoir. The four pulmonary veins branching from the left atrium are all connected to the bottom of the reservoir. On the system, the left atrium is also activated by using a cam-follower arrangement mounted on a servomotor which transfers its motion to the left atrium. Both linear and servomotor are controlled with custom-made LabView interface which controls the timing and stroke of both motors. The liquid used is a mixture of water/glycerol with a volumetric ratio of 60% / 40%, respectively. The mixture has an index of reflection = 1.4 at 20°C, while its dynamics viscosity is = 4 cP at 23°C and its density is = 1080 kg/m<sup>3</sup>. The flow rate is recorded for each case by using a magnetic inductive flow sensor with a flow range from 0.03-6.6 g/min and with a resolution of 0.01 g/min (Prosense FMM50-102, Germany), while the pressure is recorded by using a fiber optic

pressure sensor with a pressure range up to 300 mmHg and with a resolution of <0.3 mmHg (FISO FOP-M260, Canada).

### C. Mechanical aortic valve

The mechanical aortic valve used in this study is a bileaflet mechanical heart valve (On-XA-25, (manufactured by CryoLife, Inc, GA, USA)) with an inside diameter of 24.9 mm. The valve is assembled and placed inside the aorta model. The leaflets orientation relative to the sinuses of Valsalva is selected based on previous studies [13]–[16].

The investigated dysfunctional cases are summarized in Table 1. In order to induce partial valve leaflet dysfunction, a plastic wire of 0.7 mm diameter is placed at accurately

calculated positions relative to the leaflets to work as an obstacle to leaflet opening. The level of leaflet dysfunction is confirmed by analyzing the opening angle of each leaflet and comparing it to the reported values by the manufacturer. The small sized plastic wire has the advantage of not interfering with the flow upstream of the valves. Complete valve leaflet dysfunction cases (C and D) are achieved by gluing the leaflet with the valve's inner casing.

### D. Particle image velocimetry measurements

Time-resolved 2D Particle image velocimetry (PIV) measurements are carried out using a YLF laser with a 10mJ output energy at 1kHz at 527nm wave length (Litron Laser, UK). The laser sheet is placed as shown in Fig. 2. Images are captured using a Phantom V9.1 high speed camera with 1000 fps at a full resolution of 1632x1200 pixels (Vision Research, Inc., USA). Both laser and camera are controlled using a high-speed controller (Lavision GmbH, Germany). The number of recorded frames is 400 and the recording duration is 1s. The fluid inside the heart simulator is seeded with polyamide seeding particles with a mean particle diameter of 50 µm and an index of reflection of 1.5 (Dantec Dynamics A/S, Denmark).

Each captured frame contains two pairs of images where the time interval  $\Delta t$  between the two pairs is 600µs for cases N, B, and C, while  $\Delta t$  is 400 µs for A, D, and E.

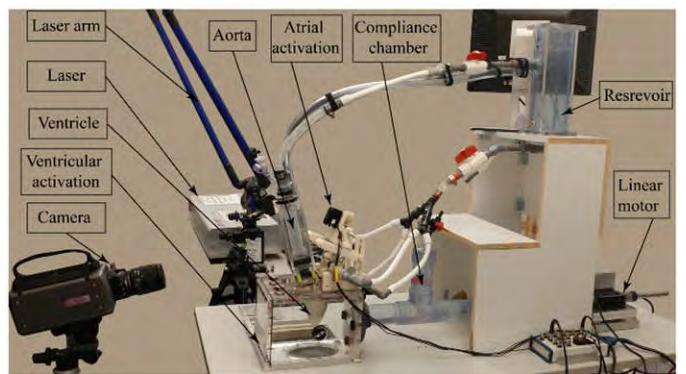

Figure 1 Experimental setup showing the camera, the laser, and the custom-made heart simulator components.

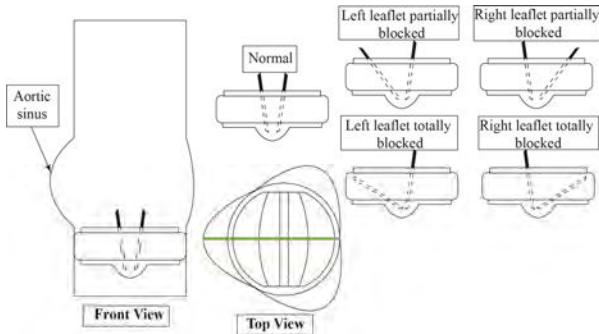

Figure 2 Front and top views of aorta showing the position of the aortic valve and the leaflets orientation with respect to the sinuses of Valsalva, beside the different dysfunction configurations of valve's leaflets. In the top view, green line represents the particle image velocimetry measurement plane.

TABLE I. SUMMARY OF INVESTIGATED CASES AND MAXIMAL VELOCITY RECORDED AT THE PEAK OF SYSTOLE

Symbol	Case	Dysfunction (%)	Maximum flow velocity (m/s)	Percentage of velocity increase relative to normal operation (%)
N	Normal	Null	1.26	Null
A	Left leaflet partially dysfunctional	40-45%	1.41	11.9%
B	Right leaflet partially dysfunctional	40-45%	1.39	10.3%
C	Left leaflet totally dysfunctional	100%	2.37	88.8%
D	Left leaflet totally dysfunctional	100%	2.48	96.8%

The difference in the time interval between the investigated cases is due to the difference in the expected maximum flow velocity and to fulfill the requirements of the “1/4th law”

DaVis 7.2 software (Lavision GmbH, Germany) is used to post-process the recorded images where it calculates the velocity vectors from the raw images by using a fast Fourier transform cross-correlation with an initial 64x64 squared interrogation window (with three passes) with 50% overlap down to a 32x32 circular window (with two passes) with 50% overlap. A linear filter is then being applied to filter the noisy vectors.

A trigger is used between the heart simulator and DaVis7.2 so that each recording starts at the same time during the cardiac cycle (start of left ventricle systole). The recording is taken after 20 cycles lapse to ensure that the flow has reached its normal operation conditions.

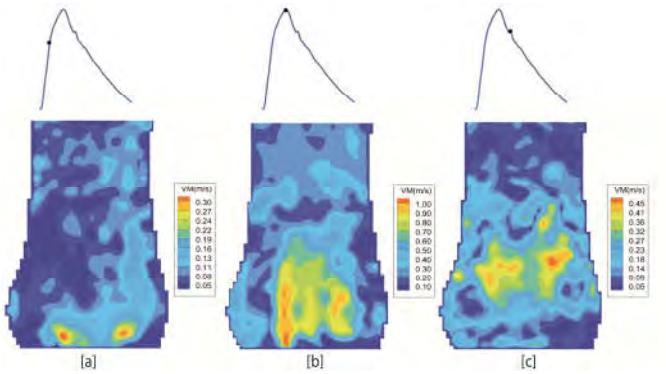

Figure 3 Velocity contours for normal case at different instants, [a] when the leaflets open, [b] at the peak of systole, [c] when the leaflets close.

## II. RESULTS

### A. Velocity field downstream of the BMHV

The maximal velocity at the peak of systole is summarized for all cases in TABLE I. Figure 3 shows the velocity contours at the measurement plane at different phases during the cardiac cycle for the normal case. The normal maximum velocity for the valve is consistent with the reported values in [8], [17] by taking into consideration that the mean flow rate in this study is 3.8 l/min. The velocities are much higher for the totally blocked cases which is directly related to the reduction in the effective orifice area (EOA) of the valve. The velocities obtained for cases C and D also agree with the values reported by [2].

### B. Vorticity and circulation

To evaluate the effect of valve dysfunction on the flow field in the ascending aorta, vorticity contours are shown in Fig. 4 for each case at the peak of systole. The vorticity is calculated using (1), using a 4<sup>th</sup> order compact Richardson scheme:

$$\omega_z = 0.5(\delta v / \delta x - \delta u / \delta y) \quad (1)$$

where  $\omega_z$  is the vorticity in z plane,  $\delta v / \delta x$  is the derivative of y-velocity component in x direction, and  $\delta u / \delta y$  is the derivative of x-velocity component in y direction.

In the normal case, vorticity values in both directions are almost the same despite a higher value at the left side.

For a dysfunctional left leaflet or totally blocked (cases A, C), higher negative vorticity values are noticed, however the positive vorticity (counter clockwise rotation) dominates the measurements plane as shown in Fig. 4 a, b. The opposite behavior is noticed when the right leaflet is blocked, where clockwise rotation (negative sign vorticity) dominated the flow field as shown in Fig. 4 c, d. Therefore, the magnitude and distribution of circulation regions inside aorta is dependent on the position of the blocked leaflet.

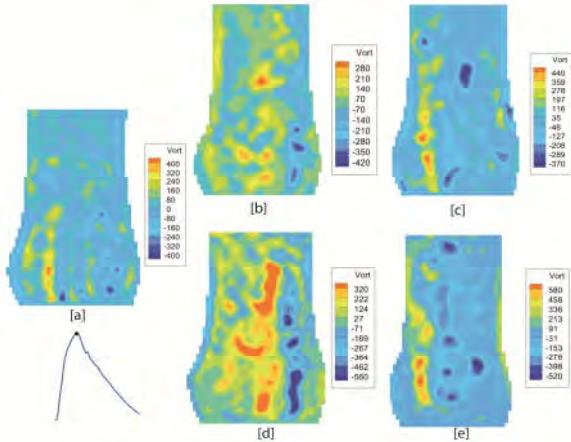

Figure 4 Vorticity contours ( $1/s$ ) at the peak systole for [a] normal case, [b] left leaflet partially blocked, [c] right leaflet partially blocked, [d] left leaflet totally blocked, and [e] right leaflet totally blocked

Circulation,  $\Gamma$  is calculated by integrating the vorticity over the 2D area in the sinus of Valsalva (SV) using (2) and is plotted against time for all cases as shown in Figure 5.

$$\Gamma = \iint_{A(x,y)} \omega_z dx dy \quad (2) [20]$$

As shown in Fig.5, circulation magnitude and direction inside the SV is dependent on the position of the blocked leaflet relative to the SV. In the normal case, the circulation inside the SV is positive during systole. When the right leaflet is blocked, positive circulation is also noticed in both B and D, however at A when the left leaflet is partially blocked, we still can notice a positive circulation which is of a lower value compared to the normal case N. Case C caused a negative circulation inside the SV, which is also noticed to be lower in magnitude compared to case D.

The effect of circulation inside the SV has been reported to be related to coronary flow and to wall shear stresses by [18], [19]. Cao and Sucosky [19] described the interaction between the circulation inside SV and the coronary flow. While Stein et al.[18] noticed that the function of SV is to reduce turbulence near the entry of the coronary artery. Therefore, future studies have to investigate the impact of BMHV dysfunction on coronary flow circulation.

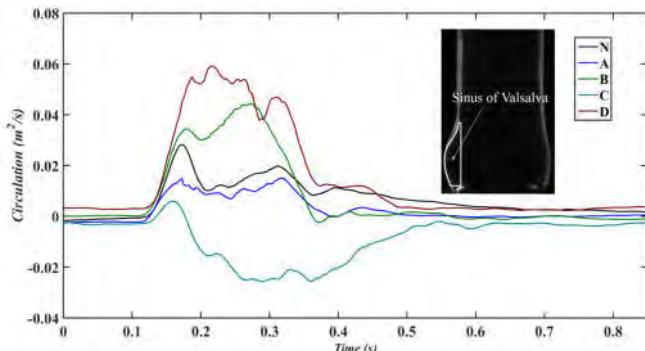

Figure 5 Temporal evolution of circulation for (N) Normal case, (A) left leaflet partially blocked, (B) right leaflet partially blocked, (C) left leaflet totally blocked, and (D) right leaflet totally blocked- over the 2D area of the sinus of Valsalva (in white).

### III. LIMITATIONS

In this study, time-resolved 2D PIV measurements are performed while the flow pattern is expected to be of a 3D nature. Time-resolved 3D PIV measurement is one of our recommendations for future studies. Another limitation is using only one type of BMHVs. Future studies have to consider testing other types of valves and different valve sizes.

### IV. CONCLUSION

In this study we investigated the fluid dynamics downstream of a dysfunctional bileaflet mechanical aortic valve. An ON-X BMHV is used with different dysfunctional configurations. Both partially and totally blocked leaflet configurations are investigated relative to the orientation with the sinus of Valsalva. Time-resolved 2D particle image velocimetry measurements are performed to determine the flow field characteristics in the ascending aorta. Vorticity and circulation inside the aorta is significantly affected by the valve orientation with respect to the SV. The magnitude and direction of flow circulation inside the SV were also affected by the position of the dysfunctional leaflet relative to the SV. This observation should be considered in future studies dealing with the flow dynamics downstream of dysfunctional BMHVs. Further studies are required to fully understand the effect of a dysfunctional leaflet on flow topology and stability.

**Abstract**—An experimental study of cough airflow fields produced by subjects who had influenza-like illness was conducted. Particle image velocimetry (PIV) and hot wire anemometry (HWA) measurements were taken in the far-field downstream of the mouth of a participant. Droplet sampling was performed at two locations within a large cough chamber, and a nasal swab confirmed the presence of an infection. The present work analyzes data from two separate cohorts, and modest differences were observed between coughs from sick and convalescent participants. The results are also compared to data obtained from a large eddy simulation (LES) which seeks to model the transient behaviour of a human cough.

## I. INTRODUCTION

Surprisingly little is known about the mechanism of respiratory virus transmission and the dispersion of viral bioaerosols, even though such information is critical in healthcare settings during viral outbreaks. Presumed safe separation distances are not based on scientific evidence, yet there is a widespread adoption of the “3ft/1m rule” and the “6ft/2m rule” [1]. Several studies have conducted measurements of cough strength at the mouth and in the near-field region ( $x < 60$  mm downstream) [2-7], but such small separation distances between people are atypical and so significant experimental data in the far field region ( $x \geq 1\text{m}$ ), while lacking, could provide useful information in the development of infection prevention measures and protocols.

The current project seeks to (1) Assess the “3 ft/1m rule” by analyzing velocity measurements taken 1m downstream, (2) Estimate and quantify the exposure to airborne viruses and (3) develop a computational fluid dynamics model of cough flow and particle transport based on Large Eddy Simulation (LES) [8,9]. The objective is to recruit 50 participants, naturally infected with influenza, conduct laboratory experiments when they are presumed ill (“sick trials”) and to repeat the experiments later when they have recovered (“convalescent trials”). The project also aims to recruit a reference cohort of up to 50 healthy volunteers. Participant recruitment and data analysis will

continue throughout 2018, therefore, the current paper represents a preliminary report.

## II. METHODOLOGY

### A. Experimental facility (*The FLUGIE cough chamber*)

The Fluids from Undergraduates Influenza Enclosure (FLUGIE) consists of a 1.81m x 1.78m x 1.81m rectangular wooden box (Fig. 1). A pear-shaped opening allows the participant to cough into the chamber with their nose and mouth unobstructed, while a padded head rest and chin rest ensure that the position of participant’s head remains constant between individual trials. The walls of the chamber are painted black, except for a glass side wall allowing optical access, and a glass insert on the bottom of the chamber, allowing a thin laser sheet ( $t=1\text{mm}$ ) to pass through base. Titanium dioxide ( $\text{TiO}_2$ ) particles are aerosolized before they fill the chamber for Particle Image Velocimetry (PIV) measurements.

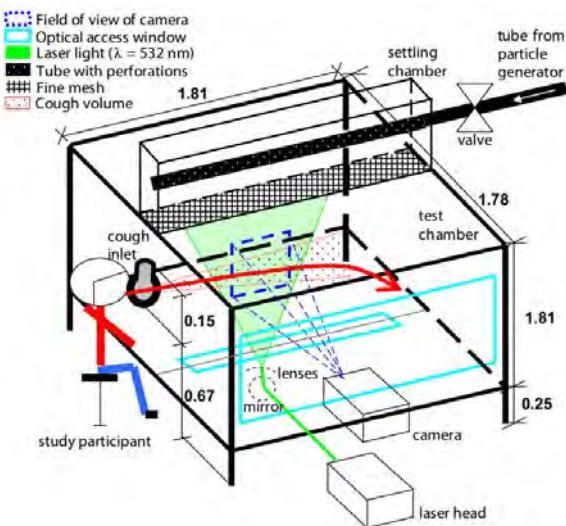

Figure 1: FLUGIE Schematic (All dimensions in m)

## B. Experimental measurements

After the chamber has been seeded with  $\text{TiO}_2$  particles, a double-pulsed Nd-Yag laser, operating at 15 Hz, generates a vertical light sheet. The 120mJ pulses have a duration of 3-5ns, and the camera operates with a PIV exposure of 400us. The measured field of view (Fig. 2) is 0.48m height x 0.89m width, and it is centered 1m downstream from the participant. Image pairs are captured by a CCD camera (TSI Inc) with a spatial resolution of 6.87pixels/mm. Eighty image pairs per cough, are then processed into 102 x 18 vector arrays using Insight 4G software. In separate trials, a single hot-wire anemometer (HWA) probe samples velocity readings at 1kHz, at a location 1m downstream and 0.170m below the inlet centre-line. This probe is calibrated using a separate facility for low air velocity measurements. To assess the presence of viral bioaerosols produced by the violent expiratory events, two low-flow air sampling pumps draw aerosols within the air onto PTFE membrane filters at a constant rate of  $4000 \pm 40\text{mL/min}$ . The membranes are transferred into individual tubes of UTM viral transport medium. A mid-turbinate swab (MTS) is also collected, to identify the pathogen causing the respiratory infection. All of the sampling tubes are shaken by a vortex shaker before they are stored at  $-80^\circ\text{C}$ . The samples are shipped on dry ice and analyzed by the Dept. of Microbiology at Sunnybrook Health Sciences Centre (Toronto).

## C. Procedure

Influenza-infected participants are recruited from the clinic at Western Student Health Services after the physicians determine their symptoms to be consistent with an influenza infection. The recruitment procedures are approved by Western's Research Ethics Board (REB approval no. 108945). The inclusion criteria are: age 18-35 and presenting with fever and cough and/or sore throat in the absence of another known cause of illness (e.g. allergies), while exclusion criteria include: immunocompromised, underlying cardiopulmonary disease, pregnancy and smoking. The referred participant is asked to cough 3 times, while aerosol sampling occurs and hot-wire measurements are recorded. There is sufficient time between

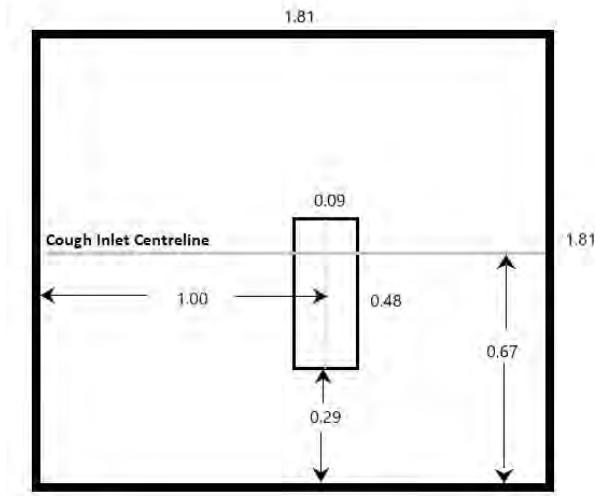

Figure 2: PIV Field of View (All dimensions in m)

trials to ensure that residual air motion within the trials is minimal. The hot-wire and sampling cassettes are then removed from the chamber so that the chamber can be seeded for PIV measurements. This is necessary since the seeding particles would damage the hot-wire upon contact. Three additional coughs are then recorded by the PIV system after an even distribution of particles is present within the chamber. Subjects then self-collect a MTS before the experiments are completed. The participant returns after at least 4 weeks, to repeat the hotwire and PIV measurements in their convalescent state. The same procedure is followed for the healthy cohort, but MTS are not collected, and there is no aerosol sampling. Healthy participants also do not return for a second laboratory visit.

## III. RESULTS AND DISCUSSION

Throughout the 2018 flu season, 7 participants have been recruited to date. From the 7 participants recruited this year, we have collected quality PIV data for 14 coughs. Coughs were excluded from this analysis if the entire width of the expired jet was not contained vertically within the field of view, and if the bulk velocity within the jet was lower than 0.2m/s, since in this scenario, it is difficult to distinguish the jet from ambient fluid motion within the chamber.

Each cough was examined, and boundaries that contain the entire jet were specified. Velocity profiles at the midpoint of these boundaries, where the highest velocities are noticed, were extracted at 1m downstream. Fig. 3 shows these profiles plotted with respect to time. The velocity obtained from the LES simulation is shown on the same plot for comparison. Boundary conditions for the LES were selected according to conditions of a representative cough based on [10]. A mouth diameter of 3cm was specified, with a maximum, transient inlet velocity of 20m/s. The average peak velocity for the PIV results is 1.4m/s, at 1m downstream, which is considerably higher than the 1.1m/s obtained from the LES. The difference may be attributed to the selection of the LES conditions as the average of coughs from 12 female and 13 male participants, whereas the experimental coughs each had different inlet velocities. The presence of

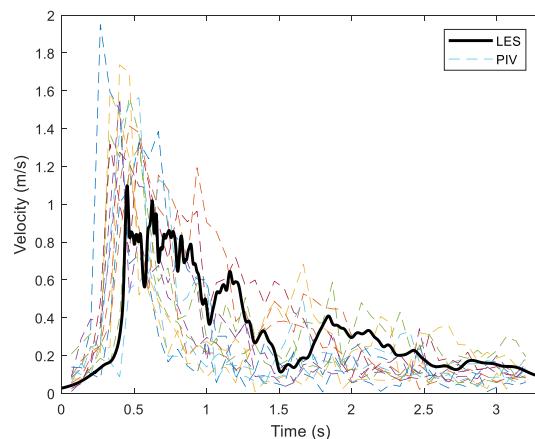

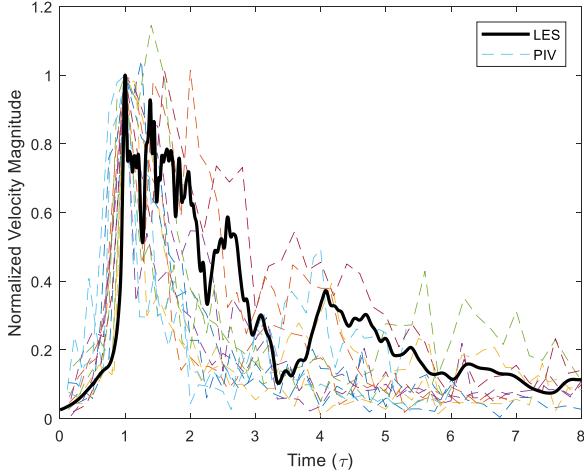

Figure 3: PIV Jet Centre 2D Velocity Magnitudes for Individual Trials

**Figure 4: Normalized Jet Centre Velocities**

several very strong coughs produced by a couple of participants has influenced the mean, and it is believed that as more participants are recruited, the average maximum velocity at this location will more closely align with the LES. The velocity profiles were normalized by the initial peak 2D velocity magnitude ( $\langle V \rangle = \langle V \rangle / \langle V \rangle_{\text{peak}}$ ), and the time that the peak occurs ( $\tau = t / t_{\text{peak}}$ ) (Fig. 4). Following normalization, it may be seen that the LES profile more closely resembles those obtained experimentally, but there are data available for many more time steps within the LES. The LES exhibits a secondary peak, which is observed experimentally as well, but this secondary peak is closer in velocity magnitude to the initial peak, and in some trials, it surpasses the velocity of the first peak. The velocity magnitude within the jet was spatially averaged and normalized (Fig. 5). The plot, again, shows a reasonable agreement between the LES and experimental data, although a large variability was observed experimentally.

In order to obtain a better understanding of the spread, and angle of entry of the studied cough jets, U-component velocity measurements were averaged across all x-values, for each y-value ( $\langle U_x \rangle$ ). These profiles were then normalized by the maximum average U velocity and the time that it occurs (Fig. 6). These directionally-averaged profiles were translated so that the jet was centered on the inlet axis. The average distance that the profiles were translated was 0.179m, indicating that the hot-wire anemometer was appropriately placed to measure velocities at the centre of the jet. An average jet entry angle of 10.2 degrees below the horizontal centreline was calculated from basic trigonometric ratios. Gupta et al. demonstrated that the average cough angle was 40 degrees [10], thus the padded headrest and chin rest successfully reduced the angle, so that the cough enters the chamber roughly horizontally.

The hot-wire data obtained from this cohort requires further analysis before the results can be presented, but hot-wire data was collected from 9 subjects who were recruited during the 2017 flu season. From these, 4 subjects had laboratory confirmed illnesses from the MTS results. Considering the recruitment methods, this is overall a good result. While the other 5 participants exhibited influenza-like symptoms, they might have had bacterial infections like pneumonia or

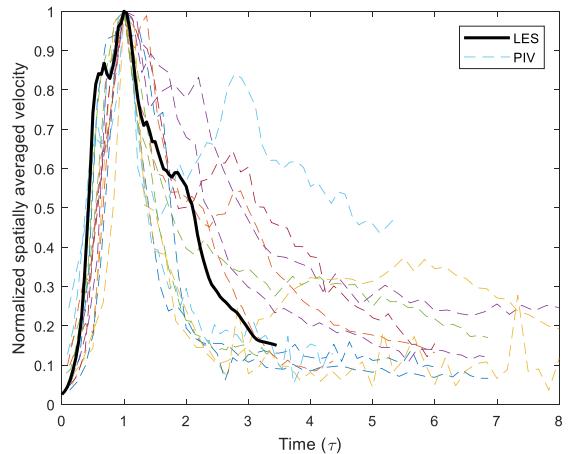

streptococcus, although the presence of these infections was not assessed. The four etiological agents that were found were: coronavirus (CoV) NL63, CoV OC43, Influenza A (H3N2) and respiratory syncytial virus (RSV). Typical velocity time histories are shown for one participant in Fig. 7. The coughs were processed using a moving average filter, with a window size of 299 samples (0.299s), so that residual turbulence fluctuations could be separated from the mean cough speed. The peak moving average cough speeds were ranked (Fig. 8), and negligible far field velocities were obtained for about a third of the coughs, in both the sick and convalescent cases. Fig. 9 shows the cumulative average of peak moving average velocity and turbulence intensity of coughs ordered from smallest to largest. The results show that for this cohort, convalescent coughs were slightly stronger but a minimal difference in turbulence intensity was noticed.

#### IV. CONCLUSION

At the time of writing 44 participants have been recruited since the study began in 2014. Of these 44, 21 have exhibited influenza-like symptoms and were included in the “sick” cohort. Altogether, HWA data were collected for 48 “sick” coughs, 24 “convalescent” coughs, and 33 “healthy” coughs. PIV data were collected for 29 “sick” coughs, 9 “convalescent” coughs and 15 “healthy” coughs, though much of the data requires further analysis, and were not included in the present paper. MTS and filter cassettes from the most recent cohort of “sick” participants will soon be assessed for viral content. When comparing the preliminary data with the LES model there is reasonable agreement. As more data are collected, it is expected that the agreement will improve, and that it should then be possible to better quantify the differences between coughs from sick and healthy subjects.

**Abstract**— Characterization of human brain material properties in the form of computationally feasible mathematical models is a complex problem; especially when the models are used in complicated Finite Element simulations. Various models have been proposed to include the tissue's hyper-viscoelasticity, most of which are quite complicated and therefore only suited to Software-based Finite Element methods. Use of linear material models simplifies the problem and saves much time and effort, allowing the researcher to verify the results of more sophisticated models with lower computational cost. However, the preciseness of the results from such models is subject to special conditions. This study proposes and validates a Generalized Maxwell linear viscoelastic model with five constants to be used as an acceptable computational method to simulate brain's viscoelastic behavior at low strain rates. To this end, an explicit numerical integration scheme is used to simulate the single-DOF tissue response with a Generalized Maxwell viscoelastic model. Using the material constants of a previous hyper-viscoelastic model, the results are compared with those obtained from a previous experiment. The comparison shows that the linear GM viscoelastic model is predicting the low-strain-rate behavior of the brain tissue with acceptable error.

**Keywords-** Viscoelasticity; Finite Element; Generalized Maxwell, Linear Viscoelastic Model; Strain Rate

The head is often considered as the most critical region of the human body for life-threatening injuries as result of accidents. The cost incurred by the accidents is estimated to be 160 billion Euros per year in the European Union alone [1]. In a 6-year period, an average of 1.4 million cases of traumatic brain injury occurred in the United States each year, of which 20% resulted from motor vehicles accidents. In order to develop effective protective measures, a better understanding of the process of injury development in the brain is required. [2-5]

Over the past three decades, several researchers have investigated the mechanical properties of brain tissue in order to establish constitutive relationships over a wide range of loading conditions. In experimental methods, dynamic oscillatory shear tests [4,8,9] and unconfined compression tests [10] have been conducted more frequently. The resulting constitutive models have been introduced in Finite Element (FE) analyses to simulate the actual response of the tissue to external stimuli. Among these modes, most of them use hyper-viscoelastic constitutive material assumption which, when combined with the complex geometry of brain parts, lead to complicated analyses [11]. The nonlinearity included in such models may lead to distorted results if the convergence problem is not handled. Therefore, simpler linear models such as the one presented here can serve as useful tools for verification of these models.

In current FE head models, brain tissue is commonly assumed to display hyper-viscoelastic material behavior. The tissue behaves like a non-linear viscoelastic solid for shear strains above 1%. The modelling of the tissue behavior with these assumptions leads to somewhat more accurate results than linear models. However, it maintains the big drawback of high

## 1- INTRODUCTION

computational cost and time-consuming nature of these constitutive nonlinear models. [5, 6, 12]. Simpler computational frameworks such as the one presented herein serve as useful tools for engineering approximations of the resulting values of stress and strain fields.

This study seeks to investigate the extent of validity of a linear viscoelastic numerical model for modelling the response of the brain tissue to single-DOF loading-unloading cycles of shear strain. In order to evaluate the model, the results are compared, on various levels, with those of an experimental study.

## 2- METHODOLOGY

### 2-1- Derivation of Mathematical Models

#### Generalized Maxwell Model

In order to derive a computational framework for solving the Generalized Maxwell (GM) model (figure 1), one may derive the equation for a single mode spring and damper in series and then sum over the number of modes. The effect of infinity spring is finally added to complete the model.

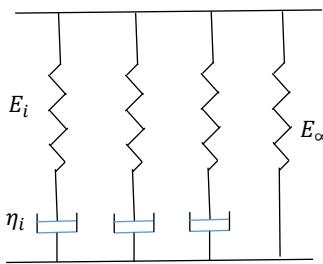

Figure 1- The Generalized Maxwell (GM) model for viscoelastic materials.  $E_i$  and  $\eta_i$  are serial spring and damping constants and  $E_\infty$  is the parallel spring constant

Considering a single mode spring and damper in series and the infinity spring in parallel, the stress can be written in terms of strain and strain rate in the following form,

$$\sigma(t) = E_\infty \epsilon(t) + \sigma^* \quad (1)$$

where

$$\sigma^* = \eta \frac{d\epsilon^*}{dt} \quad (2)$$

Solving and integrating the equation above for  $\epsilon(t)$ , the integral equation for two consecutive steps is obtained in the following form,

$$\sigma_{n+1}^* - \sigma_n^* = \frac{-1}{\lambda} \int_{t_n}^{t_{n+1}} \sigma^*(t) dt + E(\epsilon_{n+1}^* - \epsilon_n^*) \quad (3)$$

Considering that the integral is from  $t_n$  to  $t_{n+1}$ , it's possible to approximate it using Implicit or Explicit method (Forward Euler and Backward Euler)

Substituting,

$$\sigma^*(t) = E\epsilon(t) - y(t) \quad (4)$$

Where,

$$\frac{dy(t)}{dt} = \frac{-1}{\lambda} y(t) + \frac{E}{\lambda} \epsilon(t) \quad (5)$$

An explicit numerical method can be obtained to approximate the integral in the following form:

$$\sigma_{n+1}^* = e^{\frac{-\Delta t}{\lambda}} \sigma_n^* + e^{\frac{-\Delta t}{\lambda}} E \Delta \epsilon_n \quad (6)$$

Now one can add the effects of all the parallel units the single-mode model.  $\sigma_n^*$  is calculated for each unit and finally summed to obtain the total  $\sigma^*$ .

$$\sigma^* = \sigma_1^* + \sigma_2^* + \dots + \sigma_n^* \quad (7)$$

The total  $\sigma^*$  is subsequently added to the effect of infinity spring to yield the total stress by substituting into equation 1. In the above equations, n is the order of GM model denoting the number of parallel modes. Time constants need to be calculated for every parallel Maxwell unit and considered separately in the corresponding stress update algorithm:

$$\lambda_i = \frac{\eta_i}{E_i} \quad (8)$$

### 2-2- Application of Load

Two load scenarios were considered as input, namely Load Scenario A and Load Scenario B. The load scenarios were chosen to replicate a previous experiment on samples from human head (Ref [4])

#### 2-2-1- Load Scenario A

In this load scenario, triangular pulses with constant strain rate of 1.5 /s were applied to the viscoelastic single-dimensional model. The input pulses were obtained from [4] and simulated as triangular pulses (Fig. 2). The strain was applied as input by using explicit finite difference method with 600 steps and time constant of 1.1s. The strain rate was kept constant at the value of 1.5/s (Table 1).

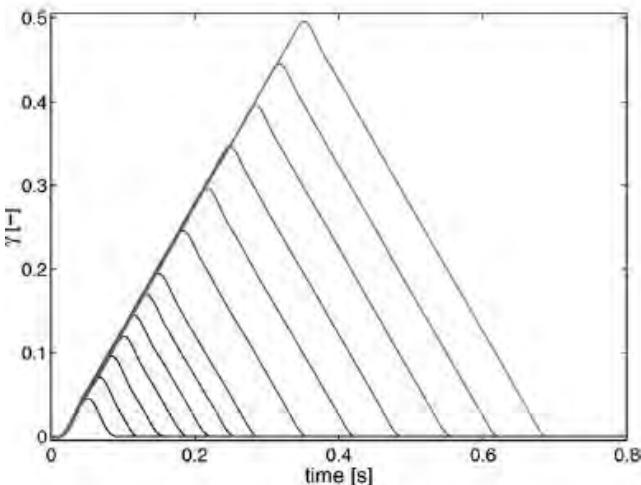

Figure 2- Triangular pulses (constant shear rate in loading and unloading) of Scenario A [4]

Table 1- Characteristics of the Triangular pulses of Scenario A [4]

Pulse number	Max. Strain	Pulse Duration (s)	strain Rate (/s)
1	0.05	0.06	1.50
2	0.10	0.13	1.50
3	0.15	0.20	1.50
4	0.20	0.26	1.50
5	0.30	0.40	1.50
6	0.50	0.66	1.50

## 2-2-2- Load Scenario B

In this load scenario, triangular pulses with various strain rates of 1 /s, 0.1 /s and 0.01 /s were applied to the viscoelastic single-dimensional model. Table 2 shows the characteristics of the input strain pulses applied to the computational model.

Table 2- Characteristics of the Triangular pulses of Scenario B

Pulse number	Max. Strain	Pulse end time (s)	Strain rate (/s)
1	0.1	0.2000	1
2	0.1	2.0000	0.1
3	0.1	20.0000	0.01

## 3- Material constants

For the 5-branch GM linear viscoelastic model, 5 sets of material data including the instantaneous and equilibrium shear moduli, time constant, and viscous damping coefficient was

obtained from Ref [4]. The input data was included in the GM model in the form of Prony Series (Table 3)

Table 3- constants of the GM model obtained from curve-fitting of a hyper-viscoelastic model on the experimental results of Ref [4]

GM Mode Number	G (Modulus) (Pa)	$\tau$ (time constant) (S)	$\eta$ (Viscous damping coefficient)	$G_e$ (Equilibrium Modulus) (pa)
Mode 1	835.50	0.012	10.02	182.90
Mode 2	231.20	0.35	80.92	182.90
Mode 3	67.10	4.62	310.00	182.90
Mode 4	3.610	12.13	43.68	182.90
Mode 5	2.79	54.31	151.49	182.90

## 4- Results

The results of the application of nine strain pulses from two scenarios to the GM model are shown in figures 3 and 4. Fig. 3 indicates the resulting stress from input strain of load scenario A with constant strain rate, and Fig. 4 shows the effect of changing the strain rate (load scenario B)

In all calculations, in order to reach better convergence and considering a recovery time as two times a full pulse, explicit algorithm has been used with 600 steps.

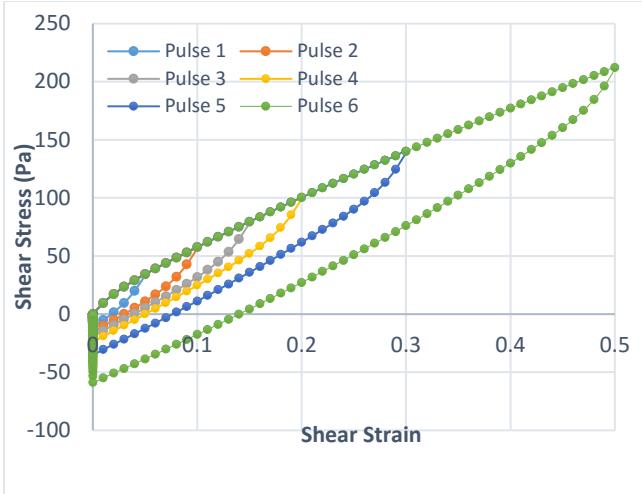

Figure 3 -Stress-Strain results obtained from applying the input pulses of Scenario A to the Generalized Maxwell Model (5 branches)

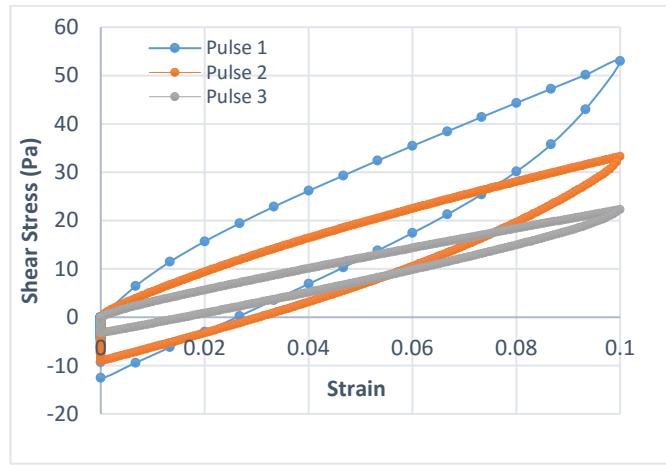

Figure 4 -Stress-Strain results obtained from applying the input pulses of Scenario B to the Generalized Maxwell Model (5 branches)

#### 4- Discussion of Results

Nine input strain pulses were applied to a single-DOF linear GM viscoelastic model in two load scenarios. The resulting stress was calculated by using a finite difference integration scheme and plotted against the stress for all pulses (Fig. 3, 4). The input strain and material constants were obtained from curve-fitting of a hyper-viscoelastic model on a set of experimental curves from the literature [4].

The results from the application of the same load pulses in the referenced experiment are shown in Fig 5 and 6. As it can be observed, the Generalized Maxwell of order 5 shows acceptable

qualitative agreement with those of the experiment. As it was predicted, the similarity of the trends is more noticeable at lower strain rates. The relative error at the end of the loading cycle (i.e. at maximum strain) for pulse 3 is 3% with respect to the experimental value. This can be observed by comparison of Fig. 3 and 5. The linearity of the model leads to differences with the experimental results which are more pronounced at higher input strains and strain rates. At the strain of 0.5, the result of stress shows 10% deviation from the experimental results (pulse 6 from load scenario A). In addition, the quantitative comparison of the results reveals the incapability of the linear model in prediction of the material behavior at high strain rates and high strains (by comparison of the stress in pulse 1 from scenario B and the corresponding curve in Fig. 6). At the strain rate of 0.1/s and strain of 0.1, the relative error of the linear model with respect to experiment results is 33% which is more than the one reported by the hyper-viscoelastic model of reference [4] (21%).

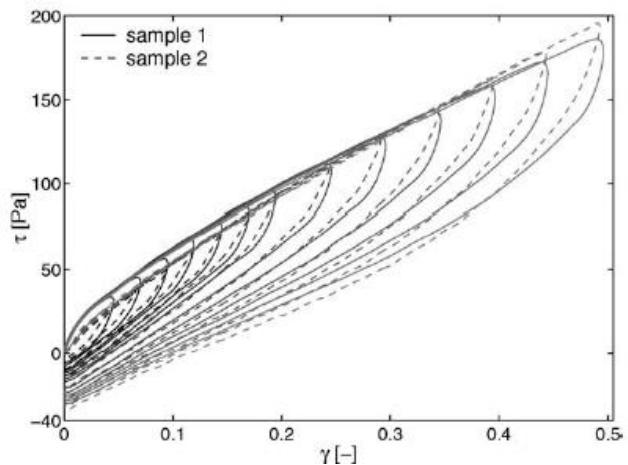

Figure 5 -Stress-Strain curve (Curve-fitted) obtained from applying the input pulses of Scenario A (constant shear rate) in the experiment of Ref [4] for two samples.

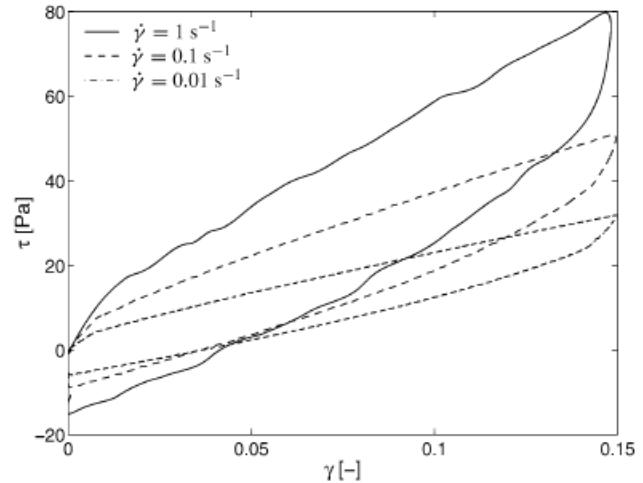

Figure 6 -Stress-Strain curve obtained from applying the input pulses of Scenario B (constant shear rate) in the experiment of Ref [4]

## 5- Conclusions

In this study, a linear viscoelastic model was used to assess the capability of linear computational models to model the complex behavior of brain material. 9 input strain pulses were replicated from a previous experiment and applied to the model and the resulting stress was compared with the ones reported in the literature.

It was observed that the results of our model show good qualitative agreement with those of the experiment. In terms of quantity, however, the agreement of the results is restricted to lower strain values and strain rates. Also, the impact of strain rate on the difference seems to be more noticeable than the absolute value of strain input. However, it seems that the mentioned deviation does not justify using a nonlinear hyper-viscoelastic model in some studies instead of a linear viscoelastic one which is simpler and has a lower computational cost. It should also be noted that, in order to use the linear viscoelastic model, the parameters of the model must be obtained through direct comparison with experimental results, which may lead to improvements in the accuracy of the present model.

Finally, the comparison of the results reveals that the linear model, although not capable to fully trace the hyper-viscoelastic nature of the phenomena, displays a maximum relative error of 10%, which can be justified given the lower computational cost. This can especially be useful in real-time simulations of surgical procedures, tumor growth and other applications involving change in brain tissue with low strain rates. The GUI used in this study to simulate and obtain the results can be an example of a useful tool for such applications (Figure 7).

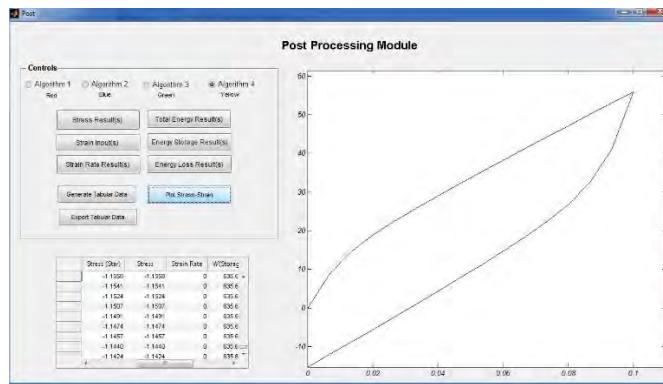

Figure 7- Stress-strain result of the application of pulse No. 2 from Scenario B to the model and visualization of the results via Matlab GUI. The GUI was developed based on the calculations presented in this paper to better visualize the results.

**Abstract**—Vibration isolation is one of the most prominent characteristics of elastic metamaterial with negative effective mass. In this work, we show that a carbon nanotube filled with a linear mass chain can behave like an elastic metamaterial with negative effective mass density and exhibit remarkable vibration isolation phenomena within a certain frequency range.

**Keywords** - carbon nanotube; metamaterial; negative effective mass; mass chain; vibration isolation.

## I. INTRODUCTION

Elastic metamaterials characterized by negative effective mass and/or negative effective modulus have attracted considerable attention [1-3]. It has been shown that the negative effective mass/modulus of elastic metamaterials are essentially attributed to their internal degrees of freedom, particularly so-called “locally resonant” microstructure [4, 5]. Inspired by an idea that a carbon nanotube (CNT) filled with a mass chain [6-8] could offer an already fabricated and available metamaterial with locally resonant microstructure, the present work aims to investigate filled carbon nanotubes as a potential new kind of elastic metamaterials. Unlike the known elastic metamaterials proposed in literature which are all based on often complicated artificial design of their microstructure, the carbon nanotube-based metamaterials proposed in the present work can exhibit negative effective mass and achieve desirable metamaterial dynamic properties even without any artificial design of their microstructure.

## II. CONTINUUM MODELING

Fig.1 shows the schematic of a single-walled CNT filled with a linear C-chain. The CNT is modeled as an elastic beam of length  $L$ , diameter  $d$ , bending rigidity  $EI$ , mass density  $\rho_1$  and cross section area  $A_1$ . The inserted C-chain is treated as an elastic string of mass density  $\rho_2$  and cross section area  $A_2$  but with no meaningful bending rigidity. Thus, the coupled governing equations for the filled CNT can be written as [7]

$$EI \frac{\partial^4 w_1}{\partial x^4} + \rho_1 A_1 \frac{\partial^2 w_1}{\partial t^2} = c(w_2 - w_1) \quad (1)$$

$$\rho_2 A_2 \frac{\partial^2 w_2}{\partial t^2} = c(w_1 - w_2) \quad (2)$$

where  $w_1$  and  $w_2$  are the transverse deflection of the CNT and the C-chain, respectively,  $t$  is the time and  $c$  is the van der Waals interaction coefficient (per unit length) between the mass chain and the CNT.

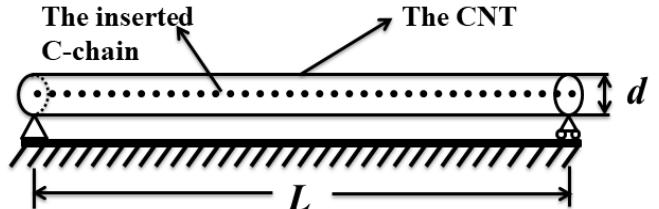

Figure 1 schematic of a single-walled CNT filled with a linear C-chain

Substituting Eq. (1) into Eq. (2), the governing equation of the filled CNT for the deflection  $w_1$  can be obtained as

$$EI \left( 1 + \frac{\rho_2 A_2}{c} \frac{\partial^2}{\partial t^2} \right) \frac{\partial^4 w_1}{\partial x^4} + (\rho_1 A_1 + \rho_2 A_2) \times \left[ 1 + \frac{\rho_1 \rho_2 A_1 A_2}{c(\rho_1 A_1 + \rho_2 A_2)} \frac{\partial^2}{\partial t^2} \right] \frac{\partial^2 w_1}{\partial t^2} = 0 \quad (3)$$

which is of the standard form of dynamic equation for a metamaterial elastic beam with negative effective mass density within a certain range of frequencies. To see this, let us consider a periodic harmonic motion  $w_1(x, t) = f(x) \exp(i\omega t)$ , where  $f(x)$  is the mode shape function,  $i$  denotes the imaginary unit and  $\omega$  represents the frequency. Substituting  $w_1$  into Eq.

(3), the effective mass density of the filled CNT can be obtained as the following form:

$$\rho_{\text{eff}} = \frac{1 - \frac{\rho_1 \rho_2 A_1 A_2}{c (\rho_1 A_1 + \rho_2 A_2)} \omega^2}{1 - \frac{\rho_2 A_2}{c} \omega^2} \rho_{\text{avg}} \quad (4)$$

It is clearly seen that the effective mass density become negative when the frequency is within the bandgap

$$\sqrt{\frac{c}{\rho_2 A_2}} = \omega_0 < \omega < \omega_0 \sqrt{1 + \frac{\rho_2 A_2}{\rho_1 A_1}} \quad (5)$$

It is noticed that the values and order of magnitude of this "metamaterial" bandgap are determined by the van der Waals interaction coefficient  $c$  and the mass of the inserted mass chain, and the bandgap can be wider if the mass of inserted chain is not very small as compared to the mass of the CNT.

### III. FORCED VIBRATION DRIVEN BY PERIODICALLY VIBRATING ENDS

Consider forced vibration of a hinged filled CNT driven by periodically vibrating ends:  $w_l = \delta \sin \omega t$  at  $x=0$  and  $x=L$ , where  $\delta$  is the amplitude of the vibrating ends. The stimulated steady state forced vibration of the filled CNT is of the form

$$w_l(x) = \left( 1 + \sum_{k=1}^{\infty} a_k \sin \frac{k\pi x}{L} \right) \sin \omega t \quad (6)$$

where  $a_k$  ( $k=1, 2, 3, \dots$ ) are some real constants. Substituting Eq. (6) into Eq. (3), and using the Fourier series expansion

$$1 = \sum_{k=1}^{\infty} \frac{2[1-\cos(k\pi)]}{k\pi} \sin \frac{k\pi x}{L}, \quad 0 \leq x \leq L \quad (7)$$

where the coefficients  $a_k$  are to be determined. Thus, forced vibration of the hinged filled CNT driven by two periodically vibrating ends can be evaluated. To demonstrate this, a (5, 5) CNT filled with a linear C-chain is considered. The material and geometrical properties of the CNT are taken as: Young's modulus  $E=1\text{TPa}$ , mass density  $\rho_1=2200 \text{ kg/m}^3$ , and single-walled thickness  $h=0.34\text{nm}$ .

The bandgap of the C-chain filled (5, 5) CNT is  $(\omega_0, 1.05\omega_0)$ , where  $\omega_0$  is the lower-edge frequency=3.09THz. What plotted in Fig. 2 is forced vibrational modes of a C-chain filled-CNT driven by two periodically vibrating ends for excitation frequencies within the bandgap. It is seen that when the excitation frequency is within the bandgap, the forced vibrational mode is highly localized near the two vibrating ends but is vanishingly small in all other parts of the filled CNT, in sharp contrast to other excitation frequencies out of the bandgap for which the forced vibrational mode always spreads into the entire filled CNT. Therefore, a filled CNT indeed exhibits remarkable vibration isolation when it is excited by its periodically vibrating ends.

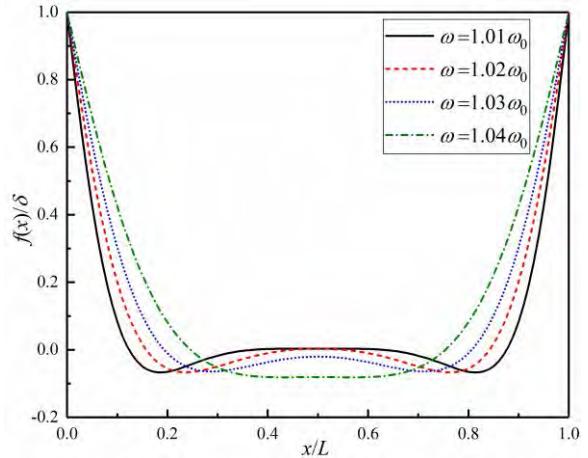

Figure 2 Forced vibrational mode shape of a filled CNT under different excitation frequencies ( $L=10d$ ).

### IV. CONCLUSIONS

A carbon nanotube filled with a mass chain can behave like a metamaterial with negative effective mass and exhibit remarkable vibration isolation within a certain frequency range without any artificial design of their microstructure. When the excitation frequency is within the bandgap, the forced vibrational mode of a filled carbon nanotube driven by periodically vibrating ends is highly localized near the two vibrating ends but is vanishingly small in all other parts of the filled CNT.

# Vibration Control of Downtown Toronto High-Rise Development

Ali Noormohamed, Oya Mercan  
Department of Civil Engineering  
University of Toronto  
Toronto, ON, Canada

Amirahmad Fathieh  
Stephenson Engineering  
Toronto, ON, Canada

**Abstract**—In this industry-academia collaboration, a multi-platform hybrid numerical simulation was performed to assess the effectiveness of a tuned liquid damper (TLD) to be installed in a high-rise condominium located in Downtown Toronto. The structure was modeled using OpenSees, while the nonlinear TLD model was developed in MATLAB. A dynamic analysis was performed using statistically-generated dynamic wind loads. It was determined that the TLD improved the performance of the structure (storey acceleration, roof drift) for various levels of wind loading, improving the comfort of the residents of the building. Minimal benefit was observed for reducing base shear as well as storey shear demands on the structure.

**Keywords**-tuned liquid damper; vibration control; structural control; hybrid simulation; wind engineering

## I. INTRODUCTION

High-rise structures are flexible structures, and are highly sensitive to dynamic excitation – even vibration caused by ordinary wind loading may be problematic from the viewpoint of serviceability and comfort of occupants. Tuned-liquid dampers (TLDs) are passive vibration absorbers which are used to control wind-induced vibrations of tall structures. The TLD's properties are tuned to the system's fundamental oscillation frequency such that the liquids sloshing action dampens the building's oscillations. In this collaboration, a multi-platform tool was developed to accurately and precisely model the components required to understand the structure-liquid interaction. The structure was modeled using OpenSees [1], while the TLD was modeled in MATLAB [2] using Yu's model. Lastly, the dynamic wind loading applied to the structure was developed using NatHaz Online Wind Simulator (NOWS) web-based tool [3]. The details of each portion of the multi-platform tool are given below.

## II. DEVELOPMENT OF MULTI-PLATFORM TOOL

### A. Structural Model

OpenSees, an object-oriented open source software framework, was used to model the tower. The structural model which was developed for the central tower of the 90 Harbour Street development from the 6th storey upwards – since the podium levels and underground parking garages are shared between the two towers, they were assumed to provide a rigid

base for each of the individual towers. As such, the base nodes of the structure were modeled as fixed nodes in OpenSees.

The structure was modeled using fibre section elements, wherein the sections were varied based on cross-sectional area, level of horizontal and vertical reinforcement, and concrete strength. Due to the complexity of the structure, and the large number of individual element properties to consider, the tower was split into seven categories (by storey), varying along the height of the structure. The individual member properties were assumed to remain constant in each section of the building.

Lastly, the floor slabs were not modeled directly in OpenSees. Rather, they were assumed to provide a rigid support at each floor level. The EqualDOF command in OpenSees was used, wherein each node at a given floor level is forced to have the same displacements as the designated master node at that floor. While the structural properties of the floor slab were not modeled, the mass of the slabs was still accounted for, with the mass being distributed to the nodes by tributary areas.

### B. TLD Model

TLDs dissipate energy through liquid boundary layer friction, free surface contamination, and wave breaking. With the horizontal component of the liquid velocity related to the wave motion, wave crests descend as amplitude of motion increases, and simple linear models are no longer adequately able to describe the liquid behaviour [4].

1) *Theory of Yu's Model*: Using shallow water wave theory, the TLD can be modeled as an equivalent nonlinear-stiffness-damping (NSD) system [5][6]. The behaviour of the NSD system is matched to that of the real TLD using an energy dissipation matching procedure, where the NSD parameters  $m_d, c_d, k_d$  are determined by introducing the interaction force created by the TLD liquid sloshing inside the tank.

The energy dissipation inside the tank can be found using

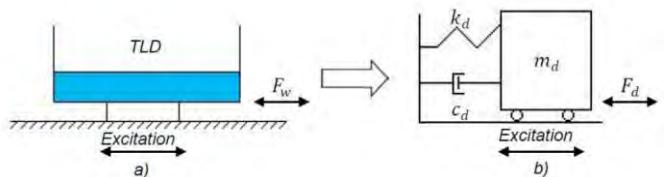

Figure 1: Schematic representation of (a) TLD and (b) equivalent NSD model.

$$E_w = \int_{T_s} F_w dx \quad (1)$$

where  $F_w$  is the force generated by the liquid sloshing inside the tank. The non-dimensionalized energy can be determined:

$$\dot{E}_w = \frac{E_w}{0.5m_w(A\omega)^2} \quad (2)$$

The non-dimensionalized energy dissipation parameter for the NSD model is determined using the behaviour when subjected to base excitation with frequency  $\beta$ :

$$\dot{E}_d = 2\pi|F_d| \sin \theta \quad (3)$$

where the non-dimensionalized magnitude  $|F_d|$  and phase angle  $\theta$  can be found using:

$$|F_d| = \frac{\sqrt{(1 + (4\zeta_d^2 - 1)\beta^2)^2 + 4\zeta_d^2\beta^6}}{1 + (4\zeta_d^2 - 2)\beta^2 + \beta^4} \quad (4)$$

$$\theta = \tan^{-1}\left(\frac{2\zeta_d\beta^3}{-1 + (1 - 4\zeta_d^2)\beta^2}\right) \quad (5)$$

where  $\zeta_d = \frac{c_d}{c_{cr}}$  is the damping ratio of the NSD model. The non-dimensionalized energy dissipation parameters are matched together using a least-squares method, analyzing the results through two parameters: the frequency shift ratio  $\xi = \frac{f_d}{f_w}$  and the stiffness hardening ratio  $\kappa = \frac{k_d}{k_w}$ . The frequency of the water in the tank is determined using:

$$f_w = \frac{1}{2\pi} \sqrt{\frac{\pi g}{L} \tanh\left(\frac{\pi h_w}{L}\right)} \quad (6)$$

The stiffness of the water in the tank can then be determined:

$$k_w = m_w(2\pi f_w)^2 \quad (7)$$

In order to calculate the restoring force that the TLD applies to the structure, the following equations were used:

$$F_{TLD} = k_d x_{TLD} + c_d \dot{x}_{TLD} \quad (8)$$

where  $x_{TLD}$  and  $\dot{x}_{TLD}$  are the displacement and velocity of the TLD determined from the OpenSees model, and  $k_d$  and  $c_d$  are the NSD stiffness and damping parameters, determined from the energy matching procedure as follows:

$$k_d = 2.52 \left(\frac{x_{TLD}}{L}\right)^{0.25} m_d (2\pi f_w)^2 \quad (9)$$

$$c_d = 0.52 \left(\frac{x_{TLD}}{L}\right)^{0.35} 2(k_d m_d)^2 \quad (10)$$

2) *Verification of Yu's Model:* To justify the use of Yu's model in this simulation, results from the MATLAB model were compared with previously performed experiments on TLDs [4]. The TLD which was tested had measurements of 464 mm x 305 mm, and a water height of 40 mm. The corresponding tank frequency was 0.667 Hz, and the weight of the water in the tank was 5.64 kg. The TLD was subjected to a sinusoidal

displacement history with amplitude of 20 mm, and the results are shown in Figure 2.

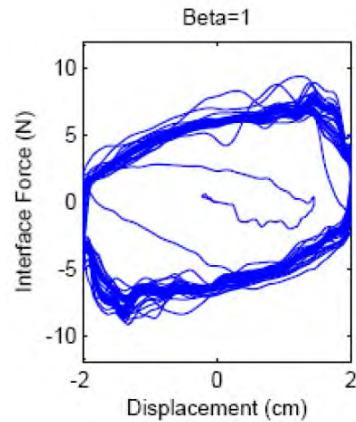

Figure 2: Experimental results for TLD force-displacement behaviour. TLD dimensions: 464 mm x 305 mm, water height 40 mm.

The same TLD was then modeled in Matlab using Yu's model. In this implementation, a simple SDOF structure (portal frame) was modeled with the TLD at the roof level. A sinusoidal force was applied to the portal frame which resulted in a TLD displacement of 20 mm, as in the experimental setup. This system was analyzed using the Newmark-beta method, and results are shown in Figure 3.

The results show that the MATLAB model matches the experimental data well – the shape of the force-displacement curve is similar, and the magnitude of the force is similar as well. Since the shallow water limit ( $\frac{h_w}{L} < 0.1$ ) is met for both experimental and numerical TLD models, we can conclude that Yu's model is able to accurately capture the experimental TLD behaviour for the shallow water scenario.

### C. Dynamic Wind Loading Simulator

The dynamic wind loading patterns for the structure were obtained using the NatHaz Online Wind Simulator (NOWS) web-based interface. The tool provides users with an on-line simulation of stationary Gaussian multivariate wind fields.

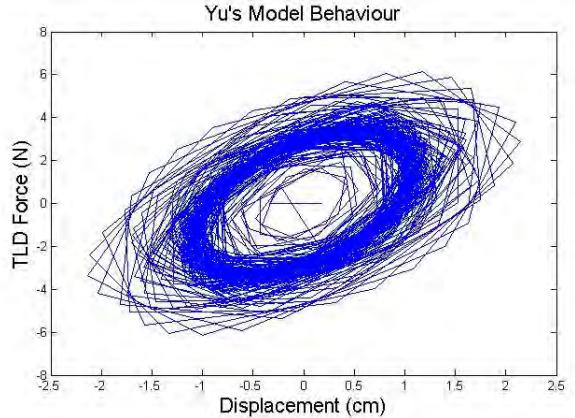

Figure 3: Matlab model results for TLD behaviour. TLD dimensions same as for experimental specimen in Figure 2.

Random wind fields of varying intensities, corresponding to various National Building Code of Canada 2010 (NBCC) limit states [7], were generated using a discrete frequency function with Cholesky decomposition and Fast Fourier Transform (FFT). The outputs of the tool were a time history of wind speeds at the various heights of the structure – a sample output from the tool is shown in Figure 4. These wind speeds were then converted to equivalent forces using the guidelines given in ISO-19902, which gives:

$$F_w = \frac{1}{2} \rho_a (U_w)^2 C_s A \quad (11)$$

where  $\rho_a$  is the mass density of air,  $U_w$  is the given wind speed in  $\frac{m}{s}$ ,  $C_s$  is the shape coefficient of the structure,  $A$  is the tributary cross-sectional area of the wind-facing surface, and  $F_w$  is the equivalent lateral force.

#### D. Multi-Platform Model Algorithm

The methodology and algorithm that was used to define the interaction between all components of the tool is shown in Figure 5. This interaction loop was repeated for each time step that the wind loading was simulated. The outputs of interest were taken from the Matlab model and the OpenSees model, and included a time history of TLD force as well as structural displacements, acceleration, storey and base shears, as well as element forces.

#### E. Solution Procedure

The model was analyzed using a transient analysis method, and the Newton numerical method. While the details of this solution method are not given in this paper, further details can be found in literature [8].

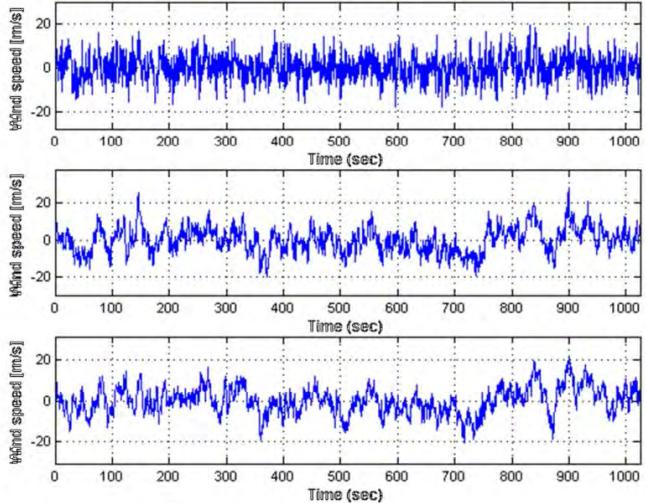

Figure 4: Fluctuating wind speed (about mean wind speed) at Floors 1, 34, and 67 for a sample wind loading scenario obtained from NROWS web tool.

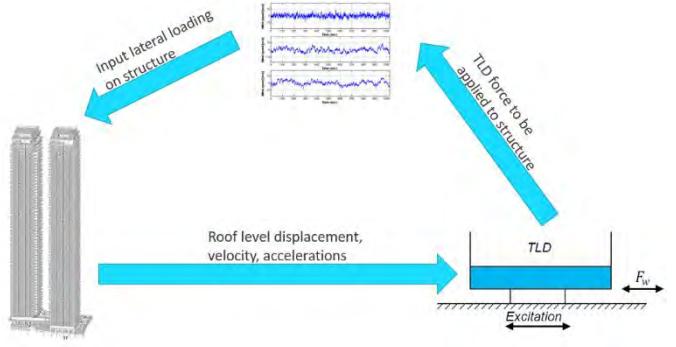

Figure 5: Schematic representation of interaction algorithm used in TLD-structure simulations.

Table 1: Comparison of periods of vibration (ETABS vs. OpenSees) for dominant modes of vibration.

	ETABS Model	OpenSees Model
Mode 1 Period	6.166 sec	6.204 sec
Mode 1 Direction	E-W	E-W
Mode 2 Period	4.970 sec	3.738 sec
Mode 2 Direction	N-S	N-S

The results show that the first mode period is quite well-matched between the two models. This is important as the structure was analyzed in the direction of the first mode (E-W).

#### F. Description of Wind Loading Profiles

Table 2 shows the three wind loading profiles which were chosen for analyzing the structure with and without the TLD. These wind loading profiles were selected in order to analyze the structure and be able to compare the results to NBCC 2010 human comfort and structural integrity checks. Scenario 1 corresponds to a 1/10 level of wind, which is recommended by the NBCC 2010 for checking serviceability comfort levels as well as structural performance. Scenario 2 corresponds to the recommended 1/50 wind level, and Scenario 3 represents a more severe wind storm.

Table 2: Summary of wind loading conditions.

	Scenario 1	Scenario 2	Scenario 3
6 <sup>th</sup> floor wind speed	12.1 m/s	35.5 m/s	53.2 m/s
30 <sup>th</sup> floor wind speed	20.4 m/s	45.4 m/s	68.2 m/s
Roof wind speed	23.1 m/s	51.4 m/s	77.2 m/s

The structure was analyzed under various performance indicators, including peak storey accelerations. These values were compared to the NBCC 2010 acceleration limit for human comfort, as well as the limit suggested by the Council for Tall Buildings and Urban Habitat (CTBUH).

In NBCC 2010, several levels of service for the performance of the building under wind loading are considered – specifically, Commentary I sentence 78 requires that the maximum acceleration be less than 1.5% of g, as any higher level of acceleration is perceptible to occupants (barring additional effects such as visual cues, body position, and orientation). This

acceleration guideline is the same in CTBUH, with the added restriction that the Root-Mean-Square (RMS) acceleration should be less than 0.5% of g. Furthermore, NBCC 2010 Commentary I sentence 74 states that the lateral deflection of the building should be no more than 1/500 of the building height [10].

### G. Discussion of Results

Table 3: Summary of key structural performance parameters with TLD (and % change compared to uncontrolled structure).

Parameter	Scenario 1	Scenario 2	Scenario 3
Peak roof drift (m)	16.8 (-12%)	172 (-20%)	395 (-21%)
Peak storey acceleration (% g)	0.69 (-12%)	9.22 (-2%)	24.8 (-0%)
Peak Base Shear (MN)	1.7 (-1.1%)	24.1 (-0.2%)	65.6 (-0.1%)

Using the multi-platform tool previously described, it was determined that for the 1/10 level of wind, the structure met the performance criteria set out in both NBCC 2010 as well as CTBUH – the storey accelerations were well below the NBCC 2010 1.5% of g guideline, and the RMS acceleration was 0.507% of g. It is important to note that in the CTBUH guidelines, a 6-year level of wind was recommended when checking RMS acceleration limits, whereas a 10-year level of wind was used in the simulations for consistency with NBCC 2010. Furthermore, the roof drift was well below the 400mm limit prescribed by NBCC 2010, with a maximum roof drift of 19mm without the TLD and 16mm with the TLD.

The roof drift limits are similarly met for Scenario 2, which represents a more severe wind level. While the peak storey acceleration limits are not met for Scenario 2, the wind level represents a more severe loading than suggested for serviceability checks (Scenario 1). The mean storey displacements for Scenario 2 are shown in Figure 6, and a marked reduction in storey displacements can be observed, with more significant improvements to be seen at the higher storeys of the structure.

Table 4: Summary of improvement in mean storey displacement/shear results (top & bottom 20 storeys) with TLD vs without TLD.

Parameter	Scenario 1	Scenario 2	Scenario 3
<b>Top 20 Storeys</b>			
% Change in mean storey displacement	-8.27%	-7.51%	-6.90%
% Change in mean storey shear	+5.71%	+2.06%	+0.62%
<b>Bottom 20 Storeys</b>			
% Change in mean storey displacement	-0.25%	+0.98%	+0.65%
% Change in mean storey shear	-1.10%	-0.36%	-0.15%

Figure 7 also shows the time history of roof displacement under the most severe wind storm, Scenario 3. The results show that even for such a high level of wind, the TLD can provide significant reductions in roof drift, keeping the structure within the NBCC 2010 limit for roof deflection.

Table 4 summarizes some key parameters for structural performance, namely storey displacements and storey shear, but for the upper 20 storeys of the structure only. This is to understand the benefits that the TLD provides to the most flexible parts of the structure. For all three wind loading scenarios, the TLD can reduce the storey displacement demands at the upper storeys of the structure – this is critical for the comfort of the occupants, as these storeys typically experience the largest displacements.

Across all three wind loading scenarios, a couple of trends can be seen for the structural performance with and without TLD. The first is that there is a negligible change in base shear for the structure with the addition of the TLD; slightly higher storey shears are observed at the upper levels of the structure, whereas slightly lower storey shears are observed at the lower levels of the structure. While the TLD can dissipate vibration energy through non-linear liquid sloshing, the addition of a significant mass (1.5% of the structural mass) at the roof level of

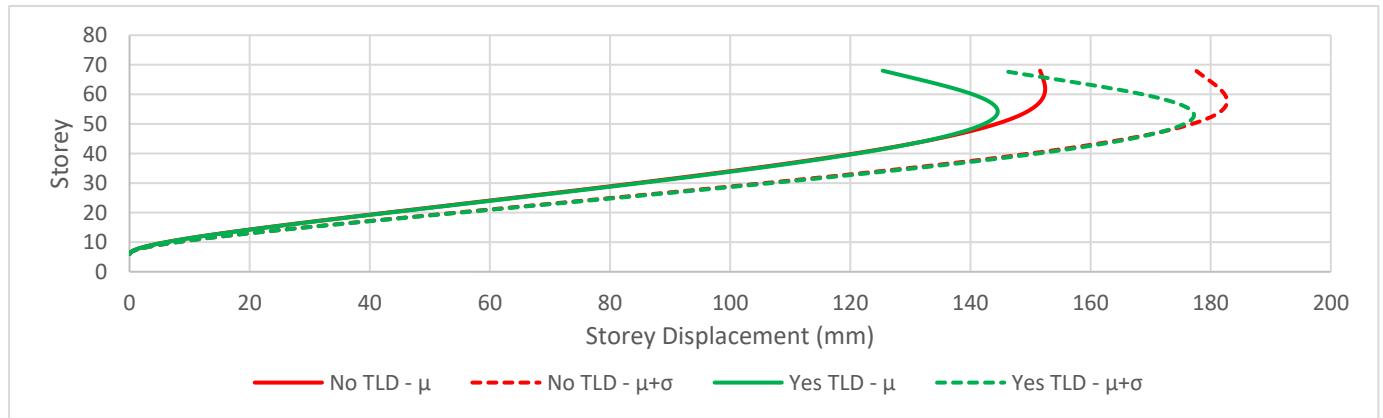

Figure 6: Mean storey displacement for wind loading scenario 2.

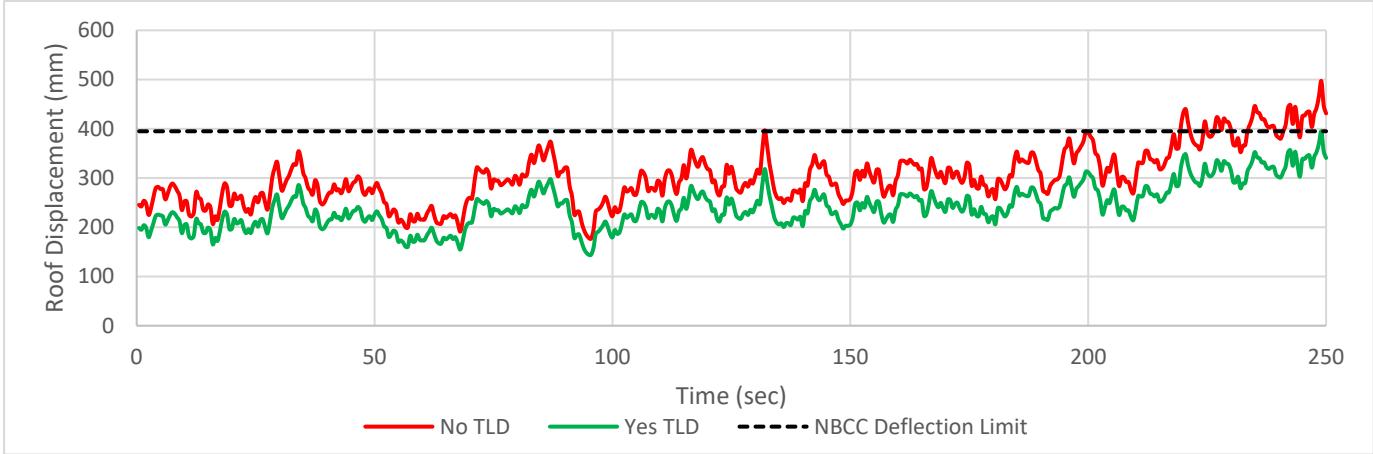

Figure 7: Roof displacement time history for wind loading scenario 3.

the structure imposes large forces on the upper storeys of the structure.

Secondly, a noticeable improvement in structural performance is observed with regards to roof displacement and global mean storey displacement, while a smaller improvement is seen with regards to storey accelerations. As was the case with the storey shears, the TLD provides more benefits at the upper storeys of the structure than at the lower storeys. This is still a good result, as these measures are critical for human comfort and serviceability checks, and the upper levels of the structure are where accelerations and displacements are the greatest – and hence the need for improved performance is also greatest.

### III. CONCLUSION AND RECOMMENDATIONS

The objective of this collaboration was to analyze structural performance of a real high-rise structure both with and without TLD under various levels of wind loading to better understand the effects and potential benefits the TLD could provide to the structure. Structural performance was then to be compared to the limits set in NBCC 2010 and CTBUH for human comfort and safety, including maximum lateral deflection of the structure and maximum storey accelerations.

The TLD model which was built was based on Yu's model, where the TLD is modeled as an equivalent non-linear-stiffness-damping oscillator. The TLD properties were tuned to the first mode of vibration of the structure, which was determined in OpenSees and cross-checked and verified with existing linear models in ETABS developed by the team at Stephenson Engineering, as well as third-party wind tunnel testing results.

The structure was analyzed under dynamic wind loading using a transient, multi-platform simulation algorithm. Three wind loading scenarios were considered, including NBCC 2010 service-level wind loads, and two more severe wind loading cases. The structure was found to remain in the elastic range for all three cases, and the structure met the NBCC 2010 and CTBUH human comfort limits. At higher levels of wind, the TLD effects were more pronounced, with benefits in terms of storey displacements and accelerations observed especially at the upper storeys of the structure. However, improvements to the structure with respect to storey and base shear were negligible.

with the TLD addition, due to the large additional mass imposed by the TLD at the roof level of the structure.

It is recommended that the TLD and structure are monitored together, with the TLD being modified such that its properties match that of the structure. TLD performance is highly correlated with the tuning of its frequency to the structure – as the structure ages and concrete cracks, it is likely that its vibration characteristics will change, and hence the TLD will likely need to be adjusted (e.g. changing water levels) to match the structure over time.

### IV. ACKNOWLEDGEMENTS

The authors would like to thank the several members of the team at Stephenson Engineering who assisted on the project, including Senior Associate Xi Xin (Fisher) Li, Senior Associate Dr. Sobhy Masoud, Principal Saundra Cullen, and Bahar Zavarei.

**Abstract**— Thermal Barrier Coatings (TBC) are used to shield hot sections of gas turbine engines, helping to prevent the melting of metallic surfaces. This paper proposes a Five-phase model to calculate the effective thermal conductivity of a TBC, taking into consideration the effect of various defects. By comparing the predicted values with experimental results, it was shown that the proposed five-phase model can predict the thermal conductivity of ceramic coatings closer to the actual values.

## I. INTRODUCTION

The advancement in high-temperature engineering alloys led to the design and development of the present era turbine engines. The laws of thermodynamics suggest that with an increase in inlet operating temperature, the performance and efficiency of an engine can be increased [1].

The components of a turbine engine are exposed to elevated temperatures as well as to an oxidative and corrosive gaseous environment. In certain cases, there are some impacts from high-velocity foreign particles during operation [2]–[4]. The components used at elevated temperatures are coated with a ceramic coating to have protection against high-temperature degradation. A Thermal Barrier Coating (TBC) provides thermal shock resistance, creep resistance, strain tolerance, protection against hot corrosion and stability to the substrate at higher temperatures [5] [6].

The simple structure of the TBC system consists of the ceramic top coat, bond coat and superalloy substrate. During service life, a thermally grown oxide (TGO) layer (mostly  $\alpha$ - $\text{Al}_2\text{O}_3$ ) forms on the bond coat surface and reduces the rate of oxidation [7]. The objective of the top ceramic coating is to reduce the metal temperature. A metallic bond coat is used to enhance the bonding between the top coat and the underlying super-alloy and to protect the super-alloy from oxidation and hot corrosion [8]. Yttria-stabilized Zirconia [YSZ] containing

6-8% $\text{Y}_2\text{O}_3$  is known as a state of the art thermal barrier coating topcoat [9].

The key properties of YSZ TBC are low thermal conductivity, high melting point, phase compatibility with alpha alumina, and the combination of good resistance to corrosion and damage from large particle impacts [10]. The microstructure of ceramic coatings is highly heterogeneous as it consists of imperfections such as pores, voids, and vacancies, along with cracks of different shapes and sizes. Overall, the thermal conductivity of the coating is highly affected by the presence of such defects [11], [12] and spraying parameters [13]. The extent of change in the thermal and mechanical properties depends on the amount, size, and morphology of the defects present in the coating.

Defects lead to a lower value for thermal conductivity and a lower thermal conductivity implies a longer service life, as heat transfer to the substrate is reduced. Lower heat transfer into the substrate also leads to lower damage to the coating interface, where most of the failure occurs [8]. To achieve lower values for thermal conductivity, better strain tolerance and higher lifetime, the distribution of cracks and pores in the coating needs to be optimized [14]. It thus becomes essential to understand the fundamental microstructural properties of the TBC in order to produce an optimized coating. Hence, one of the aims of TBC design is to design coatings with a lower thermal conductivity. Therefore, modelling provides an economical way to develop and understand the coating microstructure that will have lower thermal conductivity. This paper proposed a five-phase model for calculating the effective thermal conductivity of a TBC with the goal to improve the accuracy of modelling.

## II. MODELLING THERMAL CONDUCTIVITY

### A. Modelling approach

Modelling or/and simulation is a cost-effective and flexible approach to optimize and understand the coating microstructure. Development of new types of coatings design or new structures can easily be performed. Modification of the

parameters is simple, and the analysis can be performed quickly compared to a traditional experimental approach. Simulation can provide analysis of different microstructural parameters and their individual effect, as well as the combined effect on the TBC.

The present study is based on the different types of defects (pores, voids and cracks) that are present in the coating during the fabrication of the coating. The effect of various defects needs to be included in the model to better predict the thermal conductivity of coating and to have a better understanding of the coating microstructure. Many researchers have presented models that can predict and calculate the thermal conductivity of the porous coatings. Out of those models, Bruggeman's formula provides a model that takes into consideration the shape, orientation and volumetric fraction of pores. The details can be found in next section.

### B. Two-phase model for thermal conductivity

Thermal conductivity ( $k$ ), is the measure of heat transfer from one surface to another that is having a cross-sectional area  $A$  and are separated by a distance  $L$ . There are many formulas to calculate thermal conductivity depending on the coatings and its parameters. The thermal conductivity of free-standing materials can be determined by [15]

$$k = \alpha C_p \rho \quad (1)$$

where  $\rho$  is the density of the free-standing material ( $\text{kg}/\text{m}^3$ ),  $C_p$  indicates the heat capacity of materials at constant pressure ( $\text{J}/(\text{kg K})$ ), and  $\alpha$  is the thermal diffusion rate ( $\text{m}^2/\text{s}$ ).

Bruggeman provided a model to predict the thermal conductivity of porous coatings [16]. Bruggeman extended the Maxwell model to systems having random dispersions of spherical particles of several sizes. He proposed a model assuming that if a relatively large spherical particle is introduced into a dispersion containing much smaller particles, there will be a negligible disturbance of the field around the large sphere due to the small spheres. With this model, he showed that the limitation on a volumetric fraction of dilute dispersion can be removed. The Maxwell model is extended to [17]

$$\frac{k - k_m}{k + 2k_m} = f \frac{k_d - k_m}{k_d + 2k_m} \quad (2)$$

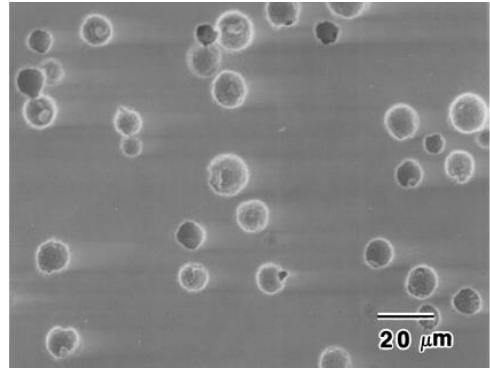

where  $k$  is the thermal conductivity of the composite,  $k_m$  is the thermal conductivity of the matrix,  $k_d$  is the thermal conductivity of the dispersed phase, and  $f$  is the volumetric fraction of the  $i^{th}$  phase. A change in conductivity  $dM$ , with the change in volume fraction of the dispersed phase, is expressed as

$$\frac{dM}{3M} = \frac{dP}{1+P} \left( \frac{k_d - M}{k_d + 2M} \right) \quad (3)$$

Integrating  $P$  from 0 to  $f/(1+f)$  and  $M$  from  $k_m$  to  $k$ . leads to Bruggeman's two-phase model given by

$$\left( \frac{\frac{k - k_m}{k_m}}{\left( \frac{k}{k_m} \right)^{\frac{1}{3}} \left( 1 - \frac{k_d}{k_m} \right)} \right) = (1-f) \quad (4)$$

An example for the two-phase coating can be seen in Figure 1. Also, in this case, it is possible to generalise the modelling to a solute dispersion of randomly oriented ellipsoids.

**Figure 1** Scanning Electron Microscopic Image of spherical pores in continuous matrix [18]

Some assumptions in this work are as follows:

- The thermal conductivity of the dispersed phase or of the defect is assumed to be negligible.
- Heat transfer is along the thickness of the coating only (or perpendicular to bond coat-substrate interface). No lateral heat transfer is assumed.
- The effect of connected pores is neglected.
- There is a linear relation between the porosity and thermal conductivity.

## III. FIVE PHASE MODEL FOR THERMAL CONDUCTIVITY

### A. Simplification of Bruggeman two-phase model

Bruggeman's model is further simplified by assuming the thermal conductivity of pores/defects is negligible i.e.  $k_d = 0$ . Under the condition of non-radiating pores, the equation (4) reduces to

$$\frac{k}{k_m} = (1-f)^{\frac{3}{2}} \quad (5)$$

This equation is the special case when the pores are of spherical shape. The Bruggeman model is based on ellipsoids of revolution, hence in general, for the dispersion of an ellipsoid, the Bruggeman model is a modified version of the equation (5) and is given by [19]

$$\frac{k}{k_m} = (1-f)^x \quad (6)$$

where the value of  $X$  depends on certain factors such as the shape factor of the ellipsoid ( $F$ ) and  $\alpha$ , which is the angle between the heat flux and the axis of revolution. The value of  $X$  can be described by [19]

$$X = \frac{1 - \cos^2 \alpha}{1 - F} + \frac{\cos^2 \alpha}{2F} \quad (7)$$

The value  $X$  is set to 3/2 when there are only spherical pores in a continuous matrix. The assumption of non-conducting pores/defects is valid for a certain temperature limit, however, its primary purpose is to simplify the model [16].

In reality, coatings contain several types of defects [11], [20]–[22]. Therefore, for more realistic modelling of coatings, superposition of the contributions of different defects types on the overall thermal conductivity is required. One approach is to iterate the Bruggeman's two-phase model to higher levels of porosities. This approach is explained in detail in subsequent paragraphs.

### B. Iteration Approach

This approach works in two steps, first of all, type 1 porosity is added in the continuous matrix so that the average thermal conductivity of a binary mixture is obtained. Then, for the second step, the binary mixture is considered as a continuous matrix, and subsequently, type 2 porosity is added in the same manner. This gives the combination of two different types of porosities in a continuous matrix. Suppose that  $f_1$  and  $f_2$  are the final percentages of type 1 and type 2 porosity, respectively, then the total porosity in the coating is given by  $f$ , which is given as the sum of the different types of porosities. Therefore,  $f = f_1 + f_2$ . There can be two ways of adding the defects in a continuous matrix. Consider if we add a Type 1 porosity first into the continuous matrix and then add a Type 2 porosity. This will lead to an equation given by

$$\left\{ \Phi \left[ \frac{f_2}{1-f_1} \right] \Psi(f_1) \right\} \quad (8)$$

Now consider if we first add Type 2 porosity in the continuous matrix and then Type 1, this will generate the formula as-

$$\left\{ \Psi \left[ \frac{f_1}{1-f_2} \right] \Phi(f_2) \right\} \quad (9)$$

The model to calculate thermal conductivity is developed by averaging the multiple values of the constituents that directly make up the composite material. Therefore, when we average the two possible cases we can have the thermal conductivity of the three-phase mixture [19] as

$$k = \frac{k_0}{2} \left\{ \Psi \left[ \frac{f_1}{(1-f_2)} \right] \Phi(f_2) + \Phi \left[ \frac{f_2}{(1-f_1)} \right] \Psi(f_1) \right\} \quad (10)$$

where  $k_0$  is the thermal conductivity of the matrix,  $\Psi(f)$  and  $\Phi(f)$  are functions describing the effect of defects on the thermal conductivity of the coating. This process is also known as an averaging technique. This process of averaging the all possible ways in which different types of defects can be added will provide the formula for  $n$  number of defects under consideration. A five-phase model will have 24 different equations that will be averaged to obtain thermal conductivity of coating. Therefore, for the five-phase model, there are four different types of defects that are assumed to be embedded in a continuous matrix.

### C. Five-phase model

The volumetric fractions of different types of defects are given by  $f_1$ ,  $f_2$ ,  $f_3$  and  $f_4$ . The effect of each defect on thermal conductivity is given by functions  $\Phi(f)$ ,  $\Psi(f)$ ,  $\Theta(f)$  and  $\beta(f)$ , respectively. The values of volumetric fraction are obtained from image analysis using Image J and from references using MIP (Mercury Intrusion Porosimetry). The functions are all defined by the equation (6). The five-phase model can be expressed as

$$k = \frac{k_0}{24} (A + B + C + D) \quad (11)$$

where  $A$ ,  $B$ ,  $C$  and  $D$  provides simplification of the formula. The formula averages all the possible conditions in which the four different types of defects can be added in different sequences. The details regarding the  $A$ ,  $B$ ,  $C$  and  $D$  can be found somewhere else [23].

## IV. DATA RESOURCES

The data for the modelling work is obtained from several references, Image analysis and from MIP. The image analysis and MIP provide the details regarding the volumetric fraction of various kinds of defects present in the coating. In this work, a spheroidal shape is used to model various kinds of defects. This shape can cover a large number of real-life defects that are present in the coating.

Image J provides the details regarding the porosity content present in the coatings. The four types of defects that are under consideration are open randomly oriented cracks, microcracks, non-flat spheroids porosity and defects having revolution axis oriented perpendicular to heat flux (penny-shaped defects). The equation (6) is used to define the functions and equation (7) is used to obtain the values of  $X$ . The  $X$ -factors obtained during this study are listed below in Table 1. Overall porosity content can be seen in Table 2 that are obtained from image analysis.

Table 1 X factor for different defects [23]

X-Factor	Functions
1.66	Open Randomly Oriented
7	Microcracks
2	Penny shaped ( $\alpha=90^\circ$ )
1.7	Non-flat porosity

## V. RESULT AND DISCUSSION

### A. Obtained Thermal Conductivity

The five-phase model is used to calculate the thermal conductivity of the coating using the porosity content, volumetric fraction and the  $X$  values. The values of thermal conductivity for various coatings can be obtained from Table 3.

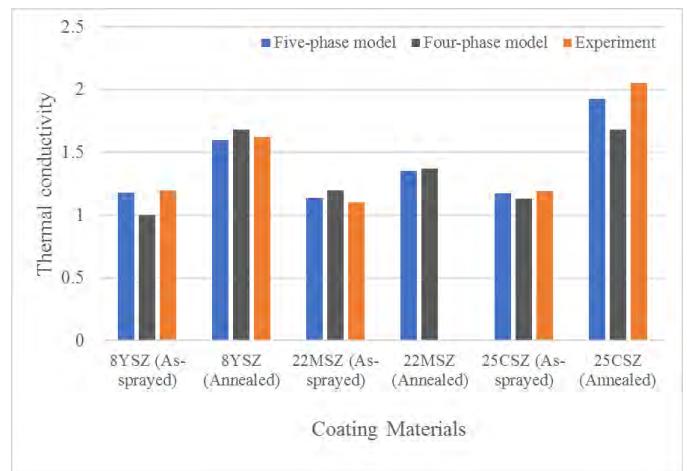

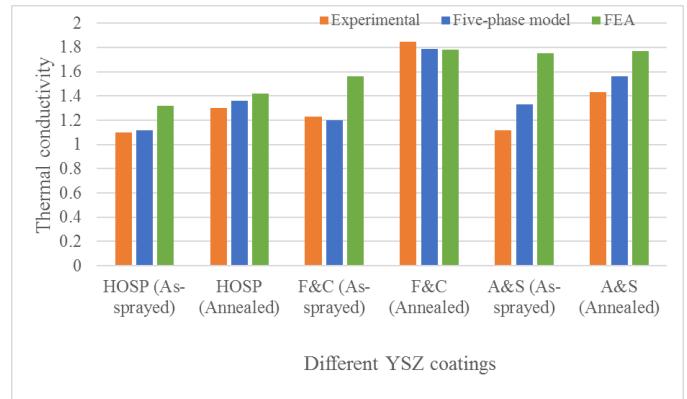

**Table 3 Thermal conductivity values obtained using five-phase model**

### B. Validation of Results

The results obtained from the five-phase model are validated against experimental results. Thermal conductivity of different coatings obtained from the five-phase model, four-phase model

and experimental results are compared in Figure 2. Thermal conductivity values of different Yttria Stabilized Zirconia (YSZ) obtained from the five-phase model, experimental and FEA model are compared in Figure 3.

**Figure 2 Comparison of thermal conductivity values.****Figure 3 Comparison of thermal conductivity values for various YSZ coatings**

## VI. CONCLUSION

A five-phase model to predict thermal conductivity of thermal barrier coatings was developed in this work and validated against the results from the four-phase model, FEA model and experimental results. The presented model takes into consideration the different types of pores that are mostly present in a topcoat. The parameters used in the model were obtained from previous models and fitting parameters. The results obtained with the new proposed model were then validated against the reference data.

By comparing the predicted values with experimental results, it was shown that the proposed five-phase model can predict the thermal conductivity of ceramic coatings closer to the actual values. The five-phase model can predict the values of thermal conductivity within 6% of the experimental results. The proposed model uses real microstructure images and MIP results to obtain porosity content in the coatings to better predict the thermal conductivity. The proposed model has the potential to predict microstructure-property relationships.

The presence of different types of pores and cracks influences the overall thermal conductivity of the coatings. Microcracks present in the coating's microstructure influence the thermal conductivity. The density of microcracks is affected by heat treatment due to the expansion of the coating material. Smaller cracks disappear in the coating due to sintering and lead to lower porosity content, which ultimately leads to an increase in thermal conductivity.

**Abstract**—The main goal of this paper is, to suggest improved higher order refined theory to the analysis of perfectly bonded stack sandwich and composite laminates with usual type lamination configurations. The analysis incorporates continuous flexural and in-plane displacements in the interface. Furthermore, the transverse shear stress is continuous and also constrained with the Lagrange multiplier technique by introducing new fourteen unknown variables. The unknown variables expressed in terms of interfacial strain energy; assuming the interfacial strain energy is continuous throughout the thickness of the laminate. To determine the newly introduced flexural and in-plane unknowns' variables, total potential energy (TPE) is minimized using variational calculus. The numerical results are compared with existing reliable published papers. In general, the aforementioned approach is sufficient enough to analyze sandwich and laminate structures with the required accuracy.

**Keywords-** Refined theory; Flexural displacement; In-plane displacement; Constraint; Strain Energy; TPE

## I. INTRODUCTION

Nowadays, light weight sandwich and composite structures are widely used in the aeronautical/aerospace and marine industries to gain superior safety, higher payload and good fatigue resistance property. To achieve the above appropriate properties, multilayered laminate structure should requires advanced understanding of statics and dynamical behavior of composite materials[1]. Likewise, sandwich and composite structures are complicated in analysis and design aspect; because some unforeseen failure modes like delamination's are considered [2-4].To overcome the aforementioned challenges inter-laminar strain energy continuity assumption based refined modeling has suggested. This approach gives limitless ways to design and optimize the laminates in accordance with the applied external load.

In general, there is no exact mathematical assumption to analyze sandwich and laminated composite plate with the required accuracy. To plug in the gap, this paper play a vital role by considering layer by layer refined theory analytical approach with assumption of perfect bond between layers and the interfacial strain energy continuity throughout the thickness of the laminate.

The energy in the interfaces to estimate the mechanical behavior of the laminate structures. The theory is implemented on layer by layer technique; in which total potential energy of each layer has minimized by Lagrange multiplier, in-plane and flexural displacement using variational calculus. To maintain the principle of continuous uniform deformation theory the plies are bounded perfectly and the continuity conditions constrained by the Lagrange multipliers to satisfy the boundary conditions in terms of in-plane and flexural displacements. Using the above approach, the in plane and flexural stresses can be easily analyzed in each layer of the lamina [5-7].

In general, we considered a refined composite and sandwich plate theory that incorporates continuous strain energy within the interfaces to calculate the mechanical behavior of laminate structures. Our theory is implemented using a layer-by-layer technique in which the total potential energy of each layer is minimized via the Lagrange multiplier to obtain in-plane and flexural displacements using variational calculus. To maintain the principles behind the continuous uniform deformation theory, the plies are perfectly bonded and the continuity conditions are constrained by the Lagrange multipliers to satisfy the governing equilibrium equation using boundary conditions to determine the unknown variables. By applying this approach, the flexural and in-plane stresses are easily analyzed at each layer of the lamina. Further, these formulations are calculated to yield easier plate configurations in two dimensions.

## II. POTENTIAL ENERGY MINIMIZATION

In order to determine the natural boundary conditions and governing equilibrium equations in flexural and in-plane form, we can use minimization of total potential energy. In order to analyze the above geometry of plate we have been made the following fundamental assumptions.(1) The laminate have uniform thickness and symmetrical at the mid-plane; to simplify the governing equilibrium equations; (2)The core is compressible ;(3) The global axes does not coincide with the local axes of symmetry; (4) The skin plies bonds to core perfectly; (5) The core and skin layers are linear elastic (6) The face and core layers are considered as 2D and 3D structures respectively; (7) The plate assumed to be flat and naturally it has no curve. Under this assumption, all odd polynomial superscript coefficients become zero in the equilibrium equations. Therefore, the nine governing equilibrium equations of the laminate can be separated into five flexural and four in-plane components. By incorporating the constraints, the total potential energy minimized as follows.

$$\begin{aligned} \frac{\partial(\Pi+U_{\text{int}})}{\partial u_i^o} &= 0, \quad \frac{\partial(\Pi+U_{\text{int}})}{\partial \phi_i} = 0 \\ \frac{\partial(\Pi+U_{\text{int}})}{\partial \psi_i} &= 0, \quad \frac{\partial(\Pi+U_{\text{int}})}{\partial \Lambda_{ui}^a} = 0 \\ \frac{\partial(\Pi+U_{\text{int}})}{\partial \theta_i} &= 0, \quad \frac{\partial(\Pi+U_{\text{int}})}{\partial \Lambda_{ij}^a} = 0 \end{aligned} \quad (1)$$

The interfacial strain energy formulated as follows

$$U_{\text{int}} = \frac{1}{2} \int_{A_{\text{int}}} \left[ \begin{aligned} &\left( \Lambda_{u_1}^{Top} u_1^{(1)} - \Lambda_{u_1}^{Top} u_1^{(2)} \right) \\ &+ \left( \Lambda_{u_2}^{Top} u_2^{(1)} - \Lambda_{u_2}^{Top} u_2^{(2)} \right) \\ &+ \left( \Lambda_{u_3}^{Top} u_3^{(1)} - \Lambda_{u_3}^{Top} u_3^{(2)} \right) \\ &+ \left( \Lambda_{13}^{CT} \tau_{13}^{(2)} - \Lambda_{13}^{CT} \tau_{13}^{(3)} \right) \\ &+ \left( \Lambda_{23}^{CT} \tau_{23}^{(2)} - \Lambda_{23}^{CT} \tau_{23}^{(3)} \right) \\ &+ \left( \Lambda_{13}^T \tau_{13}^{(3)} + \Lambda_{23}^T \tau_{23}^{(3)} \right) \\ &+ \left( \Lambda_{u_1}^{Bot} u_1^{(1)} - \Lambda_{u_1}^{Bot} u_1^{(2)} \right) \\ &+ \left( \Lambda_{u_2}^{Bot} u_2^{(1)} - \Lambda_{u_2}^{Bot} u_2^{(2)} \right) \\ &+ \left( \Lambda_{u_3}^{Bot} u_3^{(1)} - \Lambda_{u_3}^{Bot} u_3^{(2)} \right) \\ &+ \left( \Lambda_{13}^{BC} \tau_{13}^{(1)} - \Lambda_{13}^{BC} \tau_{13}^{(2)} \right) \\ &+ \left( \Lambda_{23}^{BC} \tau_{23}^{(1)} - \Lambda_{23}^{BC} \tau_{23}^{(2)} \right) \\ &+ \left( \Lambda_{13}^B \tau_{13}^{(1)} + \Lambda_{23}^B \tau_{23}^{(2)} \right) \end{aligned} \right] dx_1 dx_2 \quad (2)$$

## III. ANALYTICAL CLOSED FORM SOLUTIONS

The aim of analytical closed form solutions is, to determine the unknown variables analytically. The unknown

variables can be obtained from the displacement and inter-laminar strain energy continuity formulas. For this approach the Lagrange, in-plane and flexural displacements equations are expanded as Fourier series based on boundary conditions. Considering a load:

$$q = Q_{mn}^o \sin \alpha x_1 \sin \beta x_2 \quad (3)$$

## IV. RESULTS

Symmetric three layered simply supported square composite and sandwich plate with height is equal to  $h = 10t$  be used. Applying various aspect ratios(S) the numerical results of flexural displacement, inter-laminar shear stress and in plane stress are shown in the Table-1 and 2.Table-1 2 and 3 shows that, the percentage error obtained from the suggested approach is in a good agreement with exact elasticity solution[8] and in conclusion while the error percentages decreasing as the plate aspect ratio increase. For S, equal to 4, 10 and 20, the new approach gives a better estimate of in-plane stress and inter-laminar shear stress than other approaches for the given aspect ratios. Furthermore, for very thin ply ( $a/h=50$  and above) the suggested theory contributes a better accuracy for in-plane stresses as compared to other classical models.

The results in the tables report are obtained by the following non-dimensional formulas:

$$\begin{aligned} \bar{u}_1 &= u_1 \left( \frac{100 * h^3 E_{22}}{qa^4} \right), \bar{u}_2 = u_2 \left( \frac{100 * h^3 E_{22}}{qa^4} \right), \\ \bar{\sigma}_{22} &= \sigma_{22} \left( \frac{h^2}{qa^2} \right) \\ \bar{u}_3 &= u_3 \left( \frac{100 * h^3 E_{22}}{qa^4} \right), \bar{\sigma}_{11} = \sigma_{11} \left( \frac{h^2}{qa^2} \right), \bar{\tau}_{12} = \tau_{12} \left( \frac{h^2}{qa^2} \right), \end{aligned} \quad (4)$$

## SUMMARY

In this paper, we explored and analyzed the accuracy of a layer-by-layer refined theory model with flexural and in-plane displacement continuity in a laminate composite and sandwich plate. The improved higher-order theory was applied for efficient execution of the refined theory. Inter-laminar continuity equations were also constrained using Lagrange multipliers by introducing new variables. The existing and newly introduced variables were then solved through a total potential energy minimization technique. Here, Navier-type analytical closed-form solutions were adopted for analyses. Considering simply supported boundary conditions, we analyzed higher and lower-aspect ratio sandwich plates. Further, the sandwich plate was subjected to sinusoidal distributed loading on the top face. Given this, we calculated all flexural displacements, in-plane displacements, in-plane stress, and interfacial shear stresses and then compared them with exact values presented in previous studies. Further, we performed some parametric tests, with results showing that the aspect ratio increases the accuracy of the analysis also increases for the above approach. We also found that each displacement or stress component requires its own plate model (which differs according to the change in outputs) to obtain exact results. Further, the accuracy of the solution also depends on thickness coordinate  $x_3$ . The key advantage of our proposed approach is the ability to obtain remarkably accurate results for all ranges of aspect and modular ratios. Further, if needed, it is possible to enhance our proposed approach by decomposing the lower-aspect ratio layer into a number of higher aspect ratio layers.

**Abstract**—This paper investigates the libration stabilization control of a partial space elevator system with a moving climber in circular orbits. The system is described by a modified two-piece dumbbell model. The model consists of one main satellite, one climber and one end-body connected by two straight, massless and inextensible tethers. The climber and the end body can move along the tether. The libration motion and the tether reeling motion are separated. And a reel rate function is obtained by analyzing the equilibrium state of the libration motion, based on which an analytical control scheme is designed. Using the sliding mode control law, the proposed control scheme can be implemented effectively and robustly. The results of numerical simulations show that the proposed control scheme has good performance in keeping the stable of the climber's transfer of a partial space elevator satellite system. Furthermore, the proposed libration suppression control can be realized by using tension control only.

**Keywords:** Partial space elevator system; libration stabilization; stable transfer; analytical reel rate control

## I. INTRODUCTION

Partial space elevator system is a partial space elevator system which is a typical tethered satellite system (TTS) [1-6] where a middle body (climber) can move between the main satellite and end body. One difficulty associated with such system is to suppress the libration of the climber and the end body [7 - 9]. The libration is intrinsically unstable due to the Coriolis force produced by the moving climber. The Coriolis force could lead to the tumbling of the partial space elevator system [9, 10]. Moreover, by the end of the transfer period, the magnitude of the final libration angles of the climber and the end body apart from the equilibrium point should be limited so that the system can work in a general stable condition after transferring. Otherwise, additional energy consumption is required to stable the system [7]. Thus, the suppression of such system is critical for a successful climber transfer mission and making sure of the stable working state [10 - 12].

In this study, we aim to keep the climber at a desired constant libration angle in the transfer period. By analyzing the

system dynamic, the proposed climbing speed of the climber is obtained. The proposed transfer speed is demonstrated by numerical simulations with a modifying control. The control can be realized by controlling the reel rate of the tether. The results show that the newly developed control method can be used to kept the climber at the desired angle. The simulation results also present that using the proposed control method, the end-body motion is also suppressed in the transfer period. Moreover, the control input is smooth overall, this is a good condition for the practical use.

## II. DYNAMICS OF A PARTIAL SPACE ELEVATOR SYSTEM

Consider a partial space elevator system in an orbital plane of a circular orbit as shown in figure. 1.

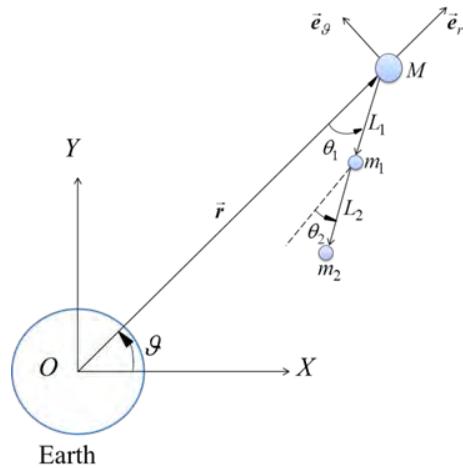

Figure 1 Partial space elevator system.

The dimensionless math model of the partial space elevator system can be expressed as [9]

$$M_1 = m_1 / m_{tot}, M_2 = m_2 / m_{tot}, l_1 = L_1 / L_0, l_2 = L_2 / L_0 \quad (1)$$

where  $\tau = \omega t$  is the dimensionless time,  $M_1$  and  $M_2$  are the dimensionless mas of the climber and the end-body, respectively.  $l_1$  and  $l_2$  are the dimensionless length of the tether 1 and tether 2, respectively.

$$\begin{aligned}\theta_1'' = & \frac{-3}{2} \sin(2\theta_1) - \frac{3M_2 \cos^2(\theta_1) \tan(\theta_1 - \theta_2)}{-M_2 + \sec^2(\theta_1 - \theta_2)} - \frac{2(1 + \theta_1')l_1'}{l_1} \\ & - \frac{2M_2(1 - l_1)\sec(\theta_1 - \theta_2)\tan(\theta_1 - \theta_2)\theta_1'}{l_1[-M_2 + \sec^2(\theta_1 - \theta_2)]} \quad (2)\\ & - \frac{M_2(1 - l_1)\sec(\theta_1 - \theta_2)\tan(\theta_1 - \theta_2)(\theta_2')^2}{l_1[-M_2 + \sec^2(\theta_1 - \theta_2)]}\end{aligned}$$

$$\begin{aligned}\theta_2'' = & \frac{-3}{2} \sin(2\theta_2) + \frac{3l_1 \cos^2(\theta_1) \sin(\theta_1 - \theta_2)}{(1 - l_1)[M_1 + M_2 \sin^2(\theta_1 - \theta_2)]} \\ & + \frac{2\sin(\theta_1 - \theta_2)l_1\theta_1'}{(1 - l_1)[M_1 + M_2 \sin^2(\theta_1 - \theta_2)]} + \frac{2(1 + \theta_2')l_1'}{1 - l_1} \\ & + \frac{2M_2 \cos(\theta_1 - \theta_2)\sin(\theta_1 - \theta_2)\theta_2'}{M_1 + M_2 \sin^2(\theta_1 - \theta_2)} \\ & + \frac{l_1 \sin(\theta_1 - \theta_2)(\theta_1')^2}{(1 - l_1)[M_1 + M_2 \sin^2(\theta_1 - \theta_2)]} \\ & + \frac{M_2 \cos(\theta_1 - \theta_2)\sin(\theta_1 - \theta_2)(\theta_2')^2}{M_1 + M_2 \sin^2(\theta_1 - \theta_2)} \\ & + \frac{3M_2 \cos^2(\theta_2)\cos(\theta_1 - \theta_2)\sin(\theta_1 - \theta_2)}{M_1 + M_2 \sin^2(\theta_1 - \theta_2)} + tol_1 \quad (3)\end{aligned}$$

where

$$\begin{aligned}tol_1 &= \frac{M_2 \sin(\theta_1 - \theta_2)[\cos(\theta_1 - \theta_2) - 1]l_1''}{l_1[M_1 + M_2 \sin^2(\theta_1 - \theta_2)]} \\ tol_2 &= -\frac{\sin(\theta_1 - \theta_2)[1 - M_2 \cos(\theta_1 - \theta_2)]l_1''}{(1 - l_1)[M_1 + M_2 \sin^2(\theta_1 - \theta_2)]} \quad (4)\end{aligned}$$

Eq. (4) is the length accelerating section that denotes the impacts of the tensions along tethers on the changes of  $\theta_1$  and  $\theta_2$ . In the analysis, these two parts are regarded as system noise and ignored, thus, they are the main disturbances source that can be deal with the modifying control.

### III. DYNAMIC ANALYSIS AND ANALYTICAL REEL RATE CONTROL DESIGN

#### A. Steady state during the moving of the climber

The steady state solution of the system can be simply obtained by setting all first and second order derivatives to zero, such that,

$$\theta_1' = 0, \theta_2' = 0, \theta_1'' = 0, \theta_2'' = 0 \quad (5)$$

To ensure climber's stable climbing with constant pitch angles, the stable libration angles can be obtained from the simple dynamic equations with ignoring the length accelerating sections, such as

$$\theta_1 = \theta_{1e} = -\frac{2M_1l_1'}{3(l_1M_1 + M_2)} \text{ and } \theta_2 = \theta_{2e} = 0 \quad (6)$$

For constant pitch angles  $\theta_{1e}$  and  $\theta_{2e}$ , the stable climbing is dependent on  $l_1'$ , which can be derived from Eq. (16) as follows

$$l_1' = -\frac{3(l_1M_1 + M_2)}{2M_1}\theta_{1e} \quad (7)$$

#### B. Control law design based on stable climbing function

To stable the libration angle during the transfer phase of the climber, control law is needed to compensate the possible disturbances. In this paper, we only aim to obtain the stable transfer of the climber, thus, the desired state for the climber in partial space elevator is  $\theta_1 = \theta_{1e}$  and  $\theta_2 = 0$  is not required. To achieve this state, define a sliding mode manifold that drives both  $\theta_1$  and  $\theta_1'$  to  $\theta_{1e}$  and zero, respectively, such that,

$$s = c(\theta_1 - \theta_{1e}) + \theta_1' = 0 \quad (23)$$

where  $c$  is a positive constant that defines the bandwidth of error dynamics of  $s$ .

The error dynamics can be derived by taking derivative with respect to  $\tau$  at both sides of Eq. (23)

$$s' = \frac{ds}{d\tau} = c\theta_1' + \theta_1'' \quad (24)$$

Assume the control input is the velocity function of the climber. Define  $\theta_1'' = f_1 + b_1 u$  where  $f_1$  is the nonlinear function of  $\theta_1''$ ,  $b_1$  is a gain function depending on  $l_1$  and  $\theta_1'$ , and the control input  $u$  is a modification velocity of the obtained function  $l_1'$ , thus, the real velocity of the climber becomes  $l_1' = u + l_1''$ .

Substituting  $\theta_1''$  into to Eq. (24) yield

$$s' = c\theta_1' + f_1 + b_1 u \quad (25)$$

Thus, the sliding mode control law is derived from Eq. (23) as,

$$\begin{cases} u = u_{eq} + u_{sw} \\ u_{eq} = -b_1^{-1}(f_1 + c\theta_1') \\ u_{sw} = -b_1^{-1}k \cdot sign(s) \end{cases} \quad (26)$$

where  $k$  is a positive control gain,  $u_{eq}$  is the equivalent control input and  $u_{sw}$  is the switching input.

For the sake of the avoidance of chattering in the sign function of Eq. (26),  $sign(s)$  is replaced by the saturation function

$$sat(s) = \begin{cases} s & \text{if } \|s\| \geq \varepsilon \\ s/\varepsilon & \text{if } \|s\| < \varepsilon \end{cases}$$

(27)

where  $\varepsilon \in \mathbb{R}_+$  is a small constant.

Next, consider a candidate Lyapunov function as

$$V = s \cdot s/2$$

Taking the derivative of  $V$  with respect to  $\tau$  yields

$$V' = s \cdot s' = -ks \cdot sign(s) \leq 0$$

Furthermore, if there is a bonded disturbance  $d$  in the system, Eq. (12) is revised as,

$$f_d = f_1 + d$$

Submitting Eq. (32) in to Eq. (31) yields

$$V' = s \cdot s' = [d - k \cdot \text{sign}(s)] s \leq 0 \Big|_{\text{if } k \geq |d|} \quad (31)$$

Thus, the system is robust when subjected to a bonded disturbance.

#### IV. CASE STUDIE

In this work,  $\text{tol}_1$  and  $\text{tol}_2$  are set zero, this equals to add dynamic errors,  $-\text{tol}_1$  and  $-\text{tol}_2$ , to the dynamic Eqs. (12) and (13). Two cases are studied  $\theta_{le}$ , the desired stability angles of  $\theta_l$  are set 0.2 and 0.4, respectively. The climber is moving upwards, such that  $l'_l < 0$ . The dimensionless masses  $M_1 = 1/3$  and  $M_1 = 2/3$ . The results are shown in Fig. 2 – Fig. 6.

Under the affection of the dynamic errors, the libration angles do not follow the obtained steady state even when the climbing speed follows the designed function, see figure 2 and 3. The libration angle of the climber increases continuously from the beginning, see figure 2. After 0.02 orbit,  $\theta_l$  is suppressed, and it converges to the desired magnitude. Meanwhile,  $\theta_2$  is also suppressed although the control law is not designed to control it exactly. Figure 4 shows the control input. In the whole transfer period, the change of the reel rate is smooth generally, this is very good for the realization of the practical condition. The moving path of the climber is shown in figure 6. In the mission program, the libration angle of the climber is kept at the desired angle generally, this matches the result shown in figure 2.

##### A. Case I:

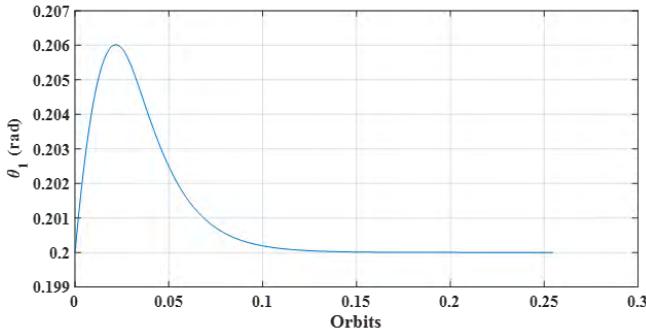

Figure 2 Libration motion of  $\theta_l$  versus orbits when  $\theta_{le} = 0.2$

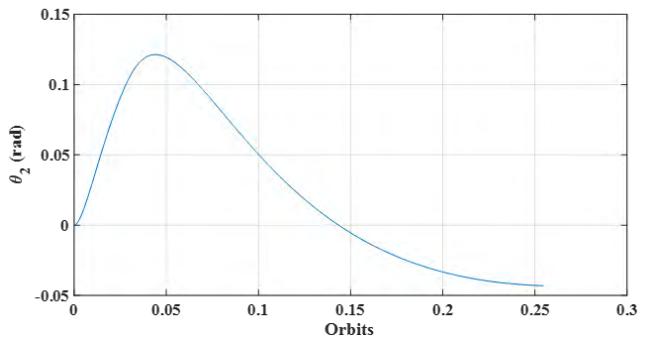

Figure 3 Libration motion of  $\theta_2$  versus orbits when  $\theta_{le} = 0.2$

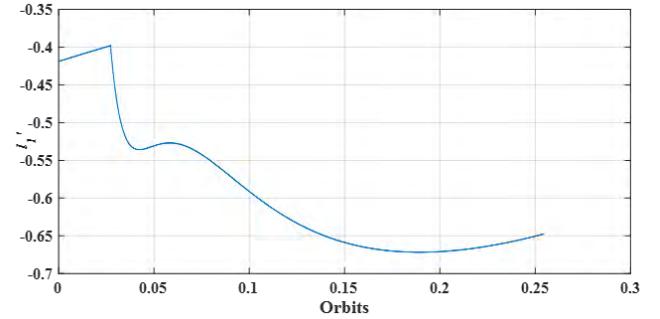

Figure 4 Dimensionless velocity of the climber along  $l_l'$  when  $\theta_{le} = 0.2$

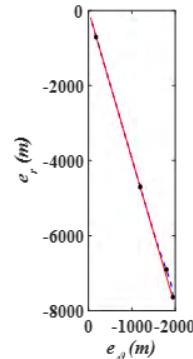

Figure 6 Trajectory of the climber when  $\theta_{le} = 0.2$

#### V. CONCLUSION

The dynamic and stable control of a partial space elevator in the transfer period is studied. By analyzing the system dynamic, the proposed climbing speed of the climber is obtained. The proposed transfer speed is demonstrated by numerical simulations with a sliding mode control with considering the input charting. The control can be realized by controlling the reel rate of the tether. The simulation results show that the newly developed control method can be used to kept the climber at the desired angle. The simulation results also present that using the proposed control method, the end-body motion is also suppressed in the transfer period. Moreover, the control input is smooth overall, this is a good condition for the practical use.

**Abstract**—In this study, we implement a finite element approach and conduct experimental impact tests to evaluate the performance of 3D printed lightweight sandwich panels with architected cellular cores of programmable six-sided cells. The standard mechanics homogenization technique is implemented through a finite element modelling to accurately predict the effective mechanical properties of architected cellular cores. We implement an explicit large deformation finite element simulation using ANSYS to analyze the elasto-plastic behavior of sandwich panels under a low-velocity impact. To experimentally corroborate the developed computational model and to evaluate the manufacturability of architected sandwich panels, we use the fused deposition modeling to 3D print samples of polylactic acid biopolymers. We conduct low-velocity impact experimental tests on the 3D printed panels to investigate their energy absorption capabilities. The results show that the auxetic sandwich panel is potentially an appropriate candidate for energy absorption applications due to its high energy absorption capability.

**Keywords-component:** *Architected 3D printed panels; Cellular solids; Energy absorption; Low-velocity impact.*

## I. INTRODUCTION

Sandwich panels are nowadays extensively used in aerospace, marine, automotive, and windmills industries due to their high flexural stiffness-to-weight ratio, excellent thermal insulation, and high energy absorption capability [1]. Sandwich panels consist of two thin but stiff face-sheets at the top and bottom of the panels separated by a lightweight and relatively thick core. The lightweight core connects the face-sheets with small increase in weight but provides sandwich panels with a high bending stiffness and buckling resistance [2] as well as superb shear stiffness and energy absorption capability [3]. The lightweight core can be made of alternative materials but it is usually in the form of cellular materials, e.g. foams or periodic

lattices. In a sandwich panel, the face-sheets carry most of in-plane and bending loads while the core mainly carries transverse shear [1].

The energy absorption capability of an architected sandwich panel mainly depends on the material properties and geometrical features of solid sheets and the cellular core. Among all cell topologies for the core of architected sandwich panels, hexagonal honeycomb has been commonly used and analyzed as a cellular core [4, 5]. Sandwich panels with conventional honeycomb cellular cores are stiff and lightweight, while they absorb high energy under impact and shockwaves for applications in sports goods, automotive, and aerospace [6, 7]. However, they have some issues due to their closed-cell architectures including gas retention, leading to low thermal conductivity, and moisture trapping [1]. An alternative sandwich core is open-cell cores such as truss-like structures [8, 9]. It has been shown that truss-like cellular cores, with low relative densities, have significantly higher buckling resistance and energy absorption capability compared to hexagonal honeycomb cellular cores [10, 11].

More recently, auxetic sandwich cores have been examined due to their unusual deformation mechanisms, which is negative Poisson's ratio. Auxetic cores possess promising properties in the aforementioned applications compared to other topologies of cellular solids. Due to the auxetic behavior, auxetic cellular cores reveal unique mechanical properties such as increased indentation resistance [12], shear resistance [13], fracture toughness [14, 15], and energy absorption capacity [16, 17]. Although a few investigations have been performed on architected sandwich panels, e.g. flexural behavior [18-20] and out-of-plane compressive strength [21, 22], less attention has been paid to explore the energy absorption capabilities of 3D printed sandwich panels with architected cellular cores.

The current study focuses on the effect of core's cell topology and relative density on the energy absorption

capability and structural design of 3D printed sandwich panels with an architected cellular core.

## II. SANDWICH PANEL AND EXPERIMENTAL TEST CONFIGURATION

Dimensions of the sandwich panel including length ( $a$ ), width ( $b$ ), and total thickness ( $h$ ) are shown in Fig. 1. The coordinate system ( $x, y, z$ ) is located at the midplane of the sandwich panel. The selected dimensions are listed in Table 1, which are chosen based on ASTM standard D3763 [23] and testing limitations.

TABLE I. GEOMETRIC PARAMETERS OF SANDWICH PANELS (UNIT: MM).

Length (a)	Width (b)	Total thickness (h)	Core thickness (tc)	Face-sheet thickness (ts)
100	100	50	40	5

### A. Sample preparation

MK2 3D printer of MACHINA Corp. with the layer height of 0.25mm manufactures the architected sandwich panels. MK2 3D printer uses fused deposition modeling technology (FDM) to additively manufacture architected samples of PLA polymers. Two types of sandwich panels (vertical or horizontal cells) with three different topologies of cellular cores (hexagonal, rectangular, and auxetic) are 3D printed.

### B. Experimental low-velocity impact test

The low-velocity impact tests are performed on sandwich panels with different 3D printed cores using a drop weight machine based on the guidelines given in the ASTM standard

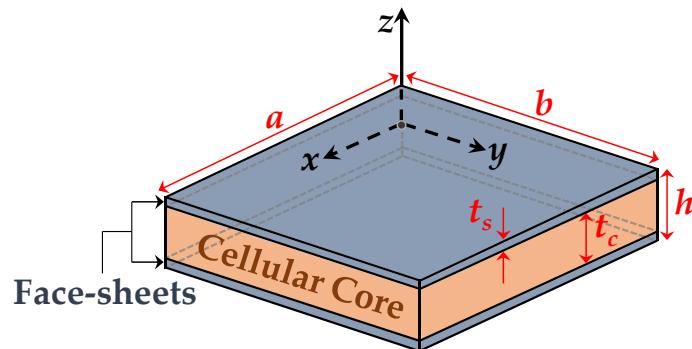

Figure 1. Geometry of an architected sandwich panel and the considered coordinate system.

## III. FINITE ELEMENT MODELING

The explicit large deformation 3D finite element modeling (FEM) is conducted using the commercial software ANSYS Workbench 18.2. Fig. 3 presents the model developed in ANSYS for conducting the low velocity impact analysis. The face-sheets and the core are meshed with quadrilateral and triangular elements and a convergence study is conducted to avoid mesh size dependency of FEM results. The spherical impactor is defined as a rigid body and the dynamic load is applied by assuming an initial velocity for the rigid impactor. The stress-strain curve of PLA is assumed as an elasto-perfectly plastic model for FEM analysis.

## IV. RESULTS AND DISCUSSION

In this section, we examine the effects of the topology and relative density of cellular core of architected sandwich panels on energy absorption when the sandwich panel is subjected to a low-velocity impact. For experimental study, the sandwich panel is subjected to a 3J low-velocity impact test.

### A. Energy-time history

Fig. 4 presents the experimental and numerical results for the energy-time history for alternative cell configuration, cell topology, and cell relative density. There is a good agreement between the results of experimental tests and numerical analyses. In the energy absorption versus time history res, the amounts of absorbed and returned (released) energies during the impact test can be observed. The absorbed energy is the energy mostly dissipated by various failure mechanisms such as delamination and cracking [24]. The returned (released) energy is the elastic energy. Herein, we define the energy performance based on the ratio of absorbed energy / maximum impact energy [24] (see Fig. 4).

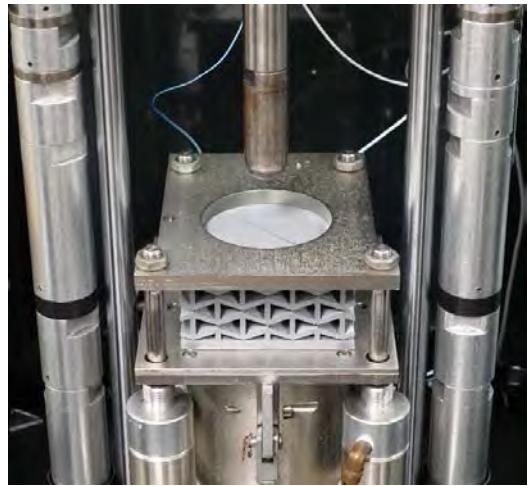

Figure 2. Low-velocity impact test configuration of 3D printed architected sandwich panels.

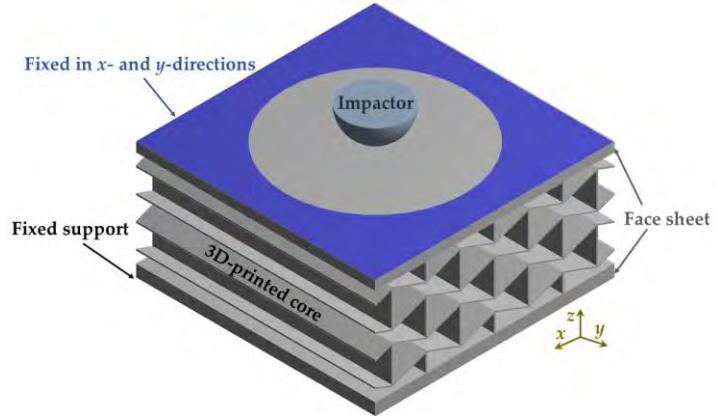

Figure 3. Model developed in ANSYS for the low-velocity impact analysis.

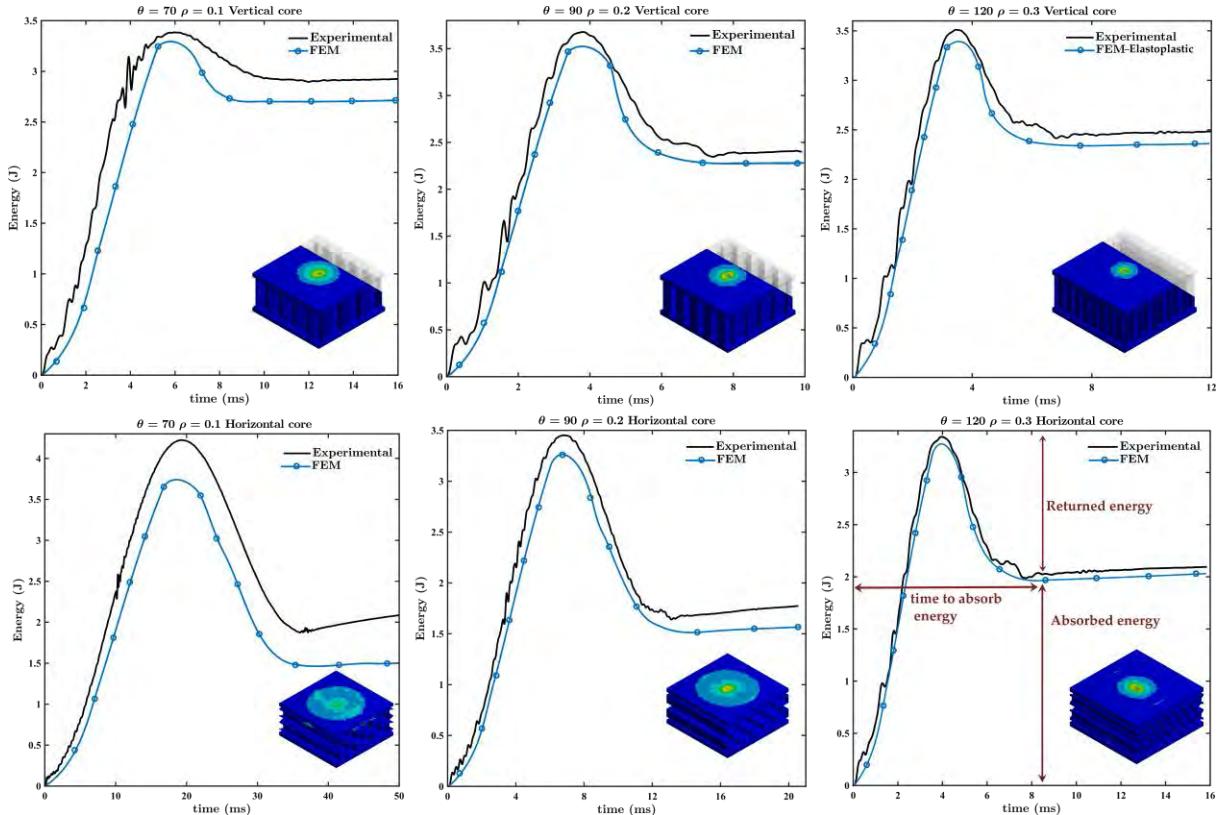

Figure 4. Energy-time history obtained from the experimental impact test on 3D printed architected sandwich panels of alternative cellular core configuration, cell topology, and cell relative density compared with FEM results

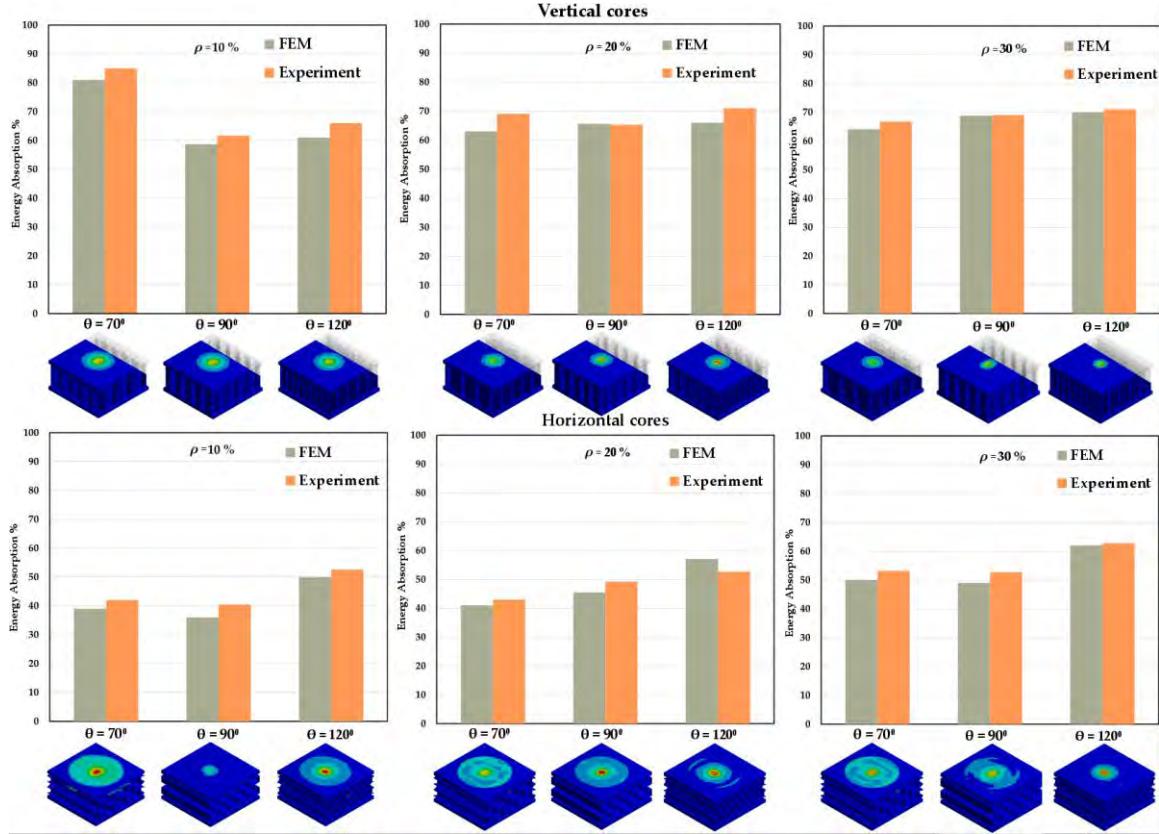

Figure 5. Experimental and FEM results for the energy absorption capability of 3D printed architected sandwich panels of alternative cellular core configuration, cell topology, and cell relative density.

### B. Energy absorption capability

Fig. 5 shows the experimental and numerical energy absorption capability of 18 3D printed sandwich panels with different core topologies including the horizontal and vertical auxetic, rectangular, and hexagonal cores (cell wall angle  $\theta = 70^\circ, 90^\circ$ , and  $120^\circ$ , respectively); and the relative densities of  $\rho = 0.1, 0.2$ , and  $0.3$ . There is a good agreement between the results of experimental tests and numerical analyses. For all considered relative densities of horizontal/vertical cellular cores, the rectangular and hexagonal cellular cores provide a slightly higher energy absorption capability than the auxetic cellular core except for the auxetic cellular core with the relative density of  $\rho = 0.1$ . It should be noted that the auxetic cellular core with the relative density of  $\rho = 0.1$  in the vertical configuration is the optimum cellular core, in terms of energy absorption, for the architected sandwich panels subjected to specific impact energy. 25% and 29% improvements for energy absorption are observed during the experimental tests by using auxetic cellular cores for architected sandwich panels in comparison with hexagonal and rectangular cores, respectively.

### V. CONCLUDING REMARKS

We develop a numerical and experimental study to determine the optimum geometry of architected 3D printed sandwich panels with a periodic cellular core. We 3D print architected sandwich panels of three different cell topologies made of biopolymers and conduct experimental low-velocity

impact tests on samples to estimate their energy absorption capability. The results show that if relative density of the auxetic cellular core is selected appropriately for a specific value of impact energy, the sandwich panels with auxetic cellular cores can have a higher level of energy absorption capability up to 33% compared to the rectangular and hexagonal cellular sandwich panels.

# The Evaluation of Modelling Techniques for Lubricant Cavitation in the application of Squeeze Film Dampers

Tieshu Fan, Kamram Behdinan

Department of Mechanical and Industrial Engineering  
University of Toronto  
Toronto, Canada

**Abstract**—Squeeze film damper (SFD) is widely adopted in turbo-engines to suppress the rotor vibration. However, the prediction of SFD performance is complicated due to the inevitable occurrence of lubricant cavitation. This paper shows the application of three different cavitation algorithms for SFD with sealed conditions. In particular, the linear complementarity problem (LCP) method, which is advanced from a previous research study, is applied to compare results from the well-known methods, i.e. the  $\pi$ -film model and the Elrod cavitation method, for SFD executing circular centered orbits with fully degassed lubricant in the absence of oil feeding. Moreover, numerical models are developed incorporating the mentioned algorithms to predict the hydrodynamic pressure distribution over the cavitated fluid film. Results show that the conventional  $\pi$ -film model overestimates the cavitation region but under-estimates the reaction force.

**Keywords:** *SFD; Cavitation; LCP; Elrod Algorithm;  $\pi$ -film model*

## I. INTRODUCTION

SFD is commonly integrated into aircraft turbine engines to attenuate the level of vibration. It helps to improve the rotor stability and decrease the engine vibration leading to a reduction in the cabin noise. The design parameter of an SFD is the damping capacity. There is an optimum damping value in each application, given the fact that the rotor-bearing system has multiple degrees of freedom and too much or too little damping leads to the overall damping being less effective [1]. The dynamic performance of an SFD is affected by factors such as the damper geometry, the lubricant property and the operating condition. Development of a model that accurately predicts the dynamic behavior and the damping capacity requires integrating the effects of sophisticated lubricant characteristics including the lubricant cavitation effect.

Lubricant cavitation is an ever-present phenomenon in hydrodynamic journal bearings. Typically, cavitation reduces the lubricant density, resulting in the degradation of damping capacity especially at high whirl frequencies and large journal eccentricities [2]. Cavitation in the SFD arises under three scenarios, including the entrapment of surrounding air at low

hydrodynamic pressure, the release of dissolved gas in the lubricant due to the rapid change of the oscillating pressure, and the liquid vaporization at vapor pressure. Air entrapment is usually prevented by placing seals on the SFD [3]. In addition, the lubricant is regarded as well-degassed for application in a rotor-SFD system operating under steady-state conditions [4]. Consequently, only the vapor cavitation is considered for sealed SFDs under periodic motions. Vapor cavitation significantly influences the SFD load capacity, especially at high operating speeds.

For several decades, researchers have been working on the improvement of modelling techniques to accurately simulate the lubricant cavitation. The main challenge in SFDs is the identification of the cavitation boundaries, which determines the hydrodynamic pressure distribution and the hydrodynamic fluid film reaction forces. In conventional SFD models, the fluid cavitation is represented by using the  $\pi$ -film model (i.e. half-Sommerfeld model) [5], where the full-film extends for  $\pi$  radians in the region of positive pressure. Furthermore, Gumbel suggested that the negative pressure values based on the flow equations correspond to cavitation, while the positive pressure region is invulnerable to cavitation [6]. While the Gumbel condition is readily incorporated into pressure calculations, it violates the conservation of mass in the cavitation boundary. Swift [7] and Stieber [8] suggested an enhanced boundary condition to simulate the cavitation. This condition, which is referred to as the Reynolds boundary condition, satisfies the flow continuity at the onset of the lubricant cavitation. The more sophisticated Jakobsson-Floberg-Olsson (JFO) boundary conditions [9, 10] provide an accurate representation of the cavitation boundaries, while maintaining the conservation of mass; however, this condition has limited application due to its computational inefficiency. The computational deficiency corresponding to the cavitation models is addressed by the Elrod algorithm [11, 12]. This model transforms the governing lubricant cavitation equation from elliptic form into parabolic form for both full film and cavitation regions. It firstly calculates the lubricant mixture density in the cavitation zone and subsequently, uses the density values to determine the hydrodynamic lubricant pressure distribution. The Elrod algorithm provides accelerated computational efficiency; however, the calculation of the film pressure and the cavitation extent substantially depend on the liquid bulk modulus. A novel lubricant cavitation evaluation technique has been

recently introduced based on the principle of complementarity [13]. This method is further elaborated to successfully solve the cavitation problem for SFD with open-ended conditions [14].

This paper will evaluate three cavitation algorithms, i.e. the  $\pi$ -film model, the Elrod cavitation algorithm and the LCP method, for sealed SFD executing circular centered orbits with fully degassed lubricant in the absence of oil feeding. Firstly, the lubricant cavitation algorithms are briefly introduced, which will then be incorporated into a mathematical model to generate simulation results. Several different scenarios are subsequently studied and the results are presented for discussion.

## II. NOMENCLATURE

Symbol	Quantity	Unit
$c$	SFD Radial Clearance	$m$
$F_r$	Radial Force	$N$
$F_t$	Tangential Force	$N$
$g$	Switch Function	
$h = c(1 + \varepsilon \cos \theta)$	Fluid Film Thickness	$m$
$L$	SFD Length	$m$
$p$	Fluid Pressure	$Pa$
$p_0$	Pressure at Maximum Film Thickness	$Pa$
$p_{cav}$	Cavitation Pressure	$Pa$
$R$	SFD Radius	$m$
$Re = \rho \omega c^2 / \mu$	Squeeze-Film Reynold Number	
$t$	Time	$s$
$\beta$	Fluid Bulk Modulus	$Pa$
$\varepsilon$	Eccentricity Ratio	
$\theta$	Angular Coordinate	$rad$
$\rho$	Fluid Density	$kg / m^3$
$\rho_c$	Liquid Density at Cavitation Pressure	$kg / m^3$
$\bar{\rho} = \rho / \rho_c$	Density Ratio	
$\mu$	Fluid Viscosity	$Pa \cdot s$
$\omega$	Whirling Velocity	$rad / s$
$\xi$	Complementarity Variable	$kg / m^3$
$\eta$	Complementarity Variable	$kg / m^3$

## III. SIMULATION METHOD

This section describes the governing equations for the hydrodynamic pressure and the fluid film reaction forces in SFDs. Furthermore, different lubricant cavitation models are presented.

Tightly sealed SFDs allow little lubricant flow in the axial direction, such that the pressure gradient along the bearing length becomes negligible. Conventionally, the long bearing approximation (LBA) [15] is applicable to tightly sealed SFDs. Moreover, the Reynolds equation is typically applied to

describe the pressure distribution in the thin film [16]. The Reynolds equation corresponding to LBA for the SFD is

$$\frac{1}{R^2} \frac{\partial}{\partial \theta} \left( \frac{\rho h^3}{12\mu} \frac{\partial p}{\partial \theta} \right) = \frac{\partial(\rho h)}{\partial t} \quad (1)$$

Integrating (1) twice in the axial direction and applying the Sommerfeld boundary condition [16] at the maximum lubricant thickness ( $\theta = 0$ ) yields an analytical solution for the fluid pressure. Assuming that the journal center executes circular-centered orbits (CCOs), the pressure expression becomes

$$p = -\frac{12\mu R^2 \omega}{c^2} \frac{\varepsilon \sin \theta (2 + \varepsilon \cos \theta)}{(1 + \varepsilon \cos \theta)^2 (2 + \varepsilon^2)} + p_0. \quad (2)$$

The subsequent cavitation models will be developed based on the assumption that  $p_0 = 0$ .

### A. $\pi$ -film Model

The  $\pi$ -film model [5] applies the Gumbel condition which assumes that the negative pressure that is calculated from (2) corresponds to the cavitation pressure. Accordingly, the pressure distribution is described as follows

$$p = \begin{cases} -\frac{12\mu R^2 \omega}{c^2} \frac{\varepsilon \sin \theta (2 + \varepsilon \cos \theta)}{(1 + \varepsilon \cos \theta)^2 (2 + \varepsilon^2)} & \pi < \theta \leq 2\pi \\ p_{cav} & 0 < \theta \leq \pi \end{cases}. \quad (3)$$

Furthermore, the fluid force components are determined by integrating the fluid pressure over the journal surface as

$$F_r = \int_{\pi}^{2\pi} p \cos \theta RL d\theta = -\frac{12\mu R^3 L \omega}{c^2} \frac{2\varepsilon^2}{(2 + \varepsilon^2)(1 - \varepsilon^2)} \quad (4)$$

$$\begin{aligned} F_t &= \int_{\pi}^{2\pi} p \sin \theta RL d\theta \\ &= 2p_{cav} RL - \frac{12\mu R^3 L \omega}{c^2} \frac{\pi \varepsilon}{(2 + \varepsilon^2)\sqrt{1 - \varepsilon^2}}. \end{aligned} \quad (5)$$

### B. Elrod Cavitation Model

The Elrod cavitation algorithm is widely employed to calculate the effect of cavitation. Firstly, (1) is modified as

$$\frac{1}{R^2} \frac{\partial}{\partial \theta} \left( \frac{\beta h^3}{12\mu} g \frac{\partial \bar{\rho}}{\partial \theta} \right) = \frac{\partial(\bar{\rho}h)}{\partial t}, \quad (6)$$

where  $\beta$  is the fluid bulk modulus defined as

$$\beta = \rho \frac{\partial p}{\partial \rho}. \quad (7)$$

$\bar{\rho}$  is a dimensionless parameter, which represents the ratio between the density of fluid and the liquid density at the cavitation pressure, i.e.

$$\bar{\rho} = \frac{\rho}{\rho_c}. \quad (8)$$

Note that  $\bar{\rho}$  is less than 1 in the cavitation zone due to the reduced density by the generated cavitation bubbles.

$g$  is a switch function defined as

$$g = \begin{cases} 0 & \text{in cavitation zone} \\ 1 & \text{in full-film zone} \end{cases}. \quad (9)$$

Furthermore, the switch function can be expressed by the relative density as follows to meet the required condition in both flow regions

$$g = \frac{1}{2} + \frac{1}{2} \left( \frac{|\bar{\rho} - 1|}{\bar{\rho} - 1} \right). \quad (10)$$

Subsequently, numerical techniques are applied to iteratively solve  $\bar{\rho}$  and  $g$ . The pressure distribution is calculated based on the direct integration of the bulk modulus, i.e.

$$p = p_{cav} + g\beta \ln \bar{\rho}. \quad (11)$$

Accordingly, the reaction forces of the squeezed film are determined by integrating the hydrodynamic pressure over the journal center, i.e.

$$\begin{Bmatrix} F_r \\ F_t \end{Bmatrix} = \int_0^{2\pi} p \begin{Bmatrix} \cos \theta \\ \sin \theta \end{Bmatrix} L R d\theta dz \quad (12)$$

### C. LCP Method

The LCP method provides a linear complementarity equation set that can be used to efficiently find the pressure distribution.

Define two variables  $\xi$  and  $\eta$  as

$$\xi = \rho_c e^{(p-p_c)/\beta} - \rho \quad (13)$$

$$\eta = \rho_c \left[ e^{(p-p_c)/\beta} - 1 \right]. \quad (14)$$

It has been proved that  $\xi$  and  $\eta$  are non-negative and complementary to each other in the fluid domain regardless of film rupture [14], i.e.

$$\begin{cases} \xi \geq 0 \\ \eta \geq 0 \\ \xi \eta = 0 \\ \xi \frac{\partial \eta}{\partial \theta} = 0 \end{cases}. \quad (15)$$

Based on (13) & (14), the fluid density and pressure can be described in terms of  $\xi$  and  $\eta$  as

$$\rho = \rho_c + \eta - \xi \quad (16)$$

$$p = p_c + \beta \ln \left( 1 + \frac{\eta}{\rho_c} \right). \quad (17)$$

Accordingly, the pressure gradient can also be derived from (17) as

$$\frac{\partial p}{\partial \theta} = \frac{\partial p}{\partial \eta} \frac{\partial \eta}{\partial \theta} = \frac{\beta}{\rho_c + \eta} \frac{\partial \eta}{\partial \theta}. \quad (18)$$

Substitution of (16)-(18) to (1) yields the following:

$$\frac{\partial}{R^2 \partial \theta} \left[ \frac{\beta h^3 (\rho_c + \eta - \xi)}{12 \mu (\rho_c + \eta)} \frac{\partial \eta}{\partial \theta} \right] = \frac{\partial (\rho_c + \eta - \xi) h}{\partial t}. \quad (19)$$

The above equation can be reduced to the following after applying the complementarity condition described in (15):

$$\frac{\partial}{R^2 \partial \theta} \left[ \frac{\beta h^3}{12 \mu} \frac{\partial \eta}{\partial \theta} \right] = \frac{\partial (\eta - \xi) h}{\partial t} + \rho_c \frac{\partial h}{\partial t}. \quad (20)$$

Consequently, an LCP equation set is formulated with respect to the introduced complementarity variables after applying the finite difference method, i.e.

$$\begin{cases} \{\eta\} = [M]\{\xi\} + \{q\} \\ \{\eta\} \geq 0 \\ \{\xi\} \geq 0 \\ \{\eta\}\{\xi\}^T = 0 \end{cases}, \quad (21)$$

where the detailed description of (21) is provided in the Appendix.

A conventional technique for solving (21) is the Lemke's pivoting algorithm [17]. Once the pressure distribution is calculated, the fluid film reaction forces are determined based on (12).

## IV. CASE STUDY AND RESULTS

This section represents results for the three lubricant cavitation models that were discussed in the previous section. The simulation condition is described as follows: the bearing diameter is 104.9mm; the damper length is 110.2mm; the radial clearance is 0.127mm; the lubricant viscosity is 0.005 pa·s; the fluid bulk modulus is 0.069GPa; the cavitation pressure is 1kPa; the journal executes CCO and the whirling speed is 3000rpm. Based on the values of the system parameters, the squeeze Reynolds number is at 0.9935. Large squeeze Reynolds number (i.e.  $Re > 1$ ) requires extra nonlinear expressions to modify the Reynolds equation to address the fluid flow, which opens the gate to study the effect of the fluid inertia. In our study scenario, this number is less than 1, thus the effect of fluid inertia is neglected so that the Reynolds equation is applied [16]. Subsequently, the three cavitation algorithms are incorporated into a MATLAB simulation model using the finite difference method.

Fig. 1-4 compares the pressure distribution for the three cavitation models under different eccentricity ratios. In general, the  $\pi$ -film model predicts the largest cavitation zones and the smallest peak pressure amplitudes, while the LCP method provides the largest full-film regions and the highest peak pressures. As the eccentricity ratio increases, the extent of

cavitation based on the  $\pi$ -film model remains unchanged due to the corresponding assumption for the cavitation boundary condition; however, the extent of the cavitation deteriorates for the other two models. Moreover, the discrepancy between Elrod algorithm and LCP method results becomes smaller at high eccentricity ratios (i.e.  $\epsilon = 0.7$  ).

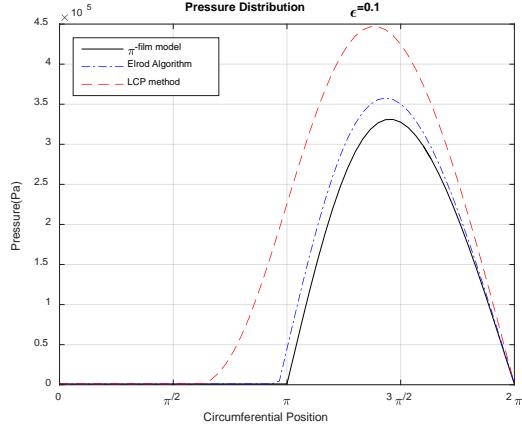

Figure 1. Comparison between the pressure distributions for the three cavitation models at eccentricity ratio 0.1

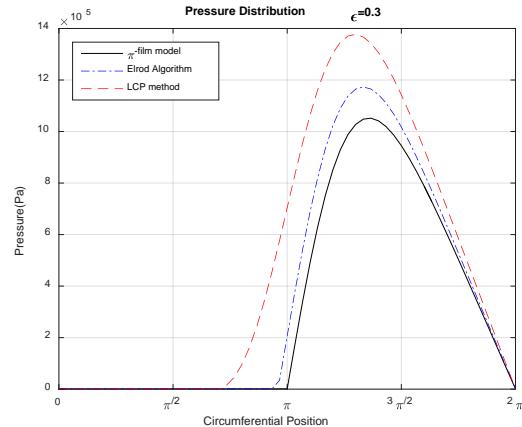

Figure 2. Comparison between the pressure distributions for the three cavitation models at eccentricity ratio 0.3

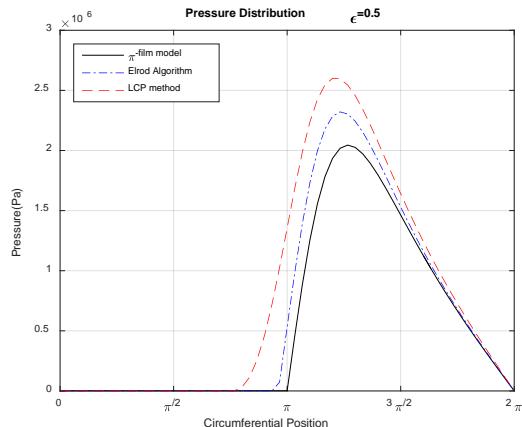

Figure 3. Comparison between the pressure distributions for the three cavitation models at eccentricity ratio 0.5

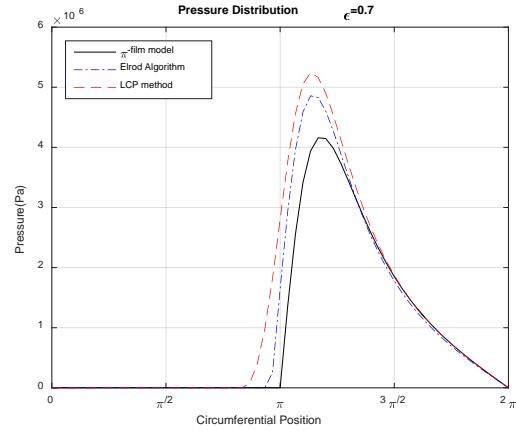

Figure 4. Comparison between the pressure distributions for the three cavitation models at eccentricity ratio 0.7

Fig. 5 and Fig. 6 compare the fluid film reaction force components at different journal eccentricity ratios. Fig. 5 shows that the magnitude of the radial force increases nonlinearly with the eccentricity ratio. Meanwhile, the  $\pi$ -film model predicts smaller magnitudes of the radial forces, while the LCP method presents the largest force components. Furthermore, Fig. 6 indicates a quasi-linear increase of the magnitude for the tangential force with the eccentricity ratio. The  $\pi$ -film model maintains the lowest predicted force magnitudes and the LCP method shows the largest force magnitudes. The discrepancies among the models are the result of differences in the pressure prediction, which can be attributed to the different assumptions about the cavitation boundary.

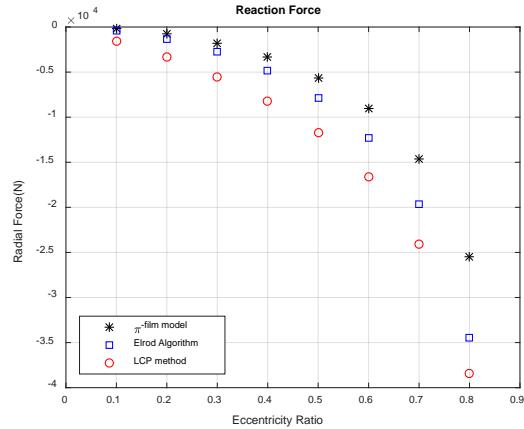

Figure 5. Comparison between the radial fluid film reaction forces for the three cavitation models at different eccentricity ratios

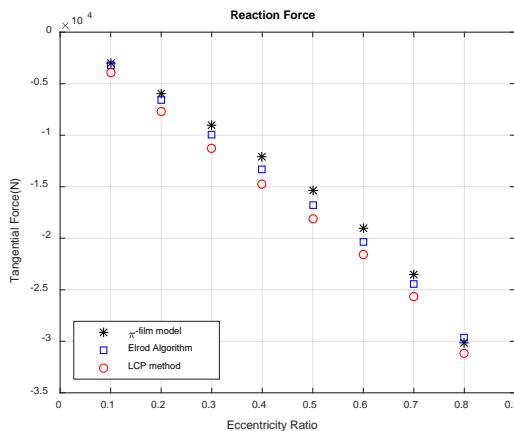

Figure 6. Comparison between the tangential fluid film reaction forces for the three cavitation models at different eccentricity ratios

Fig. 7 compares the attitude angle for the cavitation models. The attitude angel is calculated as:

$$\theta = \arctan(-F_t / F_r). \quad (22)$$

In general, the attitude angle declines as the journal eccentricity increases. The LCP method provides the prediction of the smallest angle. Furthermore, the discrepancy between the models decreases at higher amplitude motions.

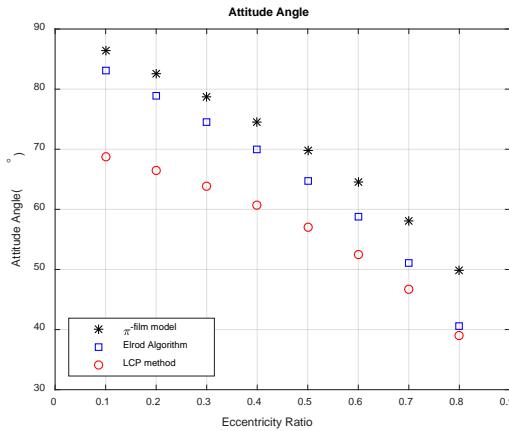

Figure 7. Comparison between the attitude angles for the three cavitation models at different eccentricity ratios

## CONCLUSION

This work compares three cavitation models for sealed SFD, namely the  $\pi$ -film model, the Elrod algorithm, and the LCP method. Simulation shows that the extent of cavitation region is superior at large eccentricities, which is associated with the rapid buildup of larger magnitude pressure. Furthermore, the Elrod algorithm and the LCP method provide larger reaction forces but smaller attitude angles than that from the simple  $\pi$ -film model. These models are computationally efficient so they have the potential to be integrated into rotordynamic studies.

## APPENDIX

The details of (21) are described as follows.

Since the journal executes CCOs, the time variation can be expressed as the partial variation in the circumferential direction, i.e.

$$\frac{\partial f}{\partial t} = -\omega \frac{\partial f}{\partial \theta}$$

where  $f$  represents a function. Accordingly, (20) can be written as

$$\frac{\partial}{R^2 \partial \theta} \left[ \frac{\beta h^3}{12\mu} \frac{\partial \eta}{\partial \theta} \right] = -\omega \frac{\partial h}{\partial \theta} (\eta - \xi) - \omega h \frac{\partial(\eta - \xi)}{\partial \theta} - \omega \rho_c \frac{\partial h}{\partial \theta}$$

After applying the finite difference method to the above, the LCP equation is formulated as (21), where

$$\{\eta\} = \{\eta_1 \quad \dots \quad \eta_N\}^T$$

$$\{\xi\} = \{\xi_1 \quad \dots \quad \xi_N\}^T$$

$$[M] = [L]^{-1} [N]$$

$$\{q\} = [L]^{-1} \{s\}$$

$$\{s\} = \begin{cases} \rho_c (e^{(p_0 - p_{cav})/\beta} - 1) \\ -\omega \rho_c \frac{\partial h_2}{\partial \theta} \\ \vdots \\ -\omega \rho_c \frac{\partial h_n}{\partial \theta} \\ \rho_c (e^{(p_0 - p_{cav})/\beta} - 1) \end{cases}$$

$$[L] = \begin{bmatrix} 1 & 0 & & & \\ a_2 - b_2 - d_2 & -2a_2 + b_2 + c_2 + d_2 & a_2 & & \\ & \ddots & \ddots & \ddots & \\ & & a_n - b_n - d_n & -2a_n + b_n + c_n + d_n & a_n \\ & & & 0 & 1 \end{bmatrix}$$

$$[N] = \begin{bmatrix} 1 & 0 & & & \\ -d_2 & c_2 + d_2 & 0 & & \\ & \ddots & \ddots & \ddots & \\ & & -d_n & c_n + d_n & 0 \\ & & & 0 & 1 \end{bmatrix}$$

$$a_i = \frac{\beta(h_i)^3}{12\mu R^2(\Delta\theta)^2}$$

$$b_i = \frac{\beta(h_i)^2}{4\mu R^2 \Delta\theta} \frac{\partial h_i}{\partial \theta}$$

$$c_i = \omega \frac{\partial h_i}{\partial \theta}$$

$$d_i = \frac{\omega h_i}{\Delta\theta}$$

$$e_i = \omega \rho_c \frac{\partial h_i}{\partial \theta}$$

The subscript  $i$  ( $i = 1, 2, \dots, n$ ) denotes the nodal position in the discretized circumferential domain.

The first row and the last row in the LCP equation represent the boundary condition given the pressure at the maximum film thickness.

# Design and Optimization of a Novel Beam-based Shimmy Damper

**Abstract**—Shimmy damper is a passive solution for undesirable oscillations in landing gears. Although it mitigates shimmy to an allowable degree, it can introduce weight, cost, and reliability penalties especially when retrofitted to existing gears. In this report, early investigations into a novel shimmy damper are presented. This damper is suitable for existing and new landing gears and is based on replacing a torque link member with a combination of springs and dampers to suppress the shimmy. The damper is then optimized for a given geometry to deliver the maximum damping force.

**Keywords-** *shimmy damper; landing gear; optimization; design;*

## I. INTRODUCTION

Nose Landing Gear (NLG) shimmy is known as self-induced simultaneous torsional and lateral vibrations arising from the coupling of gear structure, elastic tire(s), and the fuselage structure during ground operations. The oscillations are typically in the range of 10-30Hz. Shimmy impairs the pilot's visibility and control and causes passenger discomfort, structural damage, as well as sudden failure of the gear [1]. This phenomenon can occur during landing, take-off, and taxiing operations. Worn parts contribute to shimmy; however, it also happens in new aircrafts due to the resonance between the gear and the airframe [2]. It is understood that shimmy mode is excited due to transfer of kinetic energy from the moving aircraft to the wheels [3], acting as the energy source for the undesired oscillations. Close to 60% of aircraft failures are related to the landing gear systems with fatigue due to multi-axial loads (e.g. case of shimmy) playing the number-one role in these accidents [4]. Examples of accidents due to shimmy can be found in [5] and [6]. The latter involved failure of the shimmy damper in addition to the landing gear.

Shimmy needs to be prevented through adequate design during the aircraft development. In practice, shimmy is not discovered until the aircraft is flown and shimmy tests are performed on the ground. In the event of observing shimmy, it is often too late to alter the well-established gear and aircraft design, hence a damper may be designed and prescribed to remedy it. The UTAS (Goodrich) shimmy damper was presented in 2012 [7] which consisted of a damper on one side and a beam with adequate stiffness and strength on the other,

The authors gratefully acknowledge the research grant provided by SPPCA and Natural Sciences and Engineering Research Council of Canada (NSERC) in support of this work.

the combination of which makes the shimmy damper. Early studies on the UTAS damper revealed a major issue due to its unsymmetrical design [3]. Although performing better than the flagship Boeing damper [8] in most of the cases, the UTAS damper led to unsymmetrical oscillations which degrades the lifespan of components and tires due to imbalanced loading and uneven wear. The Boeing damper has drawbacks such as adding extra freeplay and weight to the system. Both existing dampers are shown in Fig. 1 along the NLG schematic.

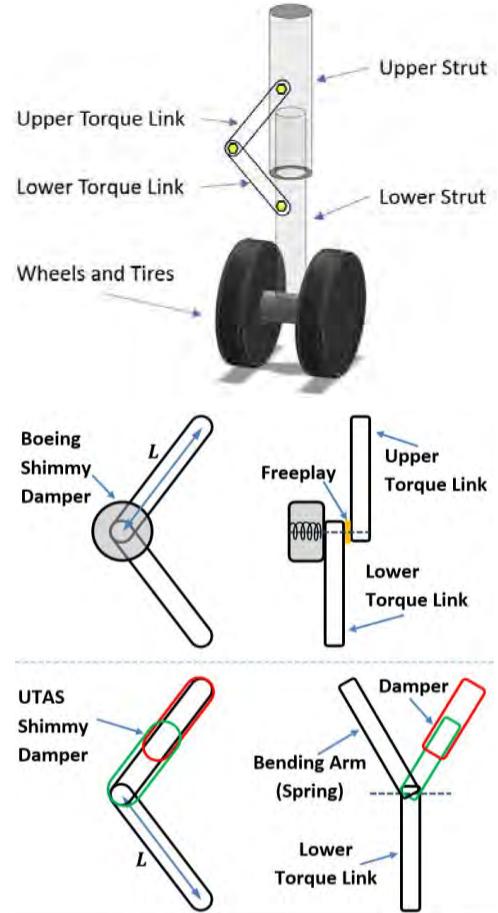

Figure 1. Schematic of the Nose Landing Gear (top), side and front views of Boeing damper (middle) and UTAS damper (bottom)

Inspired by the UTAS damper and aiming to address its shortcomings, the idea of the present design is to replace one of the torque links (here the upper one) by a flexible beam and accompanying dampers to help stabilize the NLG, while no unsymmetrical behavior is induced in the system.

## II. THE SYMMETRIC BEAM-BASED SHIMMY DAMPER

As shown in Fig. 2, the upper torque link in the proposed design includes a beam (shaded) at the center and two identical damping devices (here pure dampers) symmetrically arranged on either side. The lower torque link is assumed to be rigid. The beam is the load-bearing element of the upper torque link which acts as a spring in parallel to the side dampers as well.

In the event of shimmy, the lower part of the landing gear (tire and lower strut) tends to vibrate rotationally, hence deflecting the upper torque link. The dampers on either side experience a displacement as a result of the beam deflection. Fig. 3 depicts this effect in which the deflection of the beam at the torque link apex and its rate are designated as  $\varepsilon$  and  $\dot{\varepsilon}$ . The beam deflection and its rate at the damper attachment location are shown as  $\varepsilon_a$  and  $\dot{\varepsilon}_a$  respectively. Displacement of the right and left damping devices (measured along the device axis) are  $\lambda_1$  and  $\lambda_2$  with rates of  $\dot{\lambda}_1$  and  $\dot{\lambda}_2$  respectively.

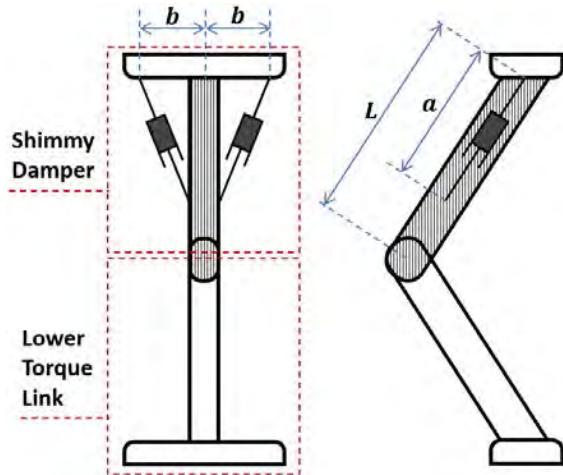

Figure 2. Schematic of the novel shimmy damper and lower torque link.  
Left: front view, Right: side view

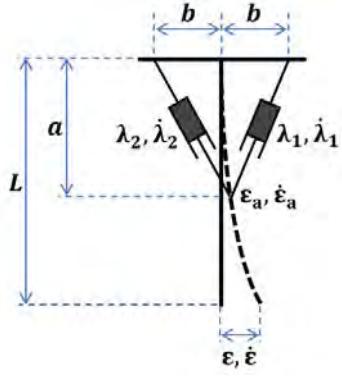

Figure 3. Schematic of the damper beam deflection and damper displacements

Here, the goal is to express the net damping force as a function of the system inputs which are  $\varepsilon$  and  $\dot{\varepsilon}$ . These two inputs are a function of the landing gear dynamics but here are treated as knowns. From the geometry of the design one can write:

$$\lambda_1 = \sqrt{a^2 + b^2 - 2b\varepsilon_a} - \sqrt{a^2 + b^2} \quad (1)$$

$$\lambda_2 = \sqrt{a^2 + b^2 + 2b\varepsilon_a} - \sqrt{a^2 + b^2} \quad (2)$$

and hence:

$$\dot{\lambda}_1 = -b\dot{\varepsilon}_a / \sqrt{a^2 + b^2 - 2b\varepsilon_a} \quad (3)$$

$$\dot{\lambda}_2 = b\dot{\varepsilon}_a / \sqrt{a^2 + b^2 + 2b\varepsilon_a} \quad (4)$$

The dampers generate forces along the damper axis which are proportional to  $\dot{\lambda}_1$  and  $\dot{\lambda}_2$ . However, only the components of these forces which are perpendicular to the beam are going to resist the beam deflection and hence alleviate shimmy. Therefore, we need to isolate the components of  $\dot{\lambda}_1$  and  $\dot{\lambda}_2$  which are perpendicular to the beam. These are designated as  $\dot{\bar{\lambda}}_1$  and  $\dot{\bar{\lambda}}_2$ . To find them we can write:

$$\dot{\bar{\lambda}}_1 = -\lambda_1(b - \varepsilon_a) / \sqrt{a^2 + (b - \varepsilon_a)^2} \quad (5)$$

$$\dot{\bar{\lambda}}_2 = \lambda_2(b + \varepsilon_a) / \sqrt{a^2 + (b + \varepsilon_a)^2} \quad (6)$$

After taking derivatives and simplifying:

$$\dot{\bar{\lambda}}_1 = -\dot{\lambda}_1 \frac{b - \varepsilon_a}{\sqrt{a^2 + (b - \varepsilon_a)^2}} + \lambda_1 \frac{a^2 \dot{\varepsilon}_a}{(a^2 + (b - \varepsilon_a)^2)^{3/2}} \quad (7)$$

$$\dot{\bar{\lambda}}_2 = \dot{\lambda}_2 \frac{b + \varepsilon_a}{\sqrt{a^2 + (b + \varepsilon_a)^2}} + \lambda_2 \frac{a^2 \dot{\varepsilon}_a}{(a^2 + (b + \varepsilon_a)^2)^{3/2}} \quad (8)$$

Assuming a viscous damper with the coefficient of  $C_d$  on each side, the total damping force can be expressed as:

$$Q = C_d \left( \dot{\bar{\lambda}}_1 + \dot{\bar{\lambda}}_2 \right) \quad (9)$$

The  $L$  and  $b$  dimensions are dictated by the geometry and strength of the torque links and existing gear design. However,  $a$  needs to be decided by the damper designer in a way to ensure maximum efficiency during the ground operations. Smaller  $a$  means the damping devices will be more perpendicular to the beam, but they will experience a smaller beam deflection. The opposite holds for a bigger  $a$ . Therefore, the optimal value of this parameter need to be determined for the range of inputs generated from the operation of the landing gear, which is the focus of the current study.

It is important to note that the beam deflection is affected by the damper force as well, as depicted in Fig. 4. Hence, the relationship between  $\varepsilon$  and  $\varepsilon_a$  (and their rates) is a function of both  $P$  and  $Q$  forces, where  $P$  is the force applied by the lower torque link. Through governing relationships of a beam with modulus of  $E$  and area moment  $I$  and assuming small deflections we can write:

$$EI\varepsilon = \frac{PL^3}{3} - \frac{Qa^2}{6}(3L-a) \quad (10)$$

$$EI\varepsilon_a = \frac{Pa^2}{6}(3L-a) - \frac{Qa^3}{3}. \quad (11)$$

Defining  $R_1 = \varepsilon_a / \varepsilon$  and  $R_2 = Q/P$  we will have:

$$R_1 = \frac{a^2(3L-a) - 2a^3R_2}{2L^3 - a^2(3L-a)R_2}. \quad (12)$$

Hence, the relationship between the beam deflection at the torque link apex and damper attachment location can be expressed through  $\varepsilon_a = R_1\varepsilon$ . For simplicity of the analysis, it is assumed here that the deflection rates are also related through the same ratio, i.e.  $\dot{\varepsilon}_a = R_1\dot{\varepsilon}$ , which is to assume that  $R_2$  does not vary significantly with time. Introducing  $R_1$  and  $R_2$  parameters allows us to optimize the performance while considering the effect of the damping force on the beam deflection, and without the need to directly estimate  $P$ , which is dictated by the NLG dynamics.

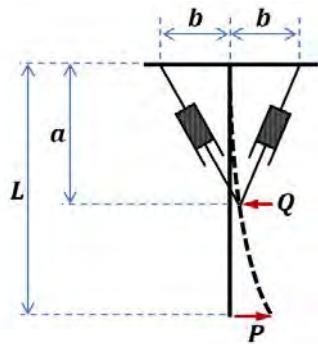

Figure 4. The forces applied to the beam

### III. PERFORMANCE ANALYSIS

The analysis is commenced by looking at the simpler case when the influence of damping force on the beam deflection is neglected, i.e.  $R_2 = 0$ . Later, we quantify the effect of this simplifying assumption. The geometry features of  $L = 0.4m$  and  $b = 0.25L$  are assumed as our demonstration case and will be used throughout the paper unless otherwise stated. The net damping force is depicted as a function of  $a/L$  in Fig. 5 with the optimal location (corresponding to the maximum damping force) marked as a star on each curve. For all cases that follow, unit damper coefficient and apex displacement rate ( $C_d = 1$ ,  $\dot{\varepsilon} = 1$ ) are used since the net damping force is a linear function of these parameters. From Fig. 5 one observes that the optimal damper location is a function of  $\varepsilon$ . However, for the practical range of  $0 \leq \varepsilon \leq 0.05m$  the optimal  $a/L$  only changes from 0.63 to 0.58. Therefore, one may choose  $a/L \approx 0.6$  for this case as a value which provides near-optimal performance for the intended range of operation.

Next, the effect of  $b$  parameter is demonstrated for a fixed apex deflection of  $\varepsilon = 0.01m$ . Again,  $R_2 = 0$  and damping force is shown in Fig. 6. Typically,  $b$  is not a design variable since it is dictated by the design of the gear to which the shimmy damper will be retrofitted. Nevertheless, it is beneficial to understand that a bigger  $b$  leads to a bigger optimal  $a/L$  and a larger damping force as shown in Fig. 6.

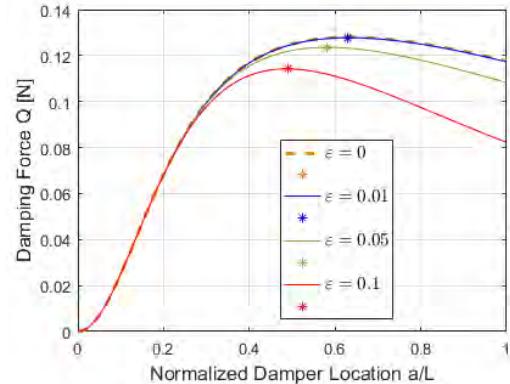

Figure 5. Damping force versus damper location for  $R_2 = 0$  and various  $\varepsilon$

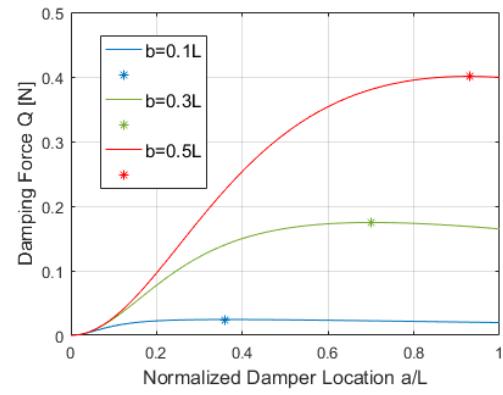

Figure 6. Damping force versus damper location for  $R_2 = 0$  and various  $b$

#### A. Effect of $R_2 = 0$ Assumption

To account for the effect of damping force on the beam deflection we need to understand the influence of  $R_2$  parameter on the predicted response. In practice, this value is non-zero due to presence of the damping force  $Q$ . In fact, we are dealing with a loop here: the calculation of damping force needs the accurate beam deformation and the beam deformation can be obtained by knowing the damping force. Hence, one may go through an iterative scheme to get the solution. Instead, here we calculate the solution for different values of  $R_2$  parameter which indicates how sensitive to the damping force the exact solution is.

In Fig. 7, the damping force and optimal damper location are depicted for various values of  $R_2$  for both small ( $\varepsilon = 0.01\text{m}$ ) and large ( $\varepsilon = 0.1\text{m}$ ) apex displacement values. As expected, it is observed that a non-zero  $R_2$  alters the estimated damping force curve and the optimal damper location. Hence, the optimal damper location is underpredicted when assuming  $R_2 = 0$ . However, for small values of  $R_2$  the difference is negligible, and one can proceed with the  $R_2 = 0$  assumption for initial concept design studies. Furthermore, the influence of  $R_2$  on the optimal damper location decreases as  $\varepsilon$  grows. This is key since performance at larger  $\varepsilon$  values should drive the design as it corresponds to severe shimmy situations.

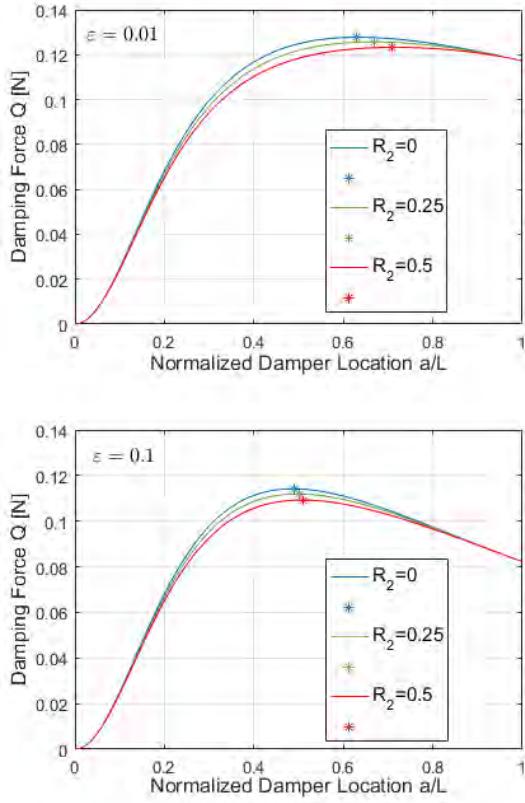

Figure 7. Damping force versus damper location for various  $R_2$ . Top:  $\varepsilon = 0.01\text{m}$ , bottom:  $\varepsilon = 0.1\text{m}$

#### IV. OPTIMIZATION

Using the analyses presented so far, we can arrive at a more complete picture of the optimal damper location for a given geometry and range of operation. Here the torque link dimensions are given as  $L = 0.4\text{m}$  and  $b = 0.25L$ . The torque link apex displacement  $\varepsilon$  is assumed to be in the  $0 \leq \varepsilon \leq 0.1\text{m}$  range. Fig. 8-top shows the optimal location versus  $\varepsilon$  for different values of  $R_2$ . Assuming  $R_2 = 0$  results in a smaller  $a_{\text{opt}} / L$  but the error can be acceptable considering the curves are converging as  $\varepsilon$  grows. For instance, in the case of a given shimmy-prone landing gear with maximum apex displacement of  $\varepsilon = 0.04\text{m}$  one can choose  $a_{\text{opt}} / L = 0.6$  (assuming  $R_2 = 0$ ) according to Fig. 8-top to ensure the damper performance is optimal for the maximum  $\varepsilon$  and near optimal (since the lines are not steep) for smaller values. Similar curves are plotted for different  $b$  values in Fig. 8-bottom. The predicted trend is that the  $a_{\text{opt}} / L$  is a function of  $\varepsilon$  but may be fixed at the value corresponding to the maximum  $\varepsilon$  in the operation range to ensure effective shimmy suppression. This embodies a worst-case scenario design strategy where the performance of the system is optimal for the severe shimmy case and near optimal for other cases. Although this decision is adequate for the initial concept design, one needs to perform more thorough analysis involving real inputs from the NLG to ensure shimmy is suppressed effectively.

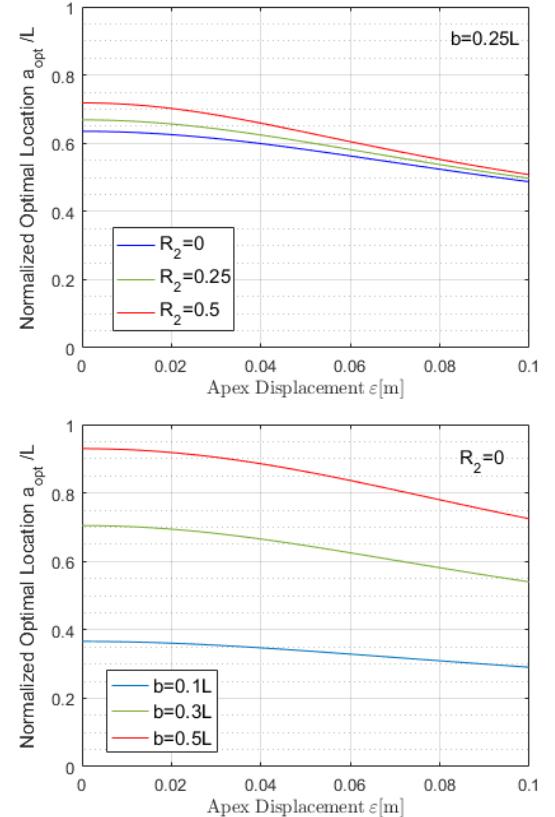

Figure 8. Optimal damper location versus  $\varepsilon$  for various  $R_2$  values (top) and various  $b$  values (bottom)

## V. CONCLUSIONS

A novel shimmy damper concept is featured in the current work and initial optimization studies are presented to ensure maximum efficiency of the damper for the most critical shimmy scenario. This damper is superior to the Boeing one in that it does not add freeplay and is easily retrofitted to existing gears. It also addresses the unsymmetrical response issue of the UTAS damper. The evidence of symmetric response of the damper based on dynamic simulation of the NLG equipped with the damper remains to be obtained, although the symmetric design of the device promises such performance.

The detail design of the beam and damping devices, as well as multi-disciplinary optimization studies require a computational dynamic model of the NLG such as [9] and [10]. The exact damping force can be estimated by adding the present damper model to the landing gear dynamic model which can provide the inputs in real-time. The damping force should also be fed back to the NLG system and the performance of the damper needs to be evaluated in ground operation simulations such as a landing scenario. Furthermore, more advanced combinations of springs, dampers, and inerters will be considered as damping devices to arrive at a more efficient and compact design. These ideas are under investigation by the authors and comprise the next steps of the present work.

**Abstract**— This paper covers a simple method of calibration for gas thrusters for the application of simulated space flight. Gas thrusters are a common means of controlling spacecraft, and proper calibration of such thrusters is essential to ensure accurate and stable control of the spacecraft. Satellite simulators attempt to replicate the behaviours of satellites in flight using a 3 degree of freedom air bearing table, which allows for frictionless flight, and gas thrusters to emulate the flight dynamics.

**Keywords**-gas; thruster; calibration; force; spacecraft; satellite; simulator

## I. INTRODUCTION

In the following we will cover the process of calibrating gas thrusters which are used to control satellite simulators on an air bearing table. The purpose of this is not to precisely determine the output force of the thrusters, but rather to ensure that each thruster outputs the same force. These satellite simulators utilize gas thrusters as their primary means of positional and attitude control. As the thrusters are only able to be toggled on or off during operations, with no adjustments to the amount of output force, the specific output of each thruster must be calibrated to be equal to allow for reliable control under continuous thrust output.

The simulator is a cube with 8 thrusters, each aligned to the horizontal plane, with two thrusters on each vertical face pointing outwards. In this configuration, motion in a straight line relative to a face is controlled by the two thrusters which are positioned in the opposite direction, and rotational maneuvers possible by firing alternating thrusters on each face. The thrusters utilize simple compressed air as propellant. The onboard air tank is charged to 20 Megapascals, this pressure is then reduced through two regulator valves to 0.4 Megapascals which is sent to the thrusters. If the two thrusters do not output the same force, then there will be a torque exerted on the simulator which causes it to turn.

## II. INSTRUMENTATION

To calibrate the thrusters, a means of detecting the output force is required. For this we utilized a digital force sensor with a magnetic mounting plate to attach the thruster and connected it via USB to a PC to record the measurements. The force sensor used here can resolve forces to an accuracy of 0.001 Newtons.

The thrusters themselves consist of a housing, which contains the actuator to toggle the output, and has a set of power cables running into the base, a set screw which allows the output to be adjusted, and an output nozzle. The set screw has an air inlet coupled with its connection to the housing.

The sensor is placed on a level surface, here using the air bearing platform which is precisely leveled. The sensor is oriented vertically, with the magnetic mount at the top, the thruster is then attached with the nozzle output oriented to either push or pull against the force sensor. Either orientation of the output will provide the same magnitude measurements, with reversed sign of the value. As the thrusters require the power and air lines to be connected to operate, additional lengths of both are added to remove tensional forces. The air line is then charged to the operating pressure as the line may move while it pressurizes. This configuration on the level surface allows us to easily consider the force due to gravity acting on the thruster and the connected lines and assume the only change in force measured is due to the thruster output. The sensor is then zeroed in this position.

## III. MEASUREMENTS

The sample rate for the sensor was set to 200 samples per second for a 10 second duration. Force measurements were taken for a 1-3 second duration with the thruster off, and it is then switched on for the remainder of the test. Fig. 1 shows a single set of data. There is a large spike in the measured force

when the thruster is switched from off to on, this is due to the actuation of the control valve in the thruster. This region of data is not included in the force determinations as it does not

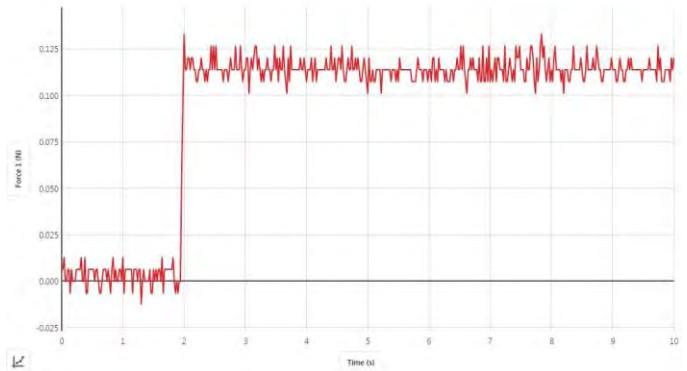

Figure 1. Force Output Data

represent the steady state output of the thruster.

The data is then averaged for both the off and on positions of the thruster, the averaging process reduces the contributions of noise and vibrations in the system due to the air flow generated by the thruster, thereby providing a more accurate representation of the steady state characteristics of the system. The average value for the off state of the thruster, representing the zeroing error and noise of the system, is then subtracted from the average value of the on state of the thruster. This final value represents the steady state output force of the thruster.

To calibrate each thruster to the same force, the performance envelope for each thruster nozzle first needs to be determined. Each nozzle is hand made and therefore has unique performance characteristics. The output force is measured with the setscrew at maximum and minimum in turn, which gives the range of pressures which are attainable with that thruster.

Following the determination of the performance envelopes and selection of thrusters to calibrate, an overlapping force is selected for each to be calibrated to, here being 0.065 Newtons. To reach this output each thruster is again mounted on the force sensor, the setscrew is adjusted slightly, and another set of measurements is taken. This process is repeated until the desired output force is reached, the setscrew is then locked in place with a nut. Table 1 shows the resulting calibration measurements.

TABLE I. FORCE CALIBRATION RESULTS

Thruster	Force Measurement		
	Measured (N)	Zero Error (N)	Force Output (N)
1	0.065	0	0.065
2	0.074	0.009	0.065
3	0.060	-0.005	0.065
4	0.068	0.003	0.065
5	0.066	0.001	0.065
6	0.073	0.008	0.065
7	0.065	0	0.065
8	0.067	0.002	0.065

#### IV. VERIFICATION

The final calibration of the thrusters is then able to be verified through a flight test of the satellite simulator system. The simulator is tasked to travel in a straight line and then stop. This requires 2 thrusters to be fired to begin moving, and then fire the 2 alternate thrusters on the same faces to bring the simulator to a stop. With the thrusters properly calibrated the simulator can perform this maneuver with no rotation occurring.

#### V. CONCLUSION

Gas thrusters are a common means of spacecraft control. Using this method of thruster calibration, the satellite simulator system can reliably demonstrate the dynamics of space flight, with stable control using gas thrusters. This method of thruster calibration proves to be simple and reliable for this application.

**Abstract**— Polymer nanocomposites have opened a new path for multifunctional materials. In particular, carbon nanotubes have the potential to be used in various applications. This study focused on the evaluation of thermal conductivity of epoxy/carbon nanotube composites using analytical modeling. The influence of the filler content, the geometry, the size, and the aspect ratio on thermal conductivity of the composite were discussed within the context of the studied models.

**Keywords** - *polymer nanocomposites; multi-walled carbon nanotubes; thermal conductivity; analytical modelling*

## I. INTRODUCTION

Polymer-based composites (PC) have received significant attention due to their promising potential in various applications. They are rapidly replacing traditional inorganic materials such as metals, and natural materials such as wood due to their superior physical and mechanical properties [1]. One of the promising applications involves the use of PC materials (e.g. thermoset or thermoplastic matrices with glass or carbon fiber reinforcement) in different structural applications such as aircrafts, ships and automobiles [2]. However, PC are usually flammable and have comparatively low resistance to fire. As such, a critical safety issue may arise when PC get exposed to fire resulting in failure and collapse of a structure, and hence causing injuries or even fatalities. Therefore, a research thrust has been emerging to improve the flammability properties of PC using nanofillers such as carbon nanotubes (CNT). Nanofillers with suitable morphology, distribution and dispersion act in the condensed phase akin to char forming flame retardants, that is, they create a thermal insulation and mass transport barrier for the underlying polymer, hence mitigating the creation and escape of gaseous fuel for combustion. In addition, nanofillers may greatly increase the viscosity of the polymer decomposition phase, thus inhibiting flow and drip-off, reducing the decomposition area available for combustion. Kashiwagi et al. [3] used multi-walled carbon nanotubes (MWCNT) as a fire retardant additive in polypropylene. They found that MWCNT significantly enhance the thermal stability of polypropylene in nitrogen atmosphere at high temperatures by greatly reducing the heat release rate of the polypropylene. However, in a different study, it was reported that an increase in MWCNT

concentration resulted in an increase in a peak heat release rate due to an increase in thermal conductivity of the nanocomposites [4]. While polymers have low thermal conductivity ranging approximately from  $0.2 \text{ W m}^{-1} \text{ K}^{-1}$  for amorphous polymers to  $0.5 \text{ W m}^{-1} \text{ K}^{-1}$  for highly crystalline polymers, CNT possess a thermal conductivity that is four order of magnitude higher ( $2000\text{-}6000 \text{ W m}^{-1} \text{ K}^{-1}$ ) [5]. Reducing the thermal insulation properties inherent to polymers may thus lead to reduced ignition times [4]. It is therefore necessary to gain a thorough understanding of the thermal response of nanocomposites, such as heat release rate, time of ignition and heat conduction, to evaluate their flammability and thus safety [2]. One of the main thermal-physical properties that controls the thermal response is thermal conductivity.

Many studies reported that the incorporation of CNT into a polymer matrix can lead to a certain enhancement of thermal conductivity of the CNT/polymer nanocomposites. Thermal conductivity is a phonon based mechanism influenced by many factors such as the thermal conductivity of each constituent, the shape, volume fraction, and the dispersion of nanofillers into the polymer matrix, as well as the interfacial thermal resistance between the filler and the polymer [6]. Manipulating one or more of these factors to observe the effect on the composite thermal conductivity might require a multitude of experiments. It is therefore imperative to find methods for estimating the thermal conductivity of the CNT/polymer nanocomposites and hence limit the number of experiments. Among these methods, analytical models supply closed-form expressions for the composite thermal conductivity. However, numerous analytical models have been proposed since the 19<sup>th</sup> century, and selecting the right model is not always straightforward.

The present paper reports on the modelling the thermal conductivity of epoxy composites filled with low content of MWCNT. Analytical models available in the technical literature were employed for this purpose, and their associated results were contrasted to experimental data from published studies. The aim of this work is explore the effectiveness of selected thermal conductivity prediction models and provide a perspective on the aforementioned factors and their significance when estimating the thermal conductivity of epoxy/MWCNT composites.

## II. REVIEW OF LITERATURE MODELS

A variety of analytical models have been developed to predict the effective thermal conductivity of a composite material. They range from simple expressions (e.g. rule of mixture models) to rather complex expressions, depending on the factors taken into consideration. In this section, the most expedient models, based on the authors' point of view, are discussed. The following notations are used:  $K_c$ ,  $K_m$ ,  $K_f$  are correspondingly the thermal conductivities (through-thickness direction) of the composite, polymer matrix and filler; and  $V_f$  is the filler volume fraction.

### A. Maxwell model [7]:

The Maxwell expression is one of the early models proposed to predict the thermal conductivity of a composite material. The model was developed in 1904 and it describes a system of dilute spherical particles embedded in a continuous matrix. The model neglects the thermal interactions between the filler particles and only accounts for the thermal conductivity of the constituents and the volume fraction of the dispersed spherical fillers as follows:

$$K_c = K_m \left( 1 - \frac{3V_f}{\frac{K_f - 2K_m}{K_f - K_m} - V_f} \right) \quad (1)$$

### B. Hamilton and Crosser model [8]:

Hamilton and Crosser improved the Maxwell expression by taking into account the effect of the geometry of the filler. They showed that for non-spherical fillers, there is a drastic increase in thermal conductivity of the composite provided that the discrepancy in thermal conductivity of the continuous phase and the dispersed phase is an order of 100 or more. Thus, they introduced an empirical shape factor,  $n$ , that accounts for such effect as follows:

$$K_c = K_m \left[ \frac{K_f + (n-1)K_m - (n-1)V_f(K_m - K_f)}{K_f + (n-1)K_m + V_f(K_m - K_f)} \right] \quad (2)$$

The shape factor,  $n$ , can be calculated using the following:

$$n = \frac{3}{\gamma} \quad (3)$$

where  $\gamma$  is the sphericity and it is defined as the ratio of the surface area of a sphere (with the same volume as the given particle) to the surface area of the particle.

### C. Lewis-Nielsen model [9]:

Even though the Lewis-Nielsen model does not consider the Kapitza or interface thermal resistance (ITR) between a filler particle and its surrounding polymer matrix, it was found to yield results that are in good agreement with measurements [9]. The model accounts for a wide range of filler and nanocomposite morphologies and can be described as follows:

$$K_c = \frac{1 + \left( \frac{K_f/K_m - 1}{K_f/K_m + A} \right) AV_f}{1 - \left( \frac{K_f/K_m - 1}{K_f/K_m + A} \right) \beta V_f} \quad (4)$$

where  $A$  is the shape coefficient of the filler particles and it depends on the particle's aspect ratio;  $\beta$  accounts for the type of packing of the particles and can be calculated by Eq.(5).

$$\beta = 1 + \left( \frac{1 - V_m}{V_m^2} \right) V_f \quad (5)$$

where  $V_m$  is the maximum packing fraction of the filler.

### D. Model by Deng et al. [10]:

Deng et al. developed a specific analytical model for predicting the thermal conductivity of CNT composites with low CNT loading. The model takes into consideration the effects of the thermal conductivity anisotropy, aspect ratio, non-straightness, interfacial thermal resistance, interaction, and either a random or aligned CNT distribution. The model can be written in the following form:

$$K_c = K_m \left[ \left( \frac{1}{3} \frac{\theta}{\frac{K_m}{\theta K_{33}^{cs}} + H(\theta p)} \right) V_f + 1 \right] \quad (6)$$

where

$$K_{33}^{cs} = \frac{K_{33}^c}{\left( 1 + \frac{2R_k K_{33}^c}{L} \right)} \quad (7)$$

$$H(\theta p) = \frac{1}{(\theta p)^2 - 1} \left[ \frac{\theta p}{\sqrt{(\theta p)^2 - 1}} \ln \left( \frac{\theta p}{\sqrt{(\theta p)^2 - 1}} \right) + \sqrt{(\theta p)^2 - 1} \right] \quad (8)$$

where  $\theta$  is the straightness ratio and is given by  $\theta = L^{ce}/L$ ;  $L^{ce}$  is the equivalent average straight length of carbon nanotubes;  $L$  is the average twisted length of carbon nanotubes;  $p$  is the aspect ratio and is given by  $p = L/d$  where  $d$  is the average carbon nanotube diameter;  $K_{33}^c$  is the equivalent longitudinal thermal conductivity;  $K_{33}^c$  is the axial thermal conductivity of the CNTs;  $R_k$  is the ITR.

## III. VALIDATION AND VERIFICATION OF MODELS

For the present study, experimentally determined thermal conductivity data for epoxy/MWCNT nanocomposites as a function of the filler volume fraction were obtained from the technical literature. The literature data collected for epoxy/MWCNT nanocomposites varied in their properties due to differences in the constituent materials used in composite fabrication and possibly also due to the measurement methods, the thermal conductivities of the composite were normalized with their respective thermal conductivity of neat epoxy. Table 1 lists the different epoxy/MWCNT nanocomposite systems that were adopted for this study.

TABLE 1. SUMMARY OF EPOXY/MWCNT NANOCOMPOSITES TAKEN FROM TECHNICAL LITERATURE AND USED IN THIS STUDY.

## IV. RESULTS AND DISCUSSION

Figure 1 depicts the normalized experimental thermal conductivity data for epoxy/MWCNT nanocomposites that were taken from the technical literature and used in the present study. The data is shown as a function of filler volume fraction. Notably, data from [11], [13] and [15], and the initial data point from [14] appear to collapse approximately onto a single straight line.

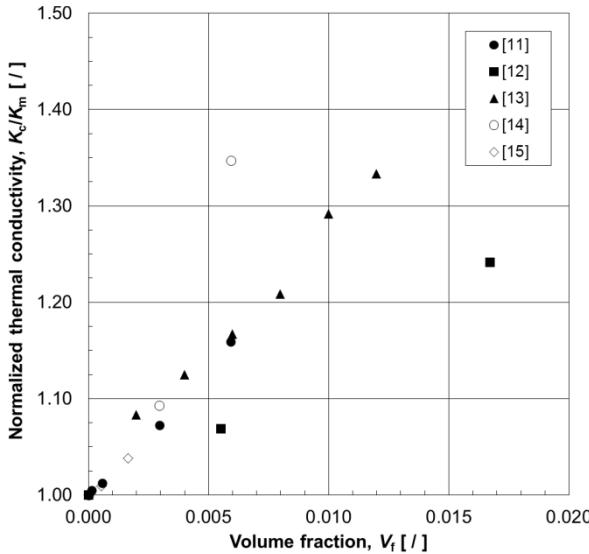

Figure 1. Normalized thermal conductivity of epoxy/MWCNT nanocomposites taken from technical literature.

An attempt was made to predict the experimental thermal conductivity data of nanocomposites shown in Fig.1. The models proposed by Maxwell [7], Hamilton and Crosser [8], Lewis-Nielsen [9] and Deng et al. [10] were employed for the predictions. Table 2 summarizes the parameter values that were used in this context. Figure 2 depicts the predicted values in terms of normalized thermal conductivity for the above models. Note that due to a lack of information on the filler morphology a filler straightness ratio  $\theta$  of 0.7 was specified for the analysis, which assumes a MWCNT with moderate curvature.

Figure 2 indicates that the Hamilton and Crosser model overestimates the experimental data. This behavior can be explained by analyzing the empirical shape factor function, Eq.(3), which was derived for geometries that deviate from sphericity ( $\gamma$ ) by as low as 0.5. In this study, the sphericity value was calculated to be 0.012, which clearly indicates that

Eq. (3) was used outside of their study range. However, the Hamilton and Crosser model can be modified by determining an empirical shape factor expression that accounts for the high aspect ratio of CNT. The Deng et al. model predicts thermal conductivity values that are higher than the experimental data from literature. Nevertheless, the Deng et al. model yielded predictions that are closer to experimental data than the Hamilton and Crosser model. It should be noted that the model by Deng et al. is rather comprehensive in the sense that it accounts for various nanocomposite morphology factors, i.e., ITR, aspect ratio, size and geometry.

In contrast, the Maxwell and the Lewis-Nielsen models underestimate the literature data. The Maxwell model was developed for spherical fillers and ignored the effect of the ITR, the filler shape and aspect ratio. According to Nan et al. [18], the aspect ratio of CNT has a strong impact on the thermal conductivity of a composite. A large aspect ratio of CNT will minimize the amount of polymer matrix in between fillers, which results in an increased thermal conductivity by reducing the ITR as the probability of direct CNT contact increases [18]. Therefore, the Maxwell model cannot effectively predict fillers with high aspect ratios especially at higher volume fractions.

An attempt was made to adjust the predictive models for the two models closest to the experimental data, i.e. Deng et al. model and the Lewis-Nielsen model. The Deng et al. model prediction was modified by adjusting the filler straightness ratio  $\theta$  while keeping other parameters constant. A straightness ratio of  $\theta=0.4$  was implemented, which is lower than the initially assumed value of 0.7. A lower  $\theta$  signifies that the CNT dispersed in the polymer matrix are not straight but rather curved. In an experimental study, an effort could be made to quantify the CNT straightness in nanocomposite samples using e.g. transmission electron microscopy.

TABLE 2. PARAMETERS USED FOR THERMAL CONDUCTIVITY PREDICTIONS.

Parameter	Value	Reference
Average $K_m$ (W m <sup>-1</sup> K <sup>-1</sup> )	0.22	
$K_f$ (W m <sup>-1</sup> K <sup>-1</sup> )	3000	Table 1
Average length (μm)	17	
Average diameter (nm)	16	
Shape coefficient $A$	8.38	[9]
$V_m$	0.52	[9]
$K_c^{33}$	3000	[16]
$R_k$ (m <sup>2</sup> K W <sup>-1</sup> )	8.30E-08	[17]
$\theta$	0.7	Assumption

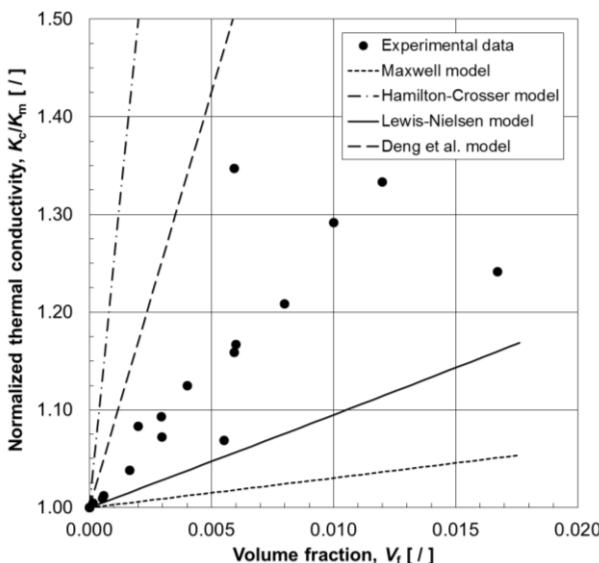

Figure 2. Normalized data for predicted thermal conductivity and experimental values as a function of filler volume fraction.

Similarly, the Lewis-Nielsen model prediction was adapted by changing the shape coefficient,  $A$ , as it is the most sensitive parameter in the model. Setting  $A = 26$  yielded values that matched the adjusted prediction based on the Deng et al. model. However, for the sake of clarity,  $A$  was set to 24 so that the reader can distinguish between the two models shown in Fig.3. For the considered filler volume fraction, these findings indicate that the filler geometry and aspect ratio play a critical role for the accurate prediction of thermal conductivity of polymer nanocomposites as demonstrated by adjusting respective parameters for both the Deng et al. and Lewis-Nielsen models.

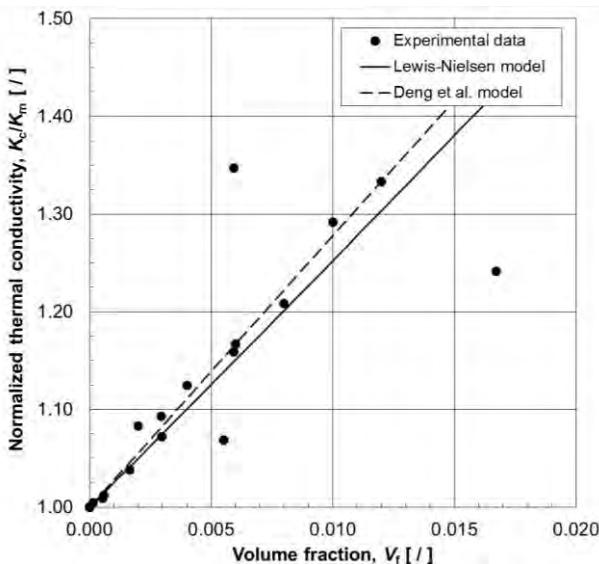

Figure 3. Normalized thermal conductivity predictions from the Lewis-Nielsen and Deng et al. models with adjusted filler morphology parameters, compared to experimental data.

## V. CONCLUSIONS AND RECOMMENDATIONS

In the present study, models for the prediction of the thermal conductivity of epoxy/MWCNT nanocomposites were examined. A set of prevalent analytical models and experimental data were selected from the technical literature. All models indicated an increase in thermal conductivity with increasing filler loading. For the range of filler volume fractions studied the following conclusions were derived.

- The Maxwell model strongly underestimated the thermal conductivity for epoxy/MWCNT nanocomposites. This model was developed for spherical fillers and is therefore limited in its ability to predict the thermal conductivity of high aspect ratio fillers.
- The Hamilton and Crosser model strongly overestimated the thermal conductivity of epoxy/MWCNT nanocomposites, which is due to a shape factor function that is incompatible with high aspect ratio CNT fillers.
- The Lewis-Nielsen model and the Deng et al. model yielded the most favorable predictions. Results from models could further be improved by adjusting the shape factor and filler straightness ratio, respectively.
- In general, it was observed that the parameters related to the filler morphology (e.g. aspect ratio, curvature) have a strong influence on thermal conductivity predictions. Predictions are less sensitive to the physical properties of the constituents such as their individual thermal conductivities.

# Application of FBG Optical Sensors to In-situ Monitoring the Thermo-mechanical Behaviour of Cold Spray Coated Samples

Bahareh Marzbanrad, Farid Ahmed, Hamid Jahed, Ehsan Toyserkani  
MME Department, University of Waterloo  
Waterloo, Canada

**Abstract**— In this research, a fiber Bragg grating (FBG) sensor is employed for monitoring thermal and mechanical strain induced by severe plastic deformation during high thermal and mechanical strain rate of cold spray technique. The FBG sensors are embedded in magnesium alloy substrates and the strain evolutions of the substrates are recorded during the cold gas spray coating process. In these experiments, the localized transient thermo-mechanical strain induced in the close vicinity of the substrate surface is monitored. Qualitative analysis of the complicated spectra shapes obtained during coating and cooling processes demonstrates the repeatability and sensitivity of the sensors in this condition. In addition, the obtained result from FBG sensors reveals the existence of compressive strain in the substrate near the interface during peening; however, it is released after a few second because of the high impact temperature of cold spray coating.

**Keywords-** *FBG Sensor; Cold Gas Spray; Magnesium alloy*

## I. INTRODUCTION

The FBG sensors have been employed for sensing the different stimulus such as strain, temperature, pressure, and vibration, because of the unique advantages (small size, immunity to external interferences, ability to operate in harsh environmental conditions, etc.) over other commercial sensors. The optical measurement is safe and superior over electrical one for wide range of applications in harsh environments such as lightening, high electromagnetic fields and in temperature ranging from cryogenic environments to high temperatures of up to 1000°C [1-3]. FBG is typically constructed by writing periodic index modulation in the core of an optical fiber, which may later be coated with acrylate, polyimide, or organic modulated ceramic for specific application [4]. The grating works as an invisible reflector that reflects only certain wavelengths of light [5]. Deformation of a grating device in presence of external stimulus is represented by wavelength shifts, which can be recorded by an interrogator. If the deformation across the grating part is not uniform (e.g. localized loading), the reflected wavelength shape appears to be asymmetric. Such asymmetric behavior of FBG spectrum can be analyzed to quantify the thermal/mechanical strains. With the recent advancement in optical data acquisition systems, FBG sensors are able to record data (the wavelength changes) with high frequency. Hence, the FBG sensors are

ideal candidates for the measurement of localized high temperature and high strain rate; a new application for FBG sensor that needs to be addressed.

Cold gas spray is a method of coating in which, high velocity particles impact a surface and create a layer of solid-state coating [6, 7]. Adiabatic shear deformation of the particles upon impact generates the localized heat and shear deformation at the contact area of the powder and substrate, which leads to mechanical and/or metallurgical bonding. Based on the cold spray mechanism, thermal softening and work hardening are in competition; since 90% of impact kinetic energy is dissipated as a heat in less than 100 ns, thermal softening may occur rather than work hardening [8]. Although the cold spray should be a low temperature coating method, the generated heat during impact process may cause to relieve the beneficial residual stress due to peening process and microstructural changes, which needs to be considered. However, it may depend on coating and substrate material characteristics. This is a special localized high temperature and fast deformation phenomenon that can be observed in situ by using a FBG sensor.

In this study, we investigate the capability of FBG sensor for revealing the localized residual stress development in magnesium during the cold spray coating process. A FBG with grating length of 4 mm was embedded in the magnesium sample; however, the phenomena happen over a few hundred microns below the substrate surface. Therefore, only a small part of the FBG was under stress. The goal of this research is to study the dynamic deformation of the substrate as well as temperature changes simultaneously. They determine the equilibrium situation of the magnesium grains, which may cause compressive or tensile residual stress and localized heat effects such as stress relief.

### *A. Response of FBG sensor to the localized external stimulus*

During the experiments, any mechanical and/or thermal strain changes can shift the reflected wavelengths of the FBG sensors, which can be recorded by an interrogator. In this research, Sm125-200 with one optical channel, and the wavelength accuracy of 10 pm was employed.

The relationship between the wavelength shifts, strain, and temperature changes is specified according to the following equations:

$$\varepsilon = \frac{1}{K} \left( \frac{\Delta\lambda}{\lambda_0} - \alpha_\delta \times \Delta T \right) \quad (1)$$

$$\varepsilon = \varepsilon_m + \varepsilon_T \quad (2)$$

$$\varepsilon_T = \alpha_{sp} \times \Delta T \quad (3)$$

$$\alpha_\delta = \frac{\delta n/n}{\delta T} \quad (4)$$

where,  $\Delta\lambda$  is the wavelength shift,  $\lambda_0$  is the base wavelength at test start,  $k$  is the gauge factor,  $\varepsilon$  is the total strain caused by force ( $\varepsilon_m$ ) and temperature ( $\varepsilon_T$ ),  $\alpha_\delta$  is defined by the change of the refractive index with temperature,  $\alpha_{sp}$  is the expansion coefficient of the sample ( $1/\text{K}$ ), and  $\Delta T$  is the temperature change ( $^{\circ}\text{K}$ ). For measuring temperature, a type K thermocouple (300  $\mu\text{m}$  wires) was attached to each sample; hence, it would be able to detect the temperature of substrate surface during coating process. The FBG was used to record the strain developed in the sample. However, if the FBG sensor experiences a non-uniform strain over the grating length, the response of the sensor will be different. For instance, if only a part of the grating experiences the strain while the rest remains unresponsive to the phenomenon, the spectral response comes only from the sensor length that is exposed to the strain. In this case, the sensor works as two individual in-line FBGs with different grating periods. Based on the optomechanical model proposed by Alemohammad *et al.* [9], the spectra of the FBG sensor was simulated when distributed strain was applied over the grating length of FBG sensor. The optomechanical model was employed to illustrate the response of the FBGs to localized strain. For instance, it was assumed that an external stimulus applied tensile stains of 0.001 and 0.002 over 200  $\mu\text{m}$  length of the 10 mm grating (Fig 1). Based on the simulation, the main wavelength peak of the sensor before applying the strain was a single peak with high intensity (black spectrum) (Fig 1-b). However, the induced strain created a lopsided peak at the right side of the main peak, while the intensity of the original peak was decreased. Increasing the strain from 0.001 to 0.002 led to significant lopsided peak shifts compared to the previous case. Therefore, it is predicted that in case of the localized strain on a small part of the grating, the main spectrum will be split to lopsided peaks and the position of the peaks is proportional to strain amplitude.

## II. EXPERIMENTAL PROCEDURES

In this study, three AZ31B-H24 Mg alloy samples with 4mm thickness were used for in-situ strain and temperature measurement. Properties of the Mg alloy can be found in [10]. The shape of samples is shown in Fig 2-a. For these tests, the specimens were finely polished to minimize surface roughness.

### A. Sample preparation

An initial step in developing a smart Mg alloy structure is specimen layout in a way that it would be enabled to accommodate the FBG sensors, respecting to the location of sensing the strain and temperature in the sample during the cold spray tests. Since the maximum strains are induced around 100  $\mu\text{m}$  below the substrate surface due to peening process, the grating needs to be embedded very close to the surface for optimum outcome. For this, two different embedding positions of the optical sensors were considered so that the propagation axis of the fiber makes an angle of 90° or 45° with the substrate surface. Three different holes were drilled in the samples. Two holes with a diameter of 700  $\mu\text{m}$  was drilled at the angle of 90° and 45° relative to the substrate surface for embedding the FBGs, while the 1mm hole was drilled in the sample for embedding the thermocouple. Fig 2-a shows the positions of thermocouple and FBG sensors in the samples. After drilling the holes, all the samples were heat treated in order to relieve the induced stress during manufacturing and preparation of the samples. The heat treatment process was conducted at a temperature of under 260°C (500°F) for 15 minutes, followed by air-cooling [11].

### B. Preparation of the FBG sensors

In this work, 10 mm long FBG sensors inscribed in Corning SMF-28 optical fiber with initial center wavelengths of 1540 nm and 1560 nm were utilized (Fig 2-b). To have more precise results, the polyimide jacket was removed from the grating part of the FBG sensors before embedding inside the magnesium alloy sample's holes.

Then, the bare FBG sensors were accommodated in such a way that the 4mm length of grating was placed inside the holes and the rest was out of the sample. High temperature EPO-TEK 353ND adhesive was used for embedding the sensors and thermocouple. To cure the epoxy resin, the samples were heated at 150°C for an hour using an electric furnace. Fig 2-c shows the setup of the sample with embedded sensors and thermocouple. After embedding the sensors and curing the resin, the 6mm extra part of the grating were cut and gently polished with 800-grit sandpaper.

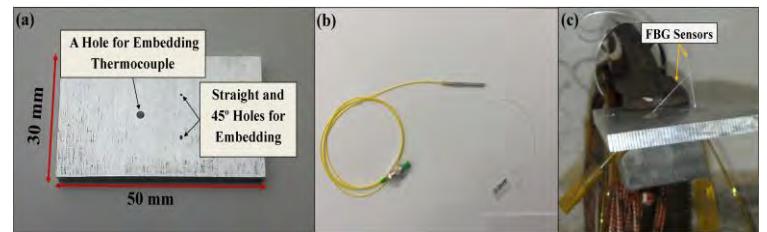

Fig 2: a) AZ31B-H24magnesium alloy sample; b) Corning SMF-28 FBG sensor; c) Test sample setup of embedding the sensor with thermal epoxy

Fig 3-a illustrates the reflected spectrum of one of the sensors, which demonstrates the initial center wavelength of 1560 nm before embedding the sensor. After embedding, the shape of spectrum was completely rough-and-tumble and the peak broadening was also observed (Fig 3-b). Moreover, the intensity of the peak was changed after curing process. Fig 3-c shows the spectrum changes after cutting and polishing the extra part of the sensor. As seen, the spectrum became narrower after cutting in comparison to the same sensor after embedding.

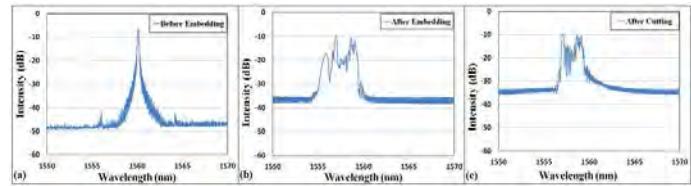

Fig 3: FBG spectrum, a) before embedding; b) after embedding with thermal epoxy; c) after cutting and polishing the sensor

### C. Cold spray process

A commercial Cold Spray system (SST Series P) manufactured by Centerline was used to deposit spherical commercial Al7075 powder (supplied by Centerline) with the mean particle size of 23 $\mu\text{m}$  (measured by Retsch technology, Camsizer XT) on the smart magnesium alloy samples. The chemical compositions of Al7075 powders are listed in Table 1. Al7075 powders were accelerated through the De Laval UltiLife TM Nozzle with reciprocating movement on the samples. To create a coating layer of aluminium with 300  $\mu\text{m}$  thickness, low porosity and high hardness, the Nitrogen gas was used with stagnation pressures of 200 Psi and temperatures of 400°C to produce the suitable particles velocity. For more clarification, all requirement parameters for conducting the relatively high quality of coating by cold spray deposition are listed in Table 2.

Table 1: Chemical compositions of Al7075 coating powders

Composition	Aluminum (Al)	Zinc (Zn)	Iron (Fe)	Nickel (Ni)	Chromium (Cr)	Copper (Cu)	Magnesium (Mg)	Other Elements
Weight %	90	5.20	0.35	0.005	0.25	1.55	2.35	0.30

Table 2: Cold Spray Coating Parameters [12]

Flow Gas	Nitrogen
Gas Temperature	400 °C
Gas Pressure	200 Psi (1.4 MPa)
Powder Feed Rate	8 gr/min (5 rpm)
Nozzle Speed	2 mm/s
Step Over	1.2 mm
Stand-off Distance	12 mm
Nozzle Type	De Laval UltiLife TM
Nozzle Length	120 mm
Nozzle Orifice	2 mm
Nozzle Exit Diameter	6.3 mm

### III. RESULTS AND DISCUSSION

In-situ monitoring of mechanical and thermal strain was implemented during the cold spray coating process through embedded FBG sensors in Mg alloy substrates. Response of FBG sensors to axial deformation (extension or contraction of the gratings) due to thermal and/or mechanical stimulus is a linear wavelength change; an increase in grating period due to elongation of the fiber causes a red shift (higher wavelength) of the central wavelength and vice versa [13, 14]. Fig 4 shows a set of critical spectrums obtained at different nozzle positions during cold spraying for three different embedded samples. It should be noted that during the cold spray experiments, only the responses of sensors embedded at a 45° directions were recorded. In all of the tests as shown in Fig 4-a, the first curves reveal the response of the sensors after embedding (before running the cold spray tests). When the nozzle approached the sensors, peak broadening and spectral red shift were observed (Fig 4-b). In this condition, thermal strain leads to the shifting and broadening of the spectrums. The asymmetric spectra of the sensors were generated because of the non-uniform strains induced along the grating length. The spectra were expanded towards higher wavelengths, which emphasized on elastic strains accumulation close to the substrate surface. With decreasing the distance between nozzle and sensors, more stretching and shifting of spectrums expected. However, with placing the nozzle exactly above the sensors, in spite of higher predicted temperature due to the adiabatic shear instability for particles/substrate bonding, the peaks narrowing were observed while the main peaks still showed more transition to the right (Fig 4-c). This shape change of spectrum uncovers that a significant compressive residual stress is developed in the surface and as a consequence, a compressive strain is induced by peening and severe plastic deformation during the deposition, diminishing the effect of thermal expansion. This observation clarified the contrast between the peening effect and temperature deviation. After passing the nozzle the peaks became broaden and shifted even further to the right where the sign of compressive strains was no more observable. This indicates that the induced stress weakened in the substrate in a few second. Fig 4-e shows the shape of the spectrums after the cold spray tests were completed and the Mg alloy samples reached to the room temperature. The shapes of spectrums became narrow; however, the peaks were shifted to the right compare to the very initial spectrums (Fig 4-a). For Test #2 before recording the spectrum after cold spray at room temperature, the FBG failed; hence, the spectrum was not recorded. It should be noted that during the experiments the temperature of samples were recorded by thermocouples, simultaneously. The results obtained from the thermocouples showed that the substrates' temperature was increased up to 330°C [15], while the annealing temperature of magnesium alloy AZ31B is about 260°C that confirmed the results obtained from FBG sensors, which demonstrated the relieving stress. Fig 5 shows the magnesium alloy sample embedded with two FBG sensors and thermocouple after conducting the cold spray coating tests.

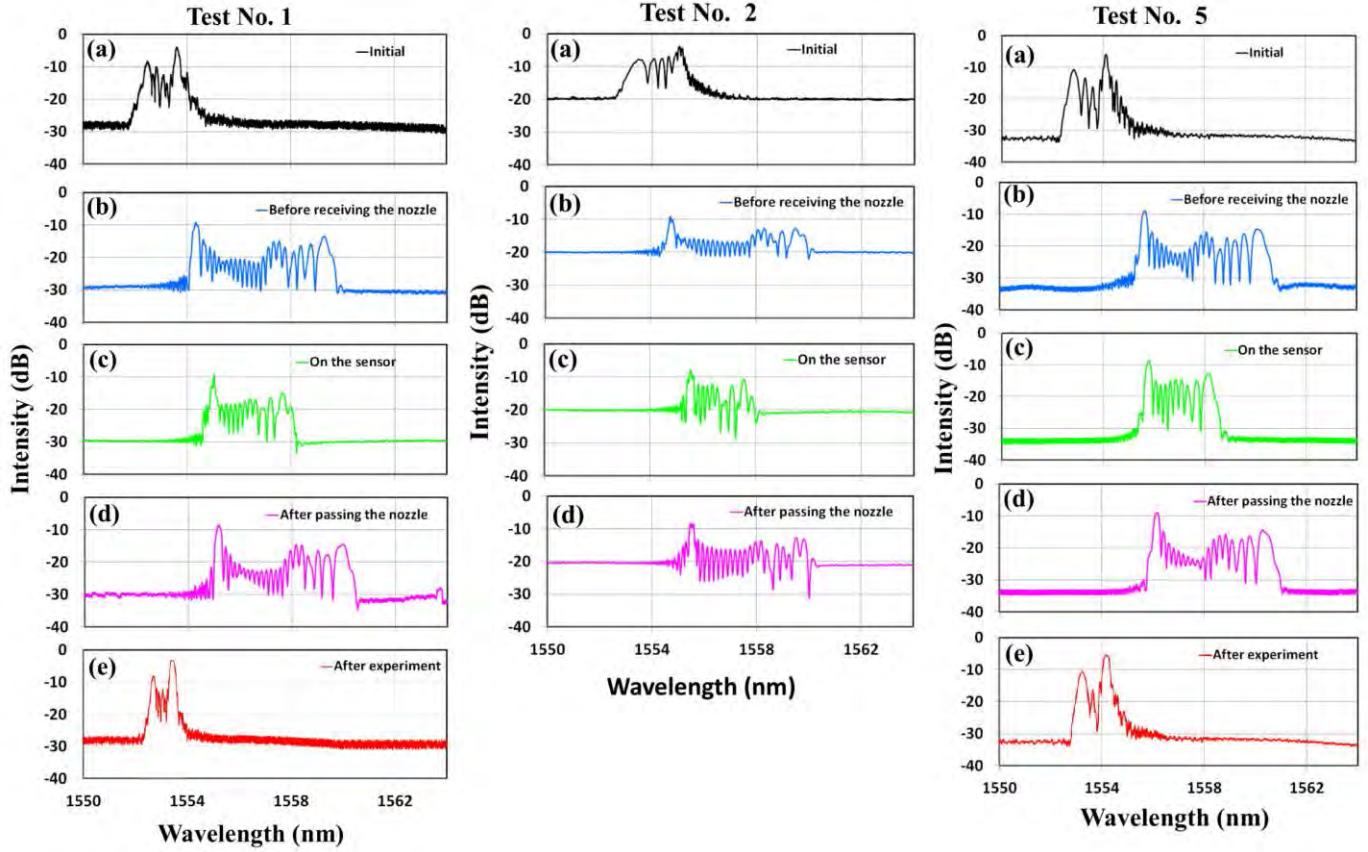

Fig 4: The spectrums of FBG sensors for three different tests in five different situations: a) after embedding a sensor; b) during coating at 10mm distance from the nozzle; c) coating on the sensor; d) at 10 mm after passing the nozzle; e) after coating at RT.

Fig 5: Smart magnesium alloy tested sample after cold spray coating test

For more clarification, the bandwidths and shifts of spectrums at different locations were measured: 1) before conducting the cold spray tests; 2) before receiving the nozzle to the tip of the sensor location; 3) where the nozzle was on the tip of sensors; 4) after passing the nozzle; and, 5) after the cold spray tests were completed and the part arrived at room temperature. The bar graphs in Fig 6-a depict the changes of spectrum bandwidth during the experiments. Usually, the bandwidth of the reflection peak is defined by Full-Width-Half-

Maximum (FWHM), which is the width of 50% of the main peak. In addition, the averages of the widths for all experiments in each situation were added to the bar graphs. Based on the measurements, for all experiments when the nozzle was on top of the sensor the bandwidths of spectra were decreased, significantly, while before and after receiving the nozzle during the cold spray the bandwidths were increased due to the raise in temperature.

In addition, the wavelength shifts during the experiments and after the cold spray tests at room temperature were measured (see Fig 6-b). Based on the observations, the wavelengths shifted to the right noticeably, during the experiments because of increased temperature; however, subtle shifts occurred at different situations during the tests. After conducting the cold spray tests, a significant amount of wavelengths shifts observed in all samples (yellow bars in Fig 6-b), which indicates the existence of tensile strains. These results highlight the effect of temperature due to carrier gas and adiabatic shear deformation on the evolution of tensile strains in the coated samples. It is noticeable that the stress relief process releases the residual elastic energy of the material while in these cases, not only the compressive stresses due to peening process were relieved, but also tensile residual strains were imposed in the substrates. This can be explained by

considering the thermal mismatch strain of the Al7075 coating and AZ31B-H24 substrate, which created tensile residual strain during the cooling process (after coating).

b) Wavelength shifts for different situations in three tests

#### IV. CONCLUSION

In this research, the capability of FBG sensors for detecting the localized thermal and mechanical strain induced in cold spray coated magnesium alloy is investigated. Localized increase in temperature and distributed deformation in a small area below the surface was implemented through the cold spray coating process. To this end, the FBG sensors were embedded in a magnesium alloy substrates and responses of the sensor recorded during the coating process. This observation revealed that the FBG sensor is able to tolerate the thermal and mechanical impact of the cold spray coating and detect the high mechanical and thermal strain rate during the process. In addition these experiments demonstrated that a compressive residual stress was induced in the substrate during coating, but it was relieved after a few second, which could be an evidence for stress relief of the magnesium alloy substrate due to the coating temperature.

**Abstract**—Anisotropic elastic/plastic plate bifurcation is investigated. The pre-bifurcation loading consists of biaxial stresses along  $\xi\nu$  axes parallel to the sides of a simply supported rectangular plate:

$\sigma_{vv} = \alpha\sigma_{\xi\xi}$ ,  $-1 \leq \alpha \leq 1$ . The  $\xi\nu$  axes are at an angle  $\beta$  with the  $xy$  principal axes of anisotropy. Analytical variational method is used together with Hill's theory of anisotropic strain-hardening plasticity. Bifurcation stresses are determined for the anisotropic, and the classical isotropic incremental and deformation theories of plasticity, for equibiaxial compression ( $\alpha = 1$ ), equal compression and tension ( $\alpha = -1$ ), and uniaxial ( $\alpha = 0$ ) cases. The plastic plate buckling paradox is examined for each of the cases.

**Keywords**—anisotropic plastic bifurcation, isotropic plastic bifurcation (incremental, deformation), buckling paradox

## 1. INTRODUCTION

The plate plastic buckling paradox originated from the work of Handelman and Prager [1]. They found that the bifurcation stresses predicted by the isotropic Mises incremental theory, the “correct” theory of strain hardening plasticity, were absurdly higher than those from the “incorrect” deformation theory of plasticity. Experiments generally favour the predictions of the deformation theory. Hence, the plastic plate buckling paradox: a correct theory yields the wrong results, while an incorrect one gives the right results. Onat and Drucker [2] explained the paradox by showing that by taking “unavoidable” out-of-plane geometric imperfection into account in a nonlinear growth analysis of a plate, the incremental theory gives maximum loads matching the deformation theory bifurcation loads. The growth analysis is quite complicated, and can only be done numerically; efforts have been made to lower the buckling loads of the incremental theory by various means, but without success.

Here, a bifurcation analysis for plate buckling is performed by considering the anisotropic behaviour of the plate material. For this purpose Hill's incremental theory [3] for anisotropic strain hardening of sheet metals is used. The  $x$  principal axis of anisotropy is taken as the rolling direction;  $y$  is the transverse principal axis. These anisotropy axes are assumed to remain fixed, uninfluenced by the loading of the plate for bifurcation. Plane stress conditions are assumed to prevail. The loading is biaxial  $\sigma_{vv} = \alpha\sigma_{\xi\xi}$ ,  $-1 \leq \alpha \leq 1$ , with  $\xi\nu$  axes parallel to the sides of the rectangular plate, simply supported at  $\xi = 0, a$  and at  $\nu = 0, b$ . The  $\xi\nu$  axes are at an angle  $\beta$  (which may or may not be zero) with respect to the  $xy$  principal axes of anisotropy. Three cases are considered: (1) equibiaxial, (2) equal compression tension, and (3) uniaxial compression. The anisotropic bifurcation stresses are compared with those from the isotropic incremental and deformation theories of plasticity.

## 2. ANISOTROPIC CONSTITUTIVE RELATIONS

The stresses along the anisotropy axes are

$$\begin{aligned}\sigma_{xx} &= \sigma_{\xi\xi} \cos^2 \beta + \sigma_{vv} \sin^2 \beta \\ \sigma_{yy} &= \sigma_{\xi\xi} \sin^2 \beta + \sigma_{vv} \cos^2 \beta \\ \sigma_{xy} &= (\sigma_{\xi\xi} - \sigma_{vv}) \cos \beta \sin \beta \\ \sigma_{yx} &= (\sigma_{\xi\xi} - \sigma_{vv}) \cos \beta \sin \beta\end{aligned}\tag{1}$$

The anisotropic yield criterion of Hill [3] is

$$2f(\sigma_{ij}) = (G + H)\sigma_{xx}^2 + (F + H)\sigma_{yy}^2 - 2H\sigma_{xx}\sigma_{yy} + 2N\sigma_{xy}^2 = 1\tag{2}$$

where

$$G + H = \frac{1}{X^2}, F + H = \frac{1}{Y^2}, 2H = \frac{1}{X^2} + \frac{1}{Y^2} - \frac{1}{Z^2}, 2N = \frac{1}{T^2}.$$

$X, Y, Z$  and  $T$  are the current direct and shear yield stresses.

For isotropy  $Z = Y = \sqrt{3}T = X$ .

Normality rule gives the plastic strain increments:

$$d\epsilon_{ij}^P = d\lambda \frac{\partial f}{\partial \sigma_{ij}} \text{ where } d\lambda = dW^P = \sigma_{ij} d\epsilon_{ij}^P. \text{ Explicitly:}$$

$$\begin{aligned} d\epsilon_{xx}^P &= dW^P \{(G\sigma_{xx} + H(\sigma_{xx} - \sigma_{yy}))\}, \\ d\epsilon_{yy}^P &= dW^P \{(F\sigma_{yy} - H(\sigma_{xx} - \sigma_{yy}))\}, \\ d\epsilon_{zz}^P &= -dW^P (G\sigma_{xx} + F\sigma_{yy}) \\ d\epsilon_{xy}^P &= 2dW^P N\sigma_{xy}, d\epsilon_{yz}^P = 0, d\epsilon_{zx}^P = 0 \end{aligned} \quad (3)$$

The elastic increments, assumed isotropic, are

$$d\epsilon_{ij}^E = \frac{1+\nu}{E} d\sigma_{ij} - \frac{\nu}{E} d\sigma_{kk} \delta_{ij}, d\epsilon_{ii}^E = \frac{1-2\nu}{E} d\sigma_{kk} \quad (4a)$$

$$d\sigma_{ij} = \frac{E}{1+\nu} \{d\epsilon_{ij}^E + \frac{\nu}{(1-2\nu)} d\epsilon_{kk}^E \delta_{ij}\} \quad (4b)$$

The total strain increments, elastic plus plastic, are

$$d\epsilon_{ij} = \frac{1+\nu}{E} d\sigma_{ij} - \frac{\nu}{E} d\sigma_{kk} \delta_{ij} + dW^P \frac{\partial f}{\partial \sigma_{ij}} \quad (5)$$

Now, as defined by Hill, the equivalent stress and the equivalent plastic strain increments are:

$$\sigma_{eq} = \sqrt{\frac{3}{2} \frac{h^2}{(F_0 + G_0 + H_0)}}, d\epsilon_{eq}^P = \sqrt{\frac{2(F_0 + G_0 + H_0)}{3h^2}} dW^P \quad (6)$$

where  $F_0, G_0, H_0$  and  $N_0$  are related to the initial yield stresses in direct and shear stresses, and

$$h = \sqrt{(F_0 + H_0)\sigma_{yy}^2 + (G_0 + H_0)\sigma_{xx}^2 - 2H_0\sigma_{xx}\sigma_{yy} + 2N_0\sigma_{xy}^2} \geq 1 \quad (7)$$

is the non-dimensional hardening function, assumed common for all yield stresses:

$$\begin{aligned} X &= hX_0, Y = hY_0, Z = hZ_0, T = hT_0 \text{ or,} \\ F_0 &= h^2 F, G_0 = h^2 G, H_0 = h^2 H, N_0 = h^2 N. \end{aligned} \quad (8)$$

Also

$$dW^P = \sigma_{mn} d\epsilon_{mn}^P = \sigma_{eq} d\sigma_{eq} \frac{d\epsilon_{eq}^P}{d\sigma_{eq}} = \frac{d(\sigma_{eq}^2)}{2} \frac{(\lambda - 1)}{E} \quad (9)$$

where  $\lambda = E / E_t$ ,  $E$  and  $E_t$  are the elastic and tangent moduli from a uniaxial stress-strain curve of the material. Hence

$$d\epsilon_{ij} = \frac{(1+\nu)d\sigma_{ij} - \nu d\sigma_{kk} \delta_{ij}}{E} + \frac{3(\lambda - 1)dh^2}{8Eh^2(F_0 + G_0 + H_0)} \frac{\partial h^2}{\partial \sigma_{ij}} \quad (10)$$

where  $\frac{\partial f}{\partial \sigma_{ij}} = \frac{1}{2h^2} \frac{\partial h^2}{\partial \sigma_{ij}}$  has been substituted.

For plane stress behaviour  $d\sigma_{zz} = 0$ , one has:

$$d\epsilon_{zz} = -\frac{\nu}{E} (d\sigma_{xx} + d\sigma_{yy}) - (d\epsilon_{xx}^P + d\epsilon_{yy}^P). \quad (11)$$

The above relations can be inverted to express  $d\sigma_{ij}$  in terms of  $d\epsilon_{ij}$ . The results can be expressed as:

$$\begin{bmatrix} d\sigma_{xx} \\ d\sigma_{yy} \\ d\sigma_{xy} \\ d\sigma_{yx} \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & C_{14} \\ C_{21} & C_{22} & C_{23} & C_{24} \\ C_{31} & C_{32} & C_{33} & C_{34} \\ C_{41} & C_{42} & C_{43} & C_{44} \end{bmatrix} \begin{bmatrix} d\sigma_{xx} \\ d\sigma_{yy} \\ d\sigma_{xy} \\ d\sigma_{yx} \end{bmatrix}, C_{ji} = C_{ij} \quad (12)$$

The incremental moduli  $C_{ij}$  depend on the stresses at bifurcation,  $\lambda = E / E_t$ , and the anisotropic parameters  $F_0, G_0, H_0, N_0$ . Referred to the  $\xi\nu$  axes:

$$\begin{bmatrix} d\sigma_{\xi\xi} \\ d\sigma_{\nu\nu} \\ d\sigma_{\xi\nu} \\ d\sigma_{\nu\xi} \end{bmatrix} = [R] \begin{bmatrix} d\sigma_{xx} \\ d\sigma_{yy} \\ d\sigma_{xy} \\ d\sigma_{yx} \end{bmatrix}, [R] = [R(\beta)], [R]^{-1} = [R]^T = [R(-\beta)], \quad (13)$$

$$[R] = \begin{bmatrix} \cos^2 \beta & \sin^2 \beta & \cos \beta \sin \beta & \cos \beta \sin \beta \\ \sin^2 \beta & \cos^2 \beta & -\cos \beta \sin \beta & -\cos \beta \sin \beta \\ -\cos \beta \sin \beta & \cos \beta \sin \beta & \cos^2 \beta & \sin^2 \beta \\ -\cos \beta \sin \beta & \cos \beta \sin \beta & \sin^2 \beta & \cos^2 \beta \end{bmatrix} \quad (14)$$

where, as defined before,  $\beta$  is the angle between the  $\xi$  axis of loading and the  $x$  principal axis of anisotropy. Thus

$$\begin{bmatrix} d\sigma_{\xi\xi} \\ d\sigma_{\nu\nu} \\ d\sigma_{\xi\nu} \\ d\sigma_{\nu\xi} \end{bmatrix} = \begin{bmatrix} B_{11} & B_{12} & B_{13} & B_{14} \\ B_{12} & B_{12} & B_{12} & B_{12} \\ B_{12} & B_{12} & B_{12} & B_{12} \\ B_{12} & B_{12} & B_{12} & B_{12} \end{bmatrix} \begin{bmatrix} d\epsilon_{\xi\xi} \\ d\epsilon_{\nu\nu} \\ d\epsilon_{\xi\nu} \\ d\epsilon_{\nu\xi} \end{bmatrix}, [B] = [R]^T [C] [R] \quad (15)$$

$B_{ji} = B_{ij}$  are too complicated to express explicitly.

### 3. CLASSICAL ISOTROPIC THEORIES

The incremental stress strain relations based upon the  $J_2$  (Mises) yield criterion are given by [4]:

$$\sigma_{\xi\xi} = B' \varepsilon_{\xi\xi} + C' \varepsilon_{vv}, \quad \sigma_{vv} = C' \varepsilon_{\xi\xi} + D' \varepsilon_{vv} \quad (16a)$$

$$\sigma_{\xi v} = 2F' \varepsilon_{\xi v}, \quad \sigma_{v\xi} = 2F' \varepsilon_{v\xi} \quad (16b)$$

where

$$B' = \frac{E\{(\lambda + 3 + 3e + 4\lambda\alpha(\alpha - 1)\}}{\Delta},$$

$$D' = \frac{E\{(\alpha^2(\lambda + 3 + 3e) - 4\lambda(\alpha - 1)\}}{\Delta},$$

$$C' = \frac{E\{2(1 + \alpha^2)(\lambda - 1 + 2\nu) + \alpha(5 + 3e - 5\lambda - 4\nu)\}}{\Delta},$$

$$F' = \frac{E}{(2 + 2\nu + 3e)},$$

$$\Delta = (1 + \alpha^2 - \alpha)\{\lambda(5 + 3e - 4\nu) - (1 - 2\nu)^2\} + 3\alpha(1 - \lambda + e)(1 - 2\nu). \quad (17)$$

The parameters  $\lambda = E/E_t, e = E/E_s - 1$  where  $E_t = d\sigma/d\varepsilon$  and  $E_s = \sigma/\varepsilon$  are the tangent and secant moduli at the equivalent stress level  $\sigma'_{eq}$  which for the biaxial state of stress  $\sigma'_{vv} = \alpha\sigma'_{\xi\xi}$ , is

$$\begin{aligned} \sigma'_{eq} &= \sqrt{3J_2} = \sqrt{(\sigma'_{\xi\xi})^2 - \sigma'_{\xi\xi}\sigma'_{vv} + (\sigma'_{vv})^2} \\ &= \sqrt{1 - \alpha + \alpha^2} \times \sigma'_{\xi\xi} \end{aligned} \quad (18)$$

Above are the current moduli of the  $J_2$  deformation theory. The current moduli of the  $J_2$  incremental theory follow by substituting  $e = 0$  in the above equations. Moduli for the elastic theory are obtained by substituting  $e = 0$  and  $\lambda = 1$ . Thus, the constitutive relations incorporate the two isotropic strain-hardening plasticity theories, and also the purely elastic behaviour. We write:

$$\begin{bmatrix} d\sigma_{\xi\xi} \\ d\sigma_{vv} \\ d\sigma_{\xi v} \\ d\sigma_{v\xi} \end{bmatrix} = \begin{bmatrix} B'_{11} & B'_{12} & B'_{13} & B'_{14} \\ B'_{21} & B'_{22} & B'_{23} & B'_{24} \\ B'_{32} & B'_{32} & B'_{33} & B'_{34} \\ B'_{41} & B'_{42} & B'_{43} & B'_{44} \end{bmatrix} \begin{bmatrix} d\varepsilon_{\xi\xi} \\ d\varepsilon_{vv} \\ d\varepsilon_{\xi v} \\ d\varepsilon_{v\xi} \end{bmatrix} \quad (19)$$

where  $B'_{ji} = B'_{ij}$  are the isotropic moduli in (19) in lieu of the anisotropic moduli in (15).

### 4. STRESS STRAIN CURVE

The material is taken to be 2024S-T3 Aluminum alloy, used in aerospace, with a stress strain curve:

$$\varepsilon = \frac{\sigma}{76,500} + 0.002\left(\frac{\sigma}{300}\right)^7 \quad (20)$$

where  $\sigma$  is in MPa units [5] and  $E = 76,500$  MPa. This is taken as the required relation between  $\sigma_{eq} = \sigma$  and  $\varepsilon_{eq}^P = \int d\varepsilon_{eq}^P$ . Yielding begins around 170 MPa. The representation is experimentally valid up to  $\sigma = 310$  MPa. Poisson's ratio is taken as 0.33.

For accounting anisotropic plasticity  $X_0 = 170$  MPa is taken. Other yield stresses  $Y_0, Z_0, T_0$  are given appropriate values in terms of  $X_0$ . The angle  $\beta$  between the loading and anisotropy axes is taken here to be just  $0^\circ$  and  $22.5^\circ$ .

### 4. FORMULATION FOR BIFURCAION

Let  $w(\xi, \nu)$  be the bifurcation transverse  $z$  displacement. Invoking the Kirchhoff kinematic hypothesis for thin plates, the incremental strains (symbol  $d$  omitted hereon) due to bifurcation are

$$\varepsilon_{\xi\xi} = -zw_{\xi\xi}, \quad \varepsilon_{vv} = -zw_{vv}, \quad \varepsilon_{\xi v} = -zw_{\xi v}, \quad \varepsilon_{v\xi} = -zw_{v\xi} \quad (21)$$

The stress increments are therefore

$$\begin{aligned} \sigma_{\xi\xi} &= -z(B_{11}\varepsilon_{\xi\xi} + B_{12}\varepsilon_{vv} + B_{13}\varepsilon_{\xi v} + B_{14}\varepsilon_{v\xi}) \\ \sigma_{vv} &= -z(B_{21}\varepsilon_{\xi\xi} + B_{22}\varepsilon_{vv} + B_{23}\varepsilon_{\xi v} + B_{24}\varepsilon_{v\xi}) \\ \sigma_{\xi v} &= -z(B_{31}\varepsilon_{\xi\xi} + B_{32}\varepsilon_{vv} + B_{33}\varepsilon_{\xi v} + B_{34}\varepsilon_{v\xi}) \\ \sigma_{v\xi} &= -z(B_{41}\varepsilon_{\xi\xi} + B_{42}\varepsilon_{vv} + B_{43}\varepsilon_{\xi v} + B_{44}\varepsilon_{v\xi}) \end{aligned} \quad (22)$$

Plastic bifurcation under increasing load (Shanley's concept) requires  $B_{ij}$  to be constants over the thickness. Hence

$$\begin{aligned} M_{\xi\xi} &= \frac{t^3}{12}(B_{11}w_{\xi\xi} + B_{12}w_{vv} + B_{13}w_{\xi v} + B_{14}w_{v\xi}), \\ M_{vv} &= \frac{t^3}{12}(B_{21}w_{\xi\xi} + B_{22}w_{vv} + B_{23}w_{\xi v} + B_{24}w_{v\xi}), \\ M_{\xi v} &= \frac{t^3}{12}(B_{31}w_{\xi\xi} + B_{32}w_{vv} + B_{33}w_{\xi v} + B_{34}w_{v\xi}), \\ M_{v\xi} &= \frac{t^3}{12}(B_{41}w_{\xi\xi} + B_{42}w_{vv} + B_{43}w_{\xi v} + B_{44}w_{v\xi}). \end{aligned} \quad (23)$$

Now, the principle of virtual work requires

$$\int_0^a \int_0^b (M_{\xi\xi} \delta w_{\xi\xi} + M_{vv} \delta w_{vv} + M_{\xi v} \delta w_{\xi v} + M_{v\xi} \delta w_{v\xi} - P_1 w_\xi \delta w_\xi - \alpha P_1 w_v \delta w_v) d\xi dv = 0 \quad (24)$$

where virtual work of axial loads  $P_1$  and  $P_2 = \alpha P_1$  per unit length has been accounted. Substitution of  $M_{\xi\xi}$  etc. renders the virtual work equation as

$$\begin{aligned} & \frac{t^3}{12} \int_0^a \int_0^b \{ (B_{11} w_{\xi\xi} + B_{12} w_{vv} + B_{13} w_{\xi v}) \delta w_{\xi\xi} + (B_{21} w_{\xi\xi} + B_{22} w_{vv} + \\ & B_{23} w_{\xi v} + B_{24} w_{v\xi}) \delta w_{vv} + (B_{31} w_{\xi\xi} + B_{32} w_{vv} + B_{33} w_{\xi v} + \\ & B_{34} w_{v\xi}) \delta w_{\xi v} + (B_{41} w_{\xi\xi} + B_{42} w_{vv} + B_{43} w_{\xi v} + B_{44} w_{v\xi}) \delta w_{v\xi} - \\ & - P_1 (w_\xi \delta w_\xi + \alpha w_v \delta w_v) \} d\xi dv = 0 \end{aligned} \quad (25)$$

#### 4. DETERMINING THE BIFURCATION STRESS

Galerkin procedure is used. The displacement  $w$  and its variation  $\delta w$  are taken of the same form, satisfying the simple support conditions around the edges. The functions

$$\begin{aligned} w &= \sum A_i \sin \frac{m_i \pi \xi}{a} \sin \frac{n_i \pi v}{b}, \\ \delta w &= \sum \delta A_i \sin \frac{m_i \pi \xi}{a} \sin \frac{n_i \pi v}{b} \end{aligned} \quad (26)$$

are such functions, where  $m_i, n_i$  are the number of half waves in  $\xi, v$  directions. The terms are such that  $m_i + n_i$  is equal to 2, 3, 4, 5, 6, 7, 8, giving 28 terms, a number assumed to provide sufficiently accurate values of the bifurcation stresses.

When substituted in the above virtual work equation and integrated, the arbitrary character of  $\delta A_i$  yields a system of linear homogeneous equations of a generalized eigenvalue problem

$$\frac{t^3}{12} [K_1] \{A\} - P_1 [K_2] \{A\} = \{0\} \quad (27)$$

For a chosen  $\sigma_{\xi\xi}$ , the problem can be cast as

$$[[K'_1] - \frac{b^2}{t^2} [K_2]] \{A\} = \{0\} \quad (28)$$

where  $[K'_1] = \frac{b^2}{12 \sigma_{\xi\xi}} [K_1]$  depends on  $\sigma_{\xi\xi}$ , moduli  $B_{ij}$  or  $B'_{ij}$

and  $r = \frac{a}{b}$ . Thus, the eigenvalue is  $\frac{b^2}{t^2}$ .

*Mathematica* programs were constructed to obtain the critical values of  $\frac{t}{b}$  versus  $\sigma_{\xi\xi}$  for the present incremental anisotropic theory of plasticity of Hill, and for the two classical isotropic theories.

#### 5. EQUIBIAXIAL COMPRESSION CASE

The results are given for rectangular plates with  $a/b = 5$ . The equibiaxial compressive stresses result in zero shear stress everywhere. The graphs below show gradual divergence between the incremental and deformation theory. At  $t/b \approx 0.0927$  the critical stress is 310 MPa for the incremental theory, whereas for the deformation theory it is around 286 MPa which is lower by 7.7%. This is not large difference and can be made still smaller by taking the transverse shear effects in the incremental theory. For circular SS plate [6] this difference is about 1%. This means that for this equibiaxial loading the paradox is practically non-existent. For a slight anisotropy  $X_0 = Y_0 = 170$  MPa  $Z_0 = 0.9 X_0$  the critical stress is around 290 MPa, somewhat higher than that from the deformation theory and lower than the incremental theory. No experimental data are available for this loading.

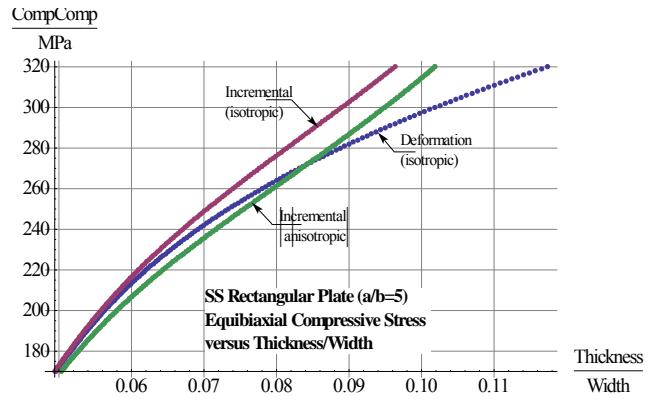

Fig 1: Critical Stress  $\sigma_{\xi\xi}$  in Equibiaxial Loading

#### 6. EQUAL COMPRESSION AND TENSION LOADING

Figure 2 below shows, for  $a/b = 1$  square plates, the extreme divergence between the bifurcation stresses predicted by the isotropic incremental and deformation theories, confirming the plastic plate buckling paradox for this case of equal compression and tension loading. The results of the incremental theory exhibit increasing stiffness with increasing  $t/b$  ratio, while those of the deformation theory show markedly softening behaviour. It seems that the result of the incremental theory are too high and those of the deformation theory too low. In the absence of any experimental results for

such loading, it is conjectured that the true values are midway between the results of the two theories.

Graphs obtained by choosing

$$X_0 = 170, Y_0 = 1.3 \times X_0, Z_0 = 1.35 \times X_0, T_0 = X_0 / \sqrt{3} \text{ MPa}$$

are shown for  $\beta = 0$  and  $\beta = 22.5^\circ$ . These graphs lie between the results of the two other theories.

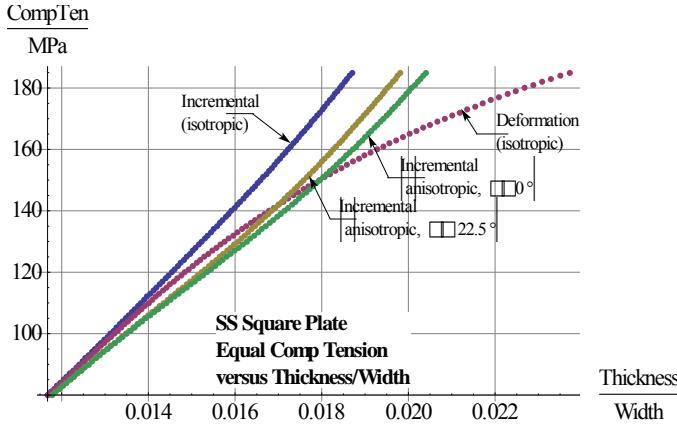

Fig. 2: Critical Stress  $\sigma_{\xi\xi}$  in Equal Comp-Tension

The above anisotropic values are not unique. They were chosen by trial and error to obtain graphs midway between the graphs of the two isotropic theories, keeping in mind that the yield stresses should not be very dissimilar.

## 7. UNIAXIAL COMPRESSION LOADING

This case, for long plates, is the one most discussed, and has many experimental studies generally favoring the results of the deformation theory. It was also the case dealt by Handleman and Prager [1], and the paradox was discovered.

Figure 3, drawn for  $a/b=5$ , shows the wide divergence between the results of the incremental and the deformation theories for the uniaxial loading. The anisotropic graphs are for

$$X_0 = 170, Y_0 = 1.6 \times 170, Z_0 = 1 \times 170, T_0 = 1.35 \times 170 \text{ MPa}, \text{ and } \beta = 0^\circ, \beta = 22.5^\circ.$$

The graphs for these anisotropic values are quite close to the critical stresses predicted by the deformation theory, especially for  $\beta = 0^\circ$ .

This holds true for the entire range of stress in plastic strain-hardening behaviour. For  $\beta = 22.5^\circ$  a slightly stiffer behaviour is predicted than for  $\beta = 0$ .

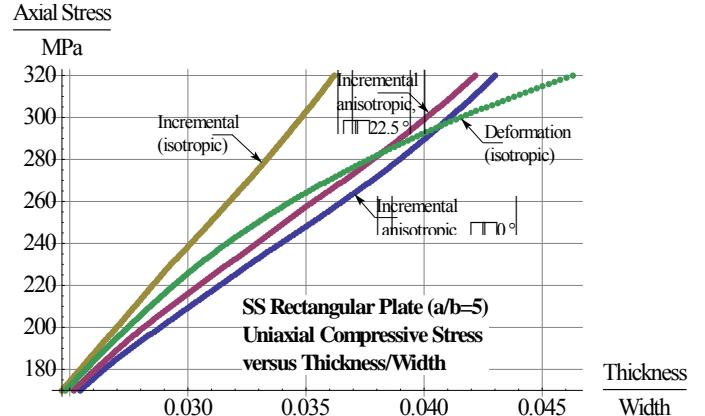

Fig. 3: Critical Stress  $\sigma_{\xi\xi}$  in Uniaxial Compression

## 8. CONCLUSION

It is clear that the incremental theory, by considering the anisotropic plastic behaviour of the plate material, predicts bifurcation stresses which are close to the isotropic deformation theory results, which in turn are close to the available experimental values.

**Abstract**— Shot peening is a process widely used in industry to improve the fatigue life of materials through induced compressive residual stresses that retard crack initiation and growth. In the peening process, there are two stages: 1) loading: shot penetrating into target; and 2) unloading: shot rebounding from the target. The strain rates in the loading process are known to be in  $10^5\text{--}10^6$  1/s range, having heavy impact on the materials' properties. However, the effect of the loading strain rates on the rebounding stage is not well studied. This paper aims to determine the effects of the loading strain rates on the unloading behavior of a material using FEM method. First, to better understand the material behavior, this study evaluates the loading-unloading responses of one element at high strain rates in different scenarios. Then, it obtains the strain rates during the loading and unloading for the different elements of a material being impinged by one shot. The results show that the unloading behavior of a material depends only on the loading equivalent plastic strain and the strain rate of the unloading step.

**Keywords:** *Shot peening, high strain rate, loading-unloading*

## I. INTRODUCTION

Shot peening is the process of impinging small spherical shots on the surface of a target material. These impacts create plastic deformation that leads to the development of compressive residual stress over the few-hundred micrometers layer of a material within the vicinity of the shot. As fatigue cracks are generally initiated from the surface of a material, this compressive stress delay crack initiation and retards crack growth, resulting in improved fatigue life of the material. Rate-independent analytical/numerical methods for calculation of residual stresses [1], with applications in many different engineering fields [2]–[4], and for multiple applications of the process [5] have been established. However, strain rate effects in shot peening cannot be ignored.

Analytical and finite element (FE) modeling has been employed to estimate residual stresses and/or model the process of shot peening. The analytical method was developed based on quasi-static response of a target material to single impingement [6], [7]. It was further developed to consider dynamic effects [8],

[9]. The FE evaluation of residual stress distribution has been established in 2D [10] and 3D modeling [11], [12].

A major issue in modeling is the incorporation of strain rate effect. The strain rates in the shot peening process can be as high as  $10^5\text{--}10^6$  1/s [13][11]. Several studies have shown the effect of strain rates in modeling residual stress distribution [11], [13]. Kim et al. [12] showed that the magnitude of the compressive residual stress increases when considering strain rate effect. Meguid et al. [11] showed that strain rate has a significant role in the modeling of residual stress profiles in the peening of AISI 4340. Attempts have also been made to extend quasi-static based analytical solutions [7] to strain rate-dependent solutions [13]. However, a comprehensive review of the literature reveals that there is no study on the effect of loading strain rates on the unloading behavior of a material and its effect on modeling the shot peening process. This paper discusses different loading-unloading scenarios to provide a simple evaluation of material response at different loading and unloading strain rates. The impact of one shot is modeled to capture the strain rate history of the different elements through the depth of a material. Also, necessary modifications for modeling the residual stress distribution have been identified.

## II. MATERIALS AND METHODS

This paper includes two parts. In part A, the effect of loading strain rates on the unloading behavior of a material is discussed. For better understanding of this effect in general, a virtual material property with an exaggerated strain rate effect has been considered using a one-element FE model. In part B, the actual one shot impact on a steel alloy has been modeled to illustrate the application of findings of the part A in the shot peening process.

### A. Effect of loading strain rate on unloading behavior of materials, using one-element simulation

To figure out the effect of loading strain rates on the unloading behavior of a material, this section discusses one-element simulation of a virtual material with an exaggerated dependency on strain rates. The one-element modeling is performed because the loading and unloading conditions can be simply applied and the response of the material can be obtained. The virtual flow curves of the material assigned to the single

element modeling is shown in Figure 1 for strain rates of 0.1 and 5 1/s.

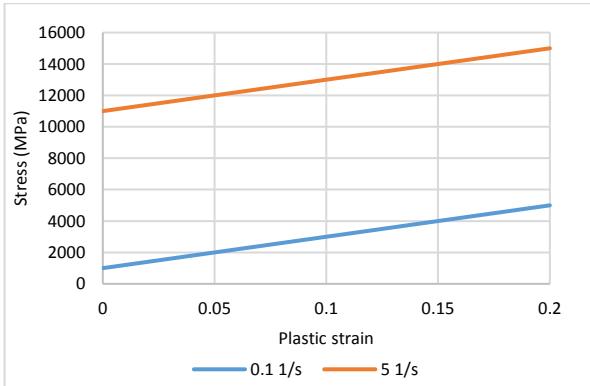

Figure 1. Virtual flow curves of the material used in one-element simulation

The FE analysis is performed using Abaqus software. One element with symmetric boundary condition at xz plane for its bottom side has been used. In this case, the strain and stress in the y-axis are the equivalent strain and stress of the element, respectively. The element size is 1 x 1 x 1 m. Figure 2 shows the geometry of one element modeling as well as the boundary, and loading conditions.

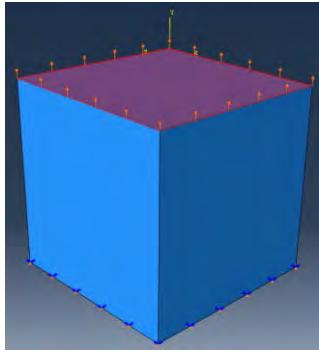

Figure 2. One element modeling geometry

To study the effect of loading and unloading strain rates on the stress-strain response of the material, a simulation using five different strain rate scenarios is considered. Table 1 and Figure 3 describes these different scenarios and represents the strain histories, respectively.

TABLE 1. FIVE LOADING AND UNLOADING SCENARIOS

Scenario	Description
0	Quasi-static loading and unloading
1	Load fast and keep the strain constant
2	Load fast and then continue loading slowly
3	High strain rate loading followed by quasi static unloading
4	High strain rate loading followed by unloading with the same rates as loading
5	High strain rate loading followed by unloading with high rates different from loading rate

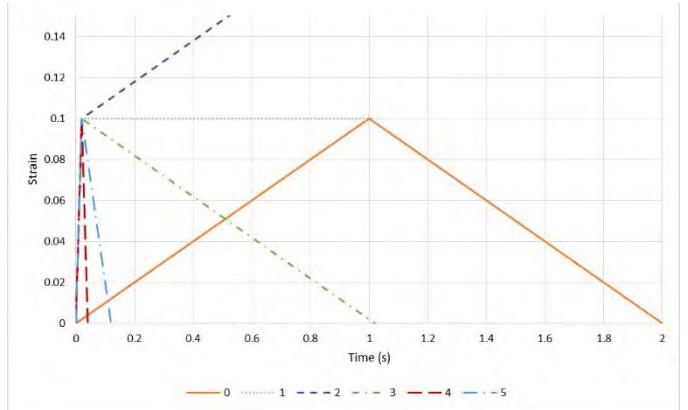

Figure 3. Strain history for the different scenarios shown in Table 1

### B. Application on modeling the shot peening process

As noted, shot peening is a process whereby loading strain rates are high and unloading behavior can be affected by these high loading rates. To determine these effects, this section discusses the finite element modeling of one shot impingement. Abaqus/Explicit was used for modeling the shot peening process. SAE1070 spring steel with dimensions of 76 mm×19 mm×1.29 mm has been used as the peened material. The stress-strain curve is assumed to be bilinear. Figure 4 presents the stress-strain curve of the SAE 1070 spring steel [14], known as Almen strip type A. The Young's modulus and Poisson's ratio are 200 GPa and 0.31, respectively. The strain rate effect on the stress-strain curve of this material has been modeled using the Johnston-Cook model with C=0.0134 and a reference strain rate of 7500 1/s [13][15].

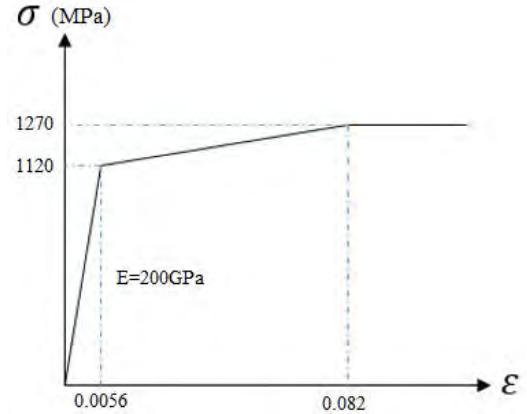

Figure 4. Stress-strain curve of SAE1070 spring steel

Figure 5 shows the flow curves of the material at different strain rates [13]. Table 2 shows the shot properties in the modeling. The shot velocity of 45 m/s has been used in this modeling. The steel shot is assumed to be elastic. The target width and height of 5R and 6R are used as suggested in [11], [16]–[18], respectively, where R is the radius of the shot. Eight-node linear brick elements with reduced integration (C3D8R) and a variable element size with minimum size of 5 x 5 x 5  $\mu\text{m}$  at the impact point are employed for the modeling.

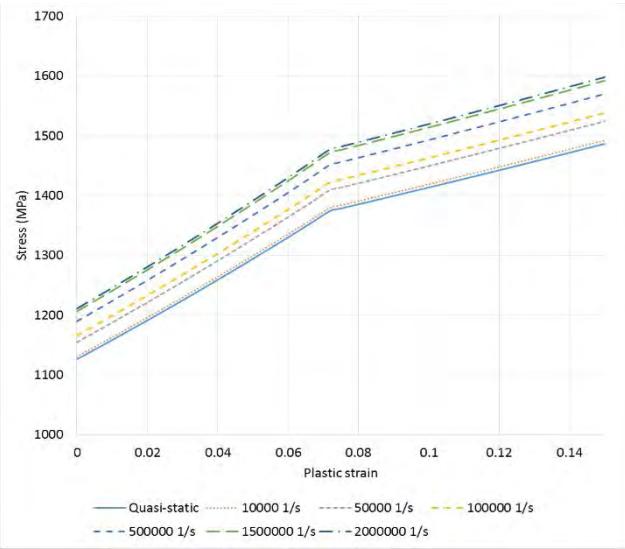

Figure 5. Effect of strain rates on the flow curve of SAE 1070 spring steel [13]

TABLE 2. SHOT PROPERTIES

Shot material	E (GPa)	$\nu$	Density (Kg.m <sup>-3</sup> )	D (mm)
Steel shot	210	0.31	7800	0.4

All degrees of freedom at the bottom side of the target are fixed, and symmetry conditions are applied at the xz and yz planes. The damping model of [11] is used to remove unnecessary oscillations. The penalty contact algorithm with an isotropic coulomb friction coefficient of 0.2 is used [19][20]. Figure 6 shows the single shot geometry and meshed model.

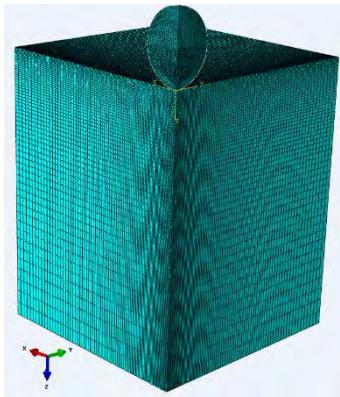

Figure 6. Single shot geometry and meshing

### III. RESULTS AND DISCUSSION

In this section, the results of one-element and one-shot impingement are discussed.

#### A. Effect of loading strain rate on unloading behavior of materials, using one-element simulation

The stress-strain response of one-element model in the loading and unloading with the properties mentioned in Figure 4 are shown in Figure 7. For scenario 0, which is quasi-static

loading and unloading, the material follows the given flow curve at the lowest strain rate. In scenario 1, in which the material is loaded fast and then the loading surface is fixed, the material follows the high strain rate behavior in the loading step, and at the end of the loading, the stress drops to the equivalent stress in the quasi-static stress-strain curve. The equivalent stress at each moment is shown to be a function of equivalent strain and the strain rate at that moment. Scenario 2, in which the material is loaded fast and then the application of tensile strain continues at a low strain rate, reveals that the material follows the stress-strain curve at the high strain rate, then the stress is dropped to follow the rest of the quasi-static loading behavior. In scenario 3, in which fast loading and then slow unloading happens, the loading behavior of the material is the same as the stress-strain behavior at the high strain rate, but the unloading curve fits the unloading curve of the quasi-static condition. Thus, if the unloading is quasi-static, its stress-strain curve, independent from the loading strain rate, follows the quasi-static unloading curve (scenario 0). Scenario 4 discusses the situation in which both the loading and unloading happen at the high strain rate. In this state, as the strain rates of both the loading and unloading steps are the same, reverse yield happens at the reverse value of the maximum loading stress if the material has isotropic hardening behavior. Finally, scenario 5, in which the loading and unloading strain rates are high but different, shows that the unloading behavior is the same as the response of a material when the unloading strain rate is applied for both loading and unloading steps.

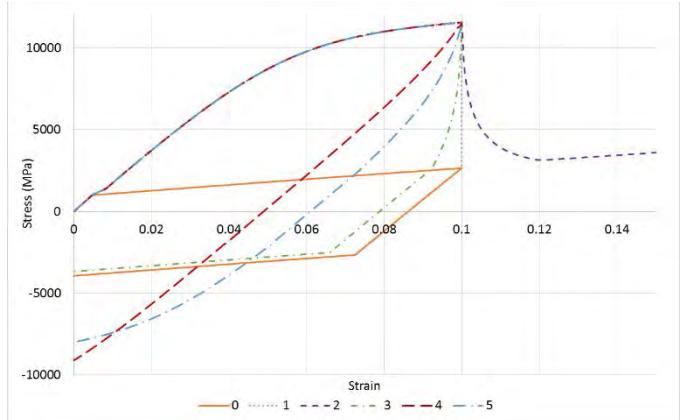

Figure 7. Stress-strain response of one-element in different loading-unloading scenarios

#### B. Application on modeling the shot peening process

This part examines the loading and unloading strain rates in the shot peening process, as well as the considerations necessary in modeling of this process, which requires evaluation of the loading-unloading and equivalent stress histories. The strain rates' histories in one-shot impingement for different elements through the thickness are shown in Figure 8. This figure shows that the history of the strain rate is a combination of the different scenarios discussed in the previous section. It also confirms that the unloading strain rates are much lower than the loading ones. The end of the loading step is defined as the moment when the shot is at its maximum penetration depth through the target; after that the shot will rebound. First, as shown, the maximum strain rate happens when a load is applied to an element. After that, the

strain rates are still high and vanish as the modeling time increases. The time of the unloading is specified in Figure 8. Although the strain rates in the unloading steps are much lower than those in the loading step, their values are still considerable.

Figure 9 shows the variation of equivalent stress for various elements through the depth of the material during the simulation time. The equivalent stresses suddenly increase, at high rates initially, and then continue to increase gradually when the shot is still pressing the target. At the end of the loading step, equivalent stresses drop elastically, with lower strain rates than during the loading step.

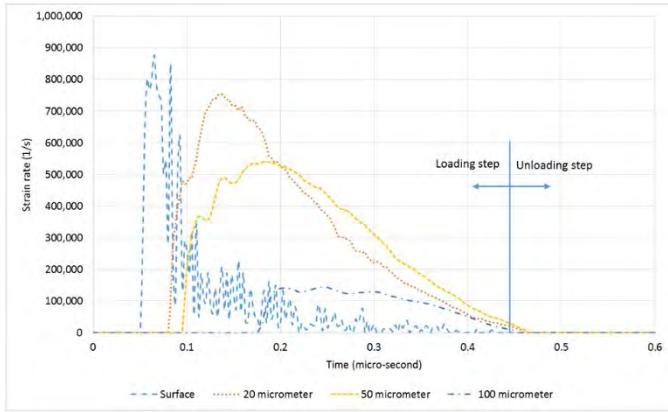

Figure 8. Strain rates of different elements through the thickness elements vs the time of modeling

Figure 10 shows the maximum unloading strain rates of the different elements through the depth of the material. For this peening example, the maximum strain rate in the unloading step occurs for the element that is 50 micrometers below the surface. Although the level of strain rates is one order of magnitude lower than those in the loading step, the strain rate values are in the order of  $10^5$  1/s. Unloading strain rates vanish quickly because when the unloading is ended, the element's strains will stabilize. Thus, the material will follow scenario 3 of the one-element simulations, in which the unloading curves are fitted to the unloading stress-strain curve of the quasi-static loading-unloading.

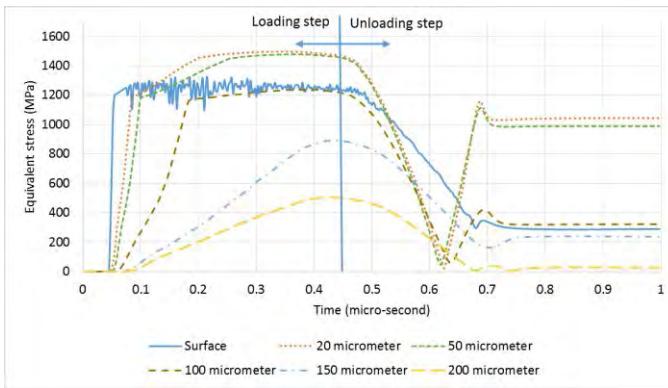

Figure 9. Equivalent stress histories of different elements through the depth of the material during the modeling time

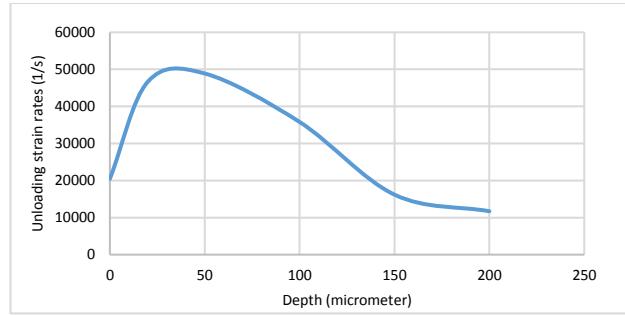

Figure 10. Elastic unloading strain rates of different elements through the depth of the material

## CONCLUSION

The effect of loading strain rates on the unloading behavior of materials has been discussed. The equivalent stress at each moment has been shown to be a function of the equivalent plastic strain and the strain rate of that moment. Also, unloading behavior was found to depend only on the loading equivalent plastic strain and the strain rate in the unloading step, meaning the unloading behavior is independent of the loading strain rate. The fact of considering just the loading strain rates, and scaling the unloading curves based on the loading rates, can lead to an error in modeling the residual stress distribution.

**Abstract**— An ultrasonic tactile sensor that can measure the stiffness of the tissue was developed. By combining analytical and numerical approaches, efficient design methodology was presented. The electrical and mechanical performance of developed sensor was experimentally validated.

*Ultrasonics; Tactile sensing; Equivalent circuit*

## I. INTRODUCTION

Pathological changes in the tissues, such as tumors, affect the tissue stiffness. It has been reported that malignant tissues are several times stiffer than normal ones [1]. In clinical diagnosis, palpation is the oldest, but still the most commonly used technique by physicians [2, 3] to determine the stiffness of target regions. While palpation is simple, it is just a qualitative assessment and the results are widely open to user interpretation. To overcome these shortcomings, various species of tactile sensors have been developed. By integrating different types of the sensing mechanisms onto the tactile probe, one can gather haptic responses from the object in standard forms and digitize them into quantitative measurement with the help of modern signal processing techniques [2, 3].

Being a direct imitation of palpation, static-force based tactile sensors are the most common types of tactile sensors. A typical design of the force-based tactile sensor can be found in the work by Sangpradit et al. [4]. They used a robotic positioning mechanism to control the sensing position and compression depths and measured the static forces with a load cell to estimate the stiffness of inclusions inside a softer phantom. The sensing mechanism is straight-forward, and the raw data is easy to comprehend. However, it can induce severe deformations on the surface of the object, which makes the method inappropriate for deformation-sensitive operations like neurosurgery. Besides, unlike the lab phantom, the real geometry of the object is usually irregular and rough, which brings tremendous challenges to the precise displacement control.

On the other hand, vibro-tactile sensors utilize resonance phenomenon, thus can be applied to force-sensitive surfaces without inducing excessive deformations. Since the vibration characteristics are very sensitive to the environment in contact with the sensor, only minimal level of force to secure the contact with the object needs be applied; hence, no excessive

pressure on the target surfaces is required. One of the examples of vibro-tactile sensors is the one developed by O.A. Lindahl et al. [5]. The device was intended to measure the stiffness of the human skin. The incident vibration signal is provided by the resonant circuit and the computer collects the filtered system response gathered by the piezoelectric pick-up. Instead of controlling the compression depths, the tactile behavior is bounded by the static force, which is done mechanically by limiting the deformation of the spring.

Based on the same principle as the Lindahl's device, our vibro-tactile sensor also works at ultrasonic frequency, but with an additional horn attached to increase the quality factor of the device. The enhanced frequency selectivity of the new design gave us a chance to use other parameters, such as quality factor and/or the sharpness of the impedance sweep response to assess the change in material properties of the target.

In this paper, the design procedures of our ultrasonic tactile sensor are presented, followed by experimental validations of mechanical and electrical performance.

## II. SENSOR DESIGN

Fig. 1 shows the assembly of our ultrasonic tactile sensor.

Figure 1. Full assembly of the ultrasonic tactile sensor

A commercially available Langevin-type piezoelectric transducer was employed as the vibrator. Usually, such transducer is not operated independently, but with a deliberately designed structure attached to the output end of the transducer with a stressed bolt connection. In the meantime, the additional attachment includes a design feature at its nodal section that permits contact with a peripheral structure without affecting the vibration behavior of the system.

In tactile sensing application of the ultrasonic transducer, a vibration concentrator, a horn with a decreasing radius towards the output end, can greatly improve the sensing performance. The concentrator not only reduces the contact area of the output end (gives an edge in precise measurement), but also increases the quality factor Q of the current system. As a result, it enhanced the frequency selectivity of the device and made the load-induced response changes in frequency domain obvious. Therefore, an aluminum horn that resonates longitudinally at transducer's resonance frequency (40 kHz) was fabricated and attached to the transducer with a bolt connection.

Last but not the least, as an interface between the electrical driving circuit and electro-mechanical transducer, two sets of wires were soldered onto the copper electrodes and were later clamped to the terminals of the impedance analyzer with clippers.

#### A. Ultrasonic Transducer

The transducer used in this research was a commercially available device designed to operate at 40 kHz (Model: HEC-1340P4BF, Honda Electronics, Japan). Technical drawings are available on their website. The typical application for this unit is ultrasonic machining where mechanical losses are the major concerns. This ensures that this type of piezoelectric transducer has a higher quality factor over its comparators. The power is not a critical design factor in this project, but the size is. So, the most compact model with the smallest power was selected.

#### B. Horn Design

The horn has a combinational shape of a step and a taper as shown in Fig. 1. Analytical derivation of precise design parameters for the horn is mathematically very challenging [6–8]. Instead, a hybrid approach was adopted in this study, i.e. initial guesses were extracted from a simple analytical model and then refine these parameters through iterative processes with the aid of FEA models.

In the initial guess stage, the horn was sketched out as a half-wavelength long stepped horn, which is a successive combination of two equally long cylinders of different diameters. Note that although a stepped horn design can be adopted for tactile sensor, it may introduce a large error between the model predictions and the actual behaviors because the continuum assumption in the pure analytical model does not hold well. To smooth the transition shape, a tapered feature was introduced to replace the step. To simplify the problem and simultaneously reduce the difficulty in machining, we have tried to avoid placing the fixture feature, the flange, at the tapered part. Next, in order to incorporate the tapered feature, we can replace the smaller end of the original design with a new cantilever stepped horn and smooth out the step with the slope afterwards (Fig. 2).

These dimensions from the analytical derivations of the simple 2D model were found according to the equivalent circuit theory based on impedance analogies as shown in Fig. 3 [9]. The electrical components' values can be derived as in (1). A MATLAB code was developed to solve for them numerically.

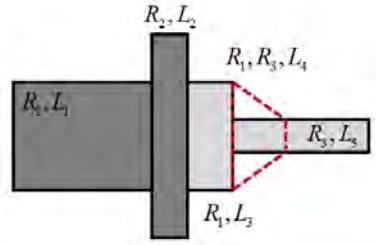

Figure 2. Design sketch for the horn: The darker grey part marks the initially designed half-wavelength ( $L_1+L_2$ ) horn with larger diameter ( $R_1$ ) with the flange ( $R_2$ ) for fixation; The lighter grey part is the cantilever design output end ( $R_3$ ) with a total length of  $L_3+L_4+L_5$ ; And, finally the red dotted line shows the slope (smoothing transition from  $R_1$  to  $R_3$  in a length of  $L_4$ )

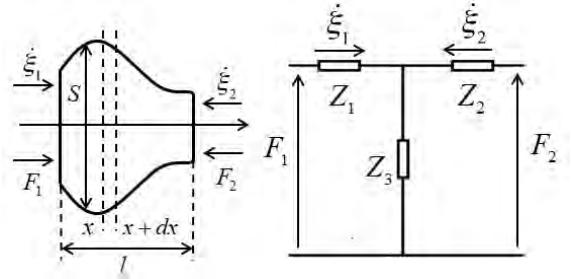

Figure 3. The analogy between the mechanical system and the corresponding electrical circuit (the impedance analogy)

$$\begin{cases} Z_1 = \frac{\rho c}{2jk} \left( \frac{\partial S}{\partial x} \right)_{x=0} + \frac{\rho c K S_1}{jk} \cot Kl - \frac{\rho c K \sqrt{S_1 S_2}}{jk \sin Kl} \\ Z_2 = -\frac{\rho c}{2jk} \left( \frac{\partial S}{\partial x} \right)_{x=0} + \frac{\rho c K S_2}{jk} \cot Kl - \frac{\rho c K \sqrt{S_1 S_2}}{jk \sin Kl}, \\ Z_3 = \frac{\rho c K \sqrt{S_1 S_2}}{jk \sin Kl} \end{cases} \quad (1)$$

where  $K = \sqrt{k^2 - \frac{1}{\sqrt{S}} \frac{\partial^2 \sqrt{S}}{\partial x^2}}$  is the generalized wave number.

In the iterative FEA simulation stage, a parametric model was constructed with a commercially validated Multiphysics package COMSOL to finalize the design with parameter sweeps. The lengthwise dimensions were tuned accordingly until the resonance frequency of the design converged within 1 kHz offset from 40 kHz. Fig. 4 shows the final design of the horn.

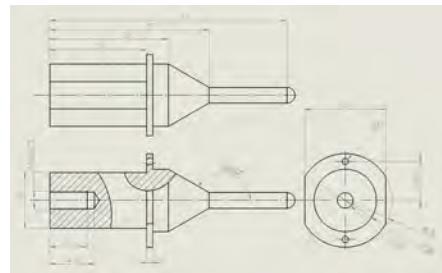

Figure 4. Final design for the horn

### III. EXPERIMENTAL VALIDATIONS

#### A. Experiment Setups

The first experiment was conducted to examine the mechanical behavior of fabricated horn. The test schematics is exhibited in Fig. 5.

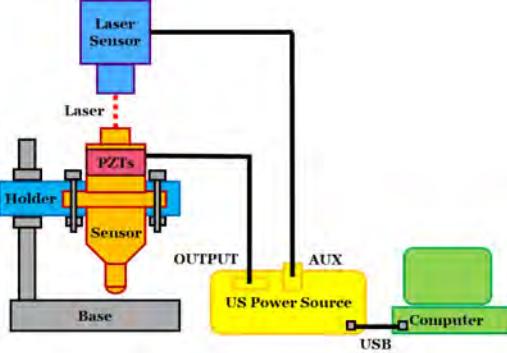

Figure 5. Test setup schematics for the design validation

A temporary holding mechanism was implemented to secure the measurement positions for the laser doppler vibrometer (Polytec OFV-505) in the experiment. The base was a bulky part made of steel, which is not sensitive to the incident vibrations generated by our sensor. The holder, made of aluminum, was fixed on the threaded pole with a set of nuts so that the height of the holder is adjustable. The sensor was fixed to the holder at its flange with two bolts. The active elements, PZTs in the transducer, were connected to the output LEMO connector on the ultrasonic power source (PDUS200, Micromechatronics, USA). The vibrometer was also connected to the power source via its auxiliary input BNC connector. The data were collected with a host computer using the controlling program for the power source via the USB connection. The actual equipment and layout are shown in Fig. 6.

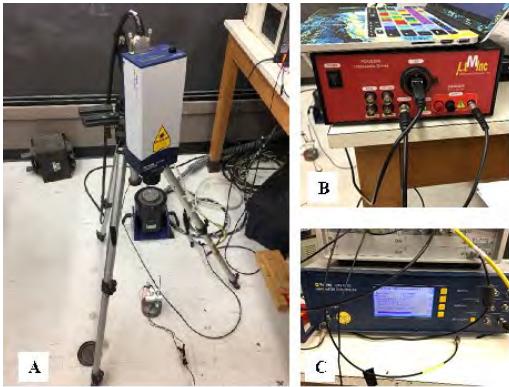

Figure 6. Actual equipment and layout of the test: A) The vibrometer head and the sensor assembly; B) The signal-collecting laptop and the ultrasonic power source; C) The vibrometer controller box

The AC signal generated by the ultrasonic power source was at the level of 20 Vpp, and the sensitivity of the laser doppler vibrometer was tuned to 1  $\mu\text{m}/\text{V}$ . For each measurement, a complete cycle sweep was conducted, i.e., it swept and recorded from 38 kHz to 42 kHz and then

backwards. The measurement was taken on both tip end and the back of the horn as in Fig. 7.

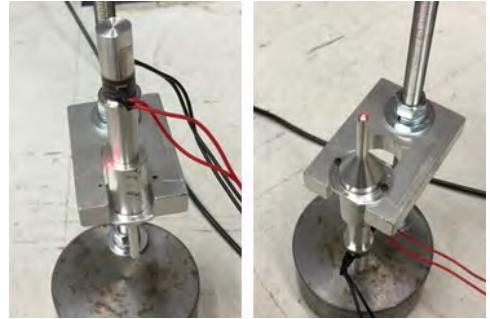

Figure 7. The laser measurement positions on the horn

The second experiment was conducted to investigate the electrical behavior of the total assembly. As discussed in the introduction, part of the designing purpose of the horn was to increase the quality factor of the sensor and thus increase the frequency selectivity. Therefore, frequency sweeps were conducted with the impedance analyzer (HP4194A) under the conditions with and without the horn.

#### B. Mechanical Vibration Measurement Results

The data collected from the experiments are plotted in Fig. 8(a) and the amplification ratio derived from Fig. 8(a) is plotted in Fig. 8(b).

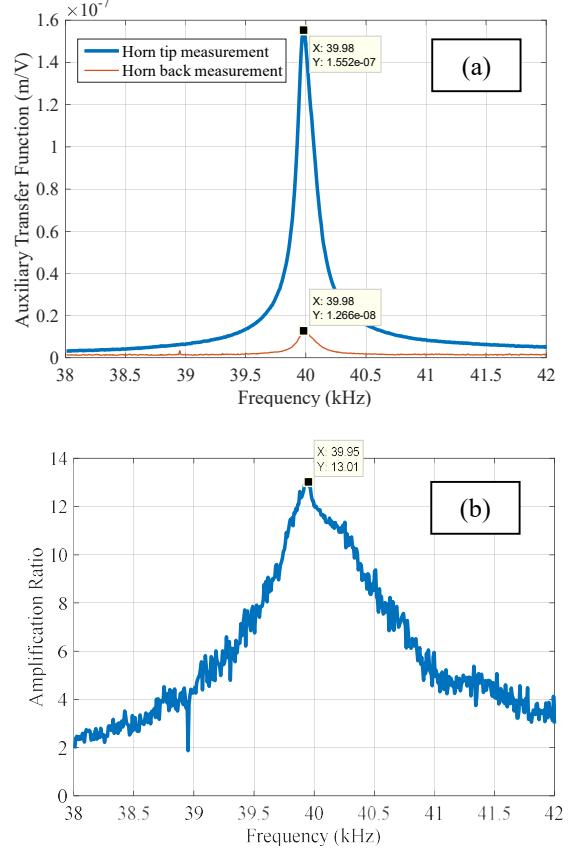

Figure 8. (a) experimental data; (b) The derived amplification ratio

The auxiliary transfer function (ratio between output voltage and auxiliary input voltage) was also automatically recorded by the embedded function in the ultrasonic power source controller program. Combining the calibration information from the laser doppler vibrometer controller box, we can find the actual transfer function ratio between the vibration magnitude (in [m]) and the input AC voltage (in [V]). It can be inferred from Fig. 8 that the system has a clear mechanical resonance at  $\sim$ 40 kHz (39.98 kHz to be exact).

Amplification ratio shown in Fig. 8(b) followed the similar trend to the transfer function in Fig. 8(a), and the maximum amplification ratio was 13.01 at 39.95 kHz.

### C. Electrical Measurement Results

Fig. 9 shows the impedance and phase angle responses of the ultrasonic device with and without the horn attached.

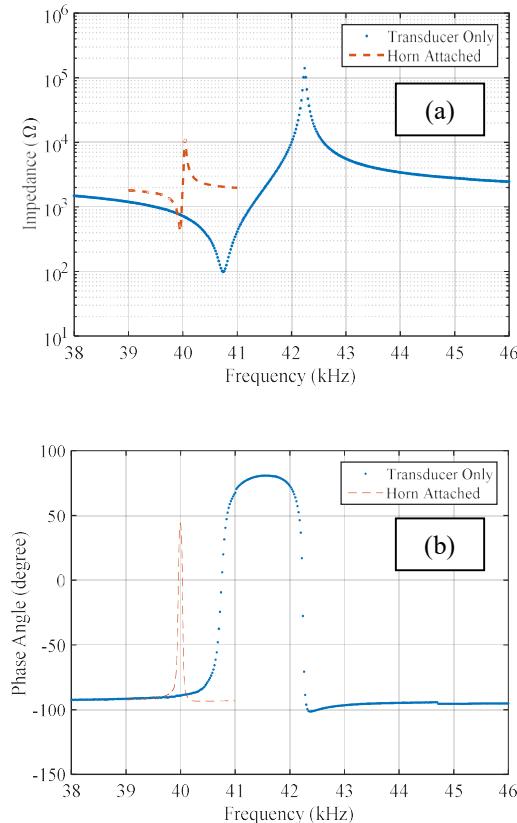

Figure 9. (a) The impedance response of the device; (b) The phase response of the device

Different ranges of frequency were used for the sweeps due to the obvious discrepancies in both responses. Both the series resonance frequency (close to the frequency where the impedance reaches minimum in Fig. 9(a) and the lower frequency where the phase angle is 0 in Fig. 9(b)) and the parallel resonance frequency (close to the frequency where the impedance reaches maximum in Fig. 9(a) and the higher frequency where the phase angle is 0 in Fig. 9(b)) shifted lower and became closer to each other (reduced difference from 2 kHz to less than 1 kHz) around 40 kHz when the horn was attached, which resulted in a steeper change from the

lowest impedance to the highest impedance in Fig. 9(a) and a sharper response in the phase angle in Fig. 9(b).

### D. Comparisons and Discussions

Table I presents the results from the analytical derivation, numerical simulation in COMSOL, and experimental measurement.

TABLE I. DATA COMPARISONS

Source	Results	
	Resonance Frequency (kHz)	Amplification Ratio
Analytical	40.00	>7.2
Numerical	40.61	11.4
Experimental	39.95	13.01

The experimental results show good agreement with the analytical and the numerical results. This clearly indicates that the “guess and optimize” approach is a valid way to design the current device, and mechanically, the ultrasonic sensor was working as expected.

As for the electrical responses, significant changes can be observed in Fig. 9. The responses were much “narrower” when the horn was attached to the transducer, which is a strong indication of the increase of quality factor Q, as pursued by our design.

In conclusion, the ultrasonic horn design was successfully performed through the hybrid approach by taking advantage of the modern computing power and the programmable software package. By integrating the ultrasonic horn into the system, the gap between both electrical resonance frequencies was significantly reduced, which made the identification of the mechanical resonance frequency (located somewhere between two electrical resonance frequencies) more accurate and easier. The increased Q factor suggests the feasibility of using Q factor deductions as a supplementary parameter to determine the mechanical property changes in the target objects.

**Abstract**—Three-dimensional digital image correlation (3D-DIC) is an imaging technique that uses cameras to measure the surface displacement of a speckled specimen under test loading from which surface strains can be derived. This study aims to investigate the effect of the speckle pattern on the uncertainty in the measurement system. A Monte-Carlo experimental approach is used by uniformly displacing a known speckle pattern by a prescribed amount. This allows the coupled influence of the image collection system, processing and post-processing to be investigated. To minimize the uncertainty of a speckle pattern, it was determined that uniform speckle size of 5-pixel diameter speckles at a density of one speckle per 20 square-pixels is optimal. The methods used to measure and analyze the speckle pattern effects on measurement uncertainty are presented.

**Keywords-digital image correlation; measurement uncertainty; speckle pattern; strain measurement**

## I. INTRODUCTION

Three-dimensional digital image correlation (3D-DIC) is a measurement technique that uses two cameras in a stereo configuration to measure all three surface displacement components of a specimen [1]. This includes bulk movement of the specimen as well as local movement generated by load and deformation of the sample. Each camera captures two images of a specimen at different stages of the experimental testing. The stereo pairs are used to locate the position of the surface and the difference between successive image pairs is used to calculate the surface displacement.

Some surfaces are intrinsically difficult to track with cameras as they may be smooth, featureless or reflective. This is typically addressed by introducing a random speckle pattern to the surface of the specimen. The approach generates visibly contrasting surface features within the images to be tracked in a manner that is minimally invasive to the specimen surface properties. However, there may be large variations in different speckle patterns due to the difficulty in controlling the application of the speckle. This potentially results in different qualities of data between speckled specimens and even within a

single specimen that has varying speckle quality. The objective of this investigation is to determine which characteristics of a speckle pattern most significantly contribute to uncertainty in a 3D-DIC measurement system [2].

## II. METHODOLOGY

### A. Materials

The image data are captured using a pair of typical commercial machine vision cameras (GX-3300, Allied Vision Prosillica) mounted in a stereo configuration with a  $\pm 40^\circ$  angle offset from the viewing region-of-interest (ROI) or target, as shown in Figure 1. These are high resolution cameras, each capturing an image  $3296 \times 2472$  pixels with an 8-bit resolution. The cameras were equipped with 80 mm fixed length commercial SLR lenses (#f2.8, Arax) with a  $5^\circ$  tilt angle. The tilt allows rotation and overlapping of the focal planes of both cameras to the same ROI. An LED white light source (CN-600SA, Nanguang Photo & Video Systems Co.) was used for illumination. Using in-house software, cameras were controlled and images were collected and stored for later post processing.

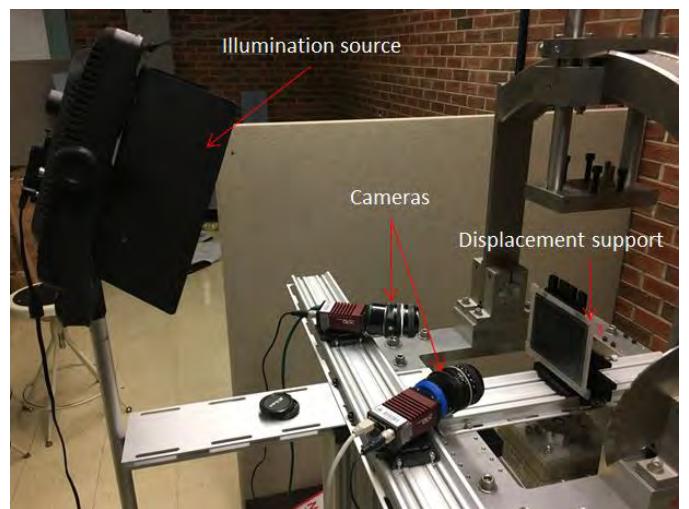

Figure 1. The 3D-DIC measurement system setup for sample testing.

The test specimens were speckle patterns that were generated by a widely used open source software [3] and printed on paper. The software allowed randomized speckle patterns of prescribed speckle densities, speckle sizes and speckle size variations to be generated. Speckle patterns of varying characteristics were printed on printing paper at 1440 dots per inch (dpi). An example comparing the file images of two of the different speckle patterns tested is shown in Figure 2. Note that these images are the same physical size.

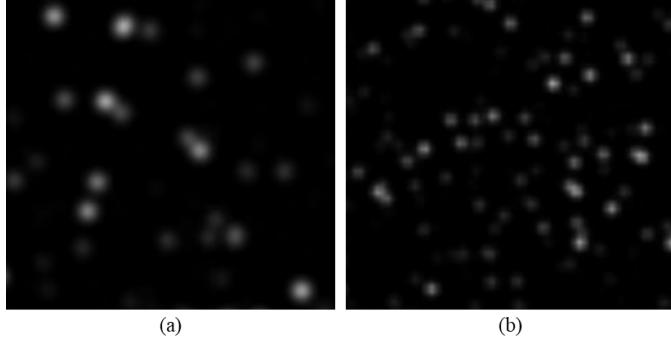

Figure 2. Comparison of file images of two different speckle patterns: (a) larger speckles at low density, and (b) smaller speckles at high density.

The printed speckle specimens were mounted onto a flat target that was connected to an optomechanical fixture that included a traversing stage. The movements of the stage were controlled and measured by a micrometer allowing movement in only one direction, as shown below in Figure 3. This allowed for the speckle sample to be displaced perpendicularly towards and away from the cameras in a general out-of-plane direction.

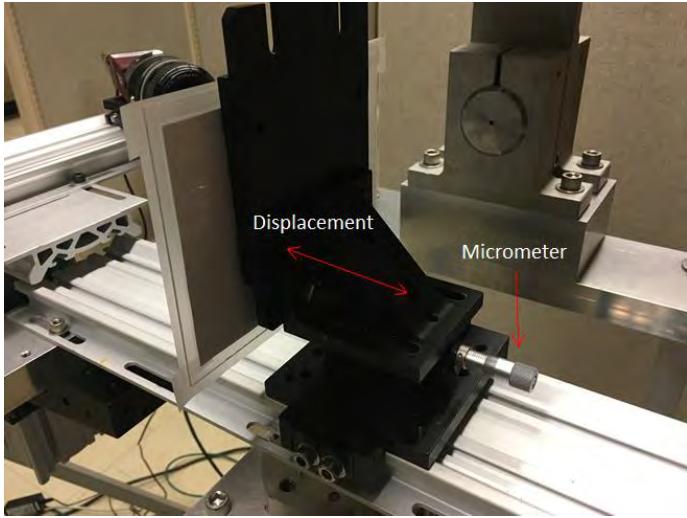

Figure 3. Displacement of micrometer-controlled stage.

### B. Digital Image Correlation

Commercial DIC software (DaVis 8.4, LaVision GmbH) was used to analyze the image data. Camera calibration was conducted with a 3D calibration plate (Type 11, LaVision GmbH) that contains a known rectangular dot pattern of known dot size and dot spacing at two different surface heights. Each camera captured an image of the calibration plate from their respective fixed positions. The DIC software used these two

images to spatially locate the cameras, allowing for the conversion of image data to physical space. The stereo cameras were located in a coordinate system associated with the location and orientation of the calibration target. The calibration target was generally aligned with the coordinate system of the experiment. Images captured post calibration were collected in the coordinate system of cameras, then de-warped and overlapped into the same coordinate system as the calibration target.

The following procedure was used to measure each speckle test specimen. First, a reference image was taken at the position of best focus relative to the cameras. All subsequent displacements were measured in relation to this image. Displacements of 1 mm steps were made from this point in the out-of-plane direction towards the cameras up to 5 mm. This direction was in the coordinate system of the experiment for which the misalignment with a coordinate system of the cameras was corrected.

After the data were collected, 3D-DIC processing was conducted to extract physical displacements from the image data. To do this, a sub-region, or window, of the image was observed and an image cross-correlation algorithm was conducted between the same window of two different images: a measured displacement image and the reference image. The window of the displaced image was then deformed and compared with the reference image to in an attempt to find a better correlation between the windows of both images. This reoccurred until a better match between the windows could not be found – the final window transformation was the resultant displacement vector of the window. The process was repeated using equally sized and equally spaced windows across the whole image. For all sample displacement images, the result was a displacement field spanning the entire image. The displacement field was then analyzed to determine the uncertainty of the measurement as detailed below.

### C. Design of Experiments

A  $2^3$  full factorial experiment based on design of experiments (DOE) was the approach used to quantify how individual characteristics of a speckle pattern affect measurement uncertainty. The responses of this experiment were the two properties used characterize uncertainty: precision and accuracy. The precision was defined as the width of the distribution of measurements in a displacement field, whereas the accuracy was defined as a measure of the difference between the expected displacement, defined by the movement of the micrometer in the experiments, and the average value of all displacement vectors in a displacement field. Thus, the highest quality speckle pattern (*i.e.*, the one with the least uncertainty) was quantifiably the most precise and accurate [4].

The factor combinations for each sample are shown in Table 1. The three input variables were the speckle density, the speckle size and variation in the speckle size. The  $2^3$  experimental design allowed both main effects and effects of interactions between two factors to be observed. Each input was tested at two levels, and the samples were different combinations of input levels.

**Table 1. Experiment sample factor combinations**

Sample no.	Speckle density (#/pixel <sup>2</sup> )	Speckle diameter (pixel)	Speckle size variation ( $\pm$ pixel)
1	0.20	10	0
2	0.20	10	3
3	0.20	5	0
4	0.20	5	3
5	0.05	10	0
6	0.05	10	3
7	0.05	5	0
8	0.05	5	3

As the focus of this study was to investigate the effect of the speckle pattern on the derived displacement, all other parameters were held constant. These included the camera components and positions, the optomechanical components used and the illumination source. The constant parameters of the speckle specimen were the type of paper used and the print settings.

### III. RESULTS AND DISCUSSION

From the DIC measurements, displacement fields were generated for each measured sample displacements. Because there was no material or local deformation occurring due to loading of the sample, the displacement was expected to be uniform across the entire region and equal to that physically determined by the micrometer. However, this was not the case such as in Figure 4. The measured out-of-plane displacement field, shown in Figure 4 (a), shows that the displacement vectors generated by the 3D-DIC processing for a single speckle pattern were not be identical throughout the entire

field. From all measured displacement vectors in the entire field, the probability density function (PDF) in Figure 4 (b) was generated. The difference between the mean and the prescribed displacement was the accuracy of the measurement. The spread of the measurement, quantified by the standard deviation, was the precision. The combination of the two characterize and quantify the uncertainty of the measurement. This measurement procedure was used for every displacement of each speckle sample to compare the uncertainties between speckle patterns of known varying parameters.

After calculating the precision and accuracy of all measurements, the DOE 2<sup>3</sup> full factorial experiment data was analyzed using commercial software (Minitab 18, Minitab Inc.) as summarized in Table 2 below. This statistical analysis used a standard  $p$ -value  $< 0.05$  to determine if a main effect or an interaction effect was significant. The analysis showed that for accuracy, all factors had a  $p$ -value that suggested significance. However, for precision the most significant factors were speckle size variation followed by the effect of the interaction between speckle density and speckle size.

**Table 2. Significance of speckle pattern parameters**

Factor	P-value	
	Accuracy	Precision
Speckle density	<b>&lt; 0.001</b>	0.395
Speckle diameter	<b>0.007</b>	0.588
Speckle size variation	<b>&lt; 0.001</b>	<b>0.023</b>
Interaction (density/diameter)	<b>&lt; 0.001</b>	<b>&lt; 0.001</b>
Interaction (density/size variation)	<b>&lt; 0.001</b>	0.690
Interaction (diameter/size variation)	<b>&lt; 0.001</b>	0.454

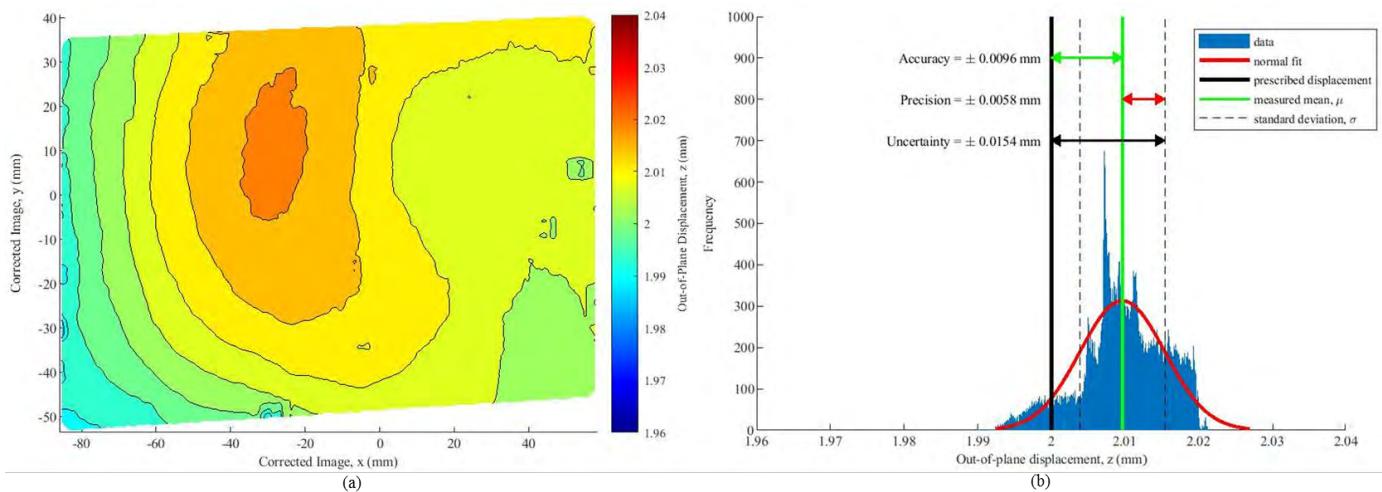

Figure 4. Displacement of a speckle sample 1 by 2 mm, showing (a) measured displacement vector field and (b) resultant PDF used to determine accuracy and precision of measurement and resultant uncertainty.

From the means plots of the factors significant to the precision in Figure 5, the most precise speckle pattern had speckle size uniformity and either larger speckles with higher density or smaller speckles with lower density. The difference between either interaction settings was minimal at these levels.

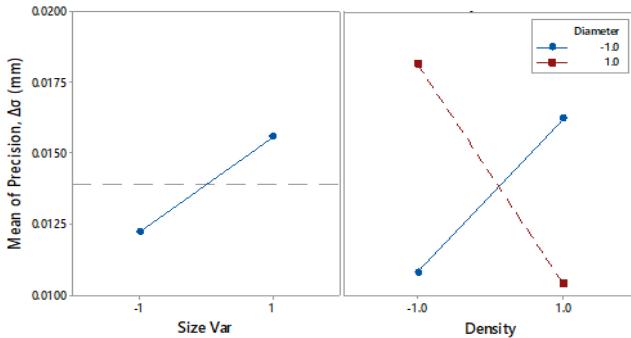

Figure 5. Means plots of effects significant to precision measurement (left – speckle size variation; right – speckle density and diameter interaction).

The reason for the reduction of precision from speckle size variation may be due to larger speckles (or larger empty spaces) physically dominating the correlation window. As a result, the smaller speckles have a less significant effect in the DIC process. This means that the displacement measurement is more heavily influenced by fewer particles, resulting in an effectively lower sample size and increasing the standard deviation of the total measurement.

The interaction between speckle density and speckle diameter was the most significant factor regarding precision. Larger speckles at low density may reduce precision similarly to the speckle size variation effect; single large speckles may be too dominant in a single window. Regarding smaller speckles at too high a density, there may be too many speckles in a single correlation window such that they appear as noise that is difficult to track. It also may be a limitation of using speckles printed on paper. The details of a small speckle may be too fine to capture on the prints and in the camera image data. Consequentially, they can appear blurry and may not represent the speckles as accurately as intended. A comparison of a camera image from the experiment and its respective original file is shown in Figure 6.

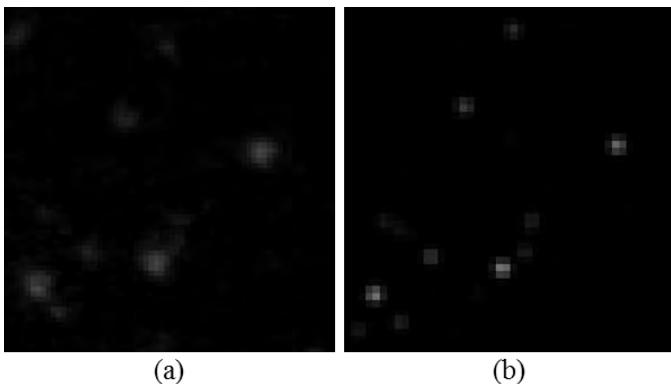

Figure 6. Comparison of (a) camera image data to (b) original file.

Because all factors were observed as statistically significant regarding accuracy, the pareto chart shown in Figure 7 was used to determine if any factors were more significant than others. The size variation and the interaction between the speckle diameter and density were the most significant in this scenario as well. Because the interactions involving speckle size variation and the other two factors were more significant than the main effects, the remaining factors may be significant by association only. Therefore, heavier emphasis was placed on the main effect of the speckle size variation and the interaction effect of the speckle diameter and density interaction.

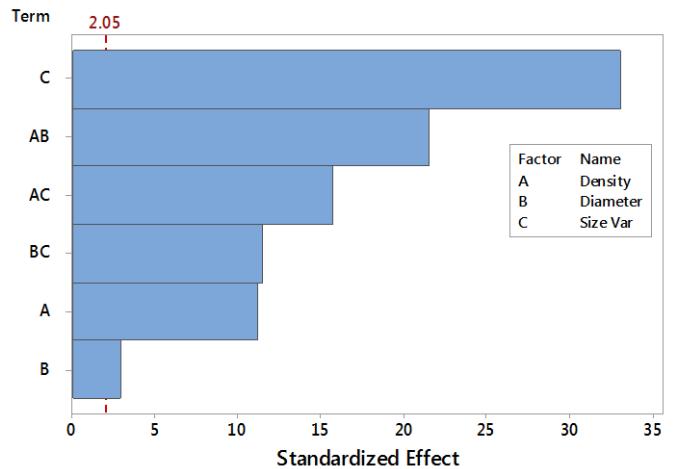

Figure 7. Pareto chart showing factor effects with respect to accuracy.

From Figure 8, the means plots for accuracy showed that the smallest uncertainty resulted from the speckle pattern with lower density, smaller speckle diameters, and speckle size uniformity. Like the statistical analysis of measurement precision, the interaction effect of speckle density and speckle diameter yielded higher accuracy with larger speckles at high density or smaller speckles at low density. However, greater accuracy resulted from the latter. This suggests that the optimal speckle characteristics for minimizing uncertainty (regarding both precision and accuracy) are 5-pixel diameter speckles at a density of 0.05 speckles per square-pixel with no variation in speckle size.

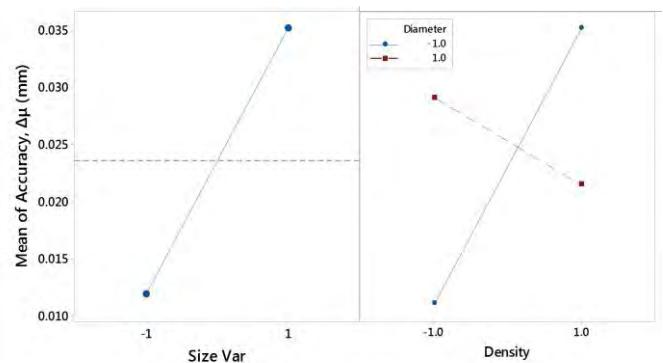

Figure 8. Means plots of effects significant to accuracy measurement (left – speckle size variation; right – speckle density and diameter interaction).

The next step would be to verify the results with physically air-brushed speckled specimens. Along with validating the results, this process would also further investigate what can physically be reproduced and what can practically be applied in an experiment setting using DIC. Additionally, it may be easier to acquire a less blurry image of a speckle pattern with the air-brush method as opposed to the printed paper method, potentially resolving this issue. Through these measures, a greater understanding of the sources of uncertainty and the approaches to limitations within a DIC measurement system can be established.

A major limitation of this study is that the specimen is flat. This serves as a necessary control in the study, but most 3D-DIC applications observe contoured surfaces. 3D surface profiles will be investigated in a future study. Also, this study only measures out-of-plane movement as in-plane movement is expected to be less significant in the overall uncertainty of the measurement of displacement in a stereo setting [5].

## CONCLUSION

This study examined how the characteristics of a speckle pattern affect measurement uncertainty. Using DOE, the effects of input variables and interactions between variables were observed and it was shown that speckle size variation and the effect of the interaction between speckle density and speckle diameter are the most significant effects regarding DIC measurement uncertainty. Within the bounds of this experiment, the optimal speckle pattern was determined to have 5-pixel diameter speckles, a density of one speckle per 20 square-pixel area, and speckle size uniformity. The knowledge from this investigation is significant in understanding the sources of uncertainty within a DIC measurement system, as well as knowing how to effectively approach future applications of DIC.

**Abstract** — In the present study, the free vibration response of symmetric thickness-and-width-tapered (doubly-tapered) laminated composite beams is investigated. Considering the continuous-plies-interspersed ply drop-off configuration, called herein as taper configuration D, both conventional and hierarchical finite element formulations are developed based on the cylindrical bending theory of laminated beam. Natural frequencies of different types of internally-tapered composite beams are determined. Comparison of the hierarchical finite element solution with the Rayleigh-Ritz solution and a higher-order finite element solution is performed. A parametric study is conducted to investigate the effects of width-taper-ratio and the thickness-taper-ratio (or equivalently thickness-tapering angle) on the free vibration response of doubly-tapered laminated composite beams.

**Keywords:** Tapered Composite Beam, Free Vibration, Hierarchical Finite Element Method, Natural Frequencies

## I. INTRODUCTION

Composite material refers to material that is created by the synthetic assembly of two or more organic or inorganic materials in order to obtain specific material properties such as high strength and stiffness to weight ratios, corrosion resistance, thermal properties, fatigue life, wear resistance and increased tolerance to damage [1]. In some specific applications of composite structures such as helicopter yoke or turbine blades, the laminate needs to be stiff at one location and flexible at another location. This type of structure is created by terminating or dropping-off selected plies at specific locations to reduce the stiffness, and is called as the tapered composite structure [2].

Finite Element Method (FEM) is one of the most accurate and powerful tools used to study the response of complex mechanical structures such as the vibration of laminated composite beams. The convergence and accuracy of the results determined using finite element formulation depend strongly on the selected type of element. The type of element that is considered for the finite element formulation in this study has two degrees of freedom per node (deflection and rotation) and two nodes per element. In Conventional Finite Element Method (CFEM), interpolation or shape functions are determined based

solely on these degrees of freedom. In the Hierarchical Finite Element Method (HFEM), a number of trigonometric terms are added to these interpolation functions in a hierarchical manner.

There are several studies on the free vibration of laminated composite beams, mostly on the subject of uniform-thickness uniform-width beams. Free vibration of uniform laminated composite beams was studied by Abarcar and Caniff [3], Chandrashekara et al. [4], Marur and Kant [5] and Miller and Adams [6]. Reddy [7], Berthelot [8], Whitney [9], and Jones [10] have given the exact solutions for the free vibrations of uniform laminated composite beams. Vinson and Sierakowski [11] determined the exact natural frequencies of a simply-supported uniform composite beam based on classical laminate theory.

There are selectively few studies conducted on tapered composite beams. He et al. [12] have conducted a review of the works on tapered laminated composite structures. Ganesan and Zabihollah have studied thickness-tapered laminated composite beams [13, 14] using a higher-order but conventional finite element formulation and performed a parametric study. Ahmed [2] has studied and conducted experiments on free and forced vibration response of thickness-tapered composite beams including the effects of axial force and damping. Badagi [15] conducted the free and forced vibration analysis of thickness-and-width-tapered laminated composite beams using Rayleigh-Ritz method. Farghaly and Gadelrab [16] have studied the free vibration of stepped uniform-width thickness-tapered Timoshenko composite beams. Salajegheh and Ganesan [17] have studied the vibrations of thickness-and-width-tapered laminated composite beams with rigid and elastic supports using a higher-order but conventional finite element.

Hierarchical Finite Element Method (HFEM) has been used in the following works. Zienkiewicz [18], Cook [19] and Reddy [20] have described the use of HFEM to analyze the vibration of metallic and composite beams. Ganesan and Chen [21] have studied the free vibration response of thickness-tapered composite beams using HFEM and Rayleigh-Ritz method. Lees and Thomas [22] conducted a modal analysis on a clamped-clamped Timoshenko beam using HFEM. Bardell [23] conducted a free vibration analysis of a rectangular plate using the HFEM. Yu et al. [24] studied a multivariable HFEM for static and vibration analysis of beams. Ribeiro and Petyt [25]

studied the non-linear free and forced vibrations of composite laminated plates using HFEM.

It is learnt that although there are several works on the study of uniform composite beams, works on the vibration of tapered composite beams are scarce to find in the literature. Also, due to its accuracy and efficiency, HFEM seems the appropriate choice to employ for vibration analysis of composite beams. In the present work, doubly-tapered composite beam is studied for its free vibration response using HFEM.

## II. FINITE ELEMENT FORMULATION

The composite beam has a large length-to-thickness ratio as shown in Fig. 1, and therefore by applying the cylindrical bending theory and considering classical laminate theory, one can get the equation of motion in variational form as:

$$\begin{aligned} & \int_0^L b(x) D_{11}(x) \left( \frac{d^2 w}{dx^2} \right) \left( \frac{d^2 \delta w}{dx^2} \right) dx - \int_0^L b(x) N_x \left( \frac{dw}{dx} \right) \left( \frac{d \delta w}{dx} \right) dx \\ & - \omega^2 \int_0^L \int_{-H/2}^{H/2} \rho b(x) w \delta w dx dz = 0 \end{aligned} \quad (1)$$

In which it is assumed that the deflection in (transverse) z-direction can be expressed as:

$$w(x, t) = W(x) e^{i \omega t} \quad (2)$$

In (1),  $L$  is the length of the beam,  $b(x)$  is the width of the beam at each cross section along the length of the tapered part of the beam ( $b(x) = (b_R - b_L)x/L + b_L$ ),  $N_x$  is the compressive axial force (if present),  $H$  is the thickness of the beam,  $\rho$  is the beam density.  $D_{11}(x)$  is the coefficient of bending stiffness of the laminated composite beam [8] and it can be calculated as:

$$D_{11}(x) = \sum_{k=1}^n \left[ t_k z_k^2 - \frac{t_k^3}{12} \right] (\bar{Q}_{11})_k \quad (3)$$

where  $t_k$  denotes the thickness of  $k^{th}$  ply and  $(\bar{Q}_{11})_k$  denotes the transformed reduced stiffness coefficient of the  $k^{th}$  ply.

### A. CFEM formulation

In Conventional Finite Element Method (CFEM), the structure is divided into a number of Euler-Bernoulli beam elements. Each element can have a number of nodes, which are the critical points. In this study, two nodes per element and two degrees of freedom per node are used in the formulation as shown in Fig. 1.

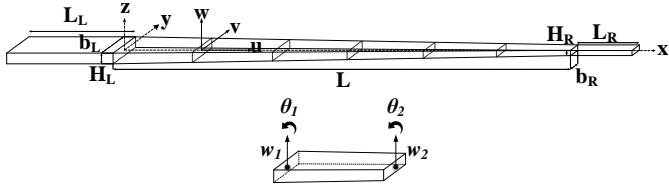

Figure 1. Global and local co-ordinates (top), and nodal displacements and rotations (bottom)

Having four degrees of freedom per element, a third-order polynomial is required for the expression of deflection to satisfy the boundary conditions as below:

$$W(x) = c_1 + c_2 x + c_3 x^2 + c_4 x^3 \quad (4)$$

After determining and using corresponding interpolation functions and following the CFEM, the equation of motion becomes:

$$\left[ \int_0^{l_e} b(x) [D_{11}[N^M]^T [N^M] - N_x[N^d]^T [N^d]] dx - \omega^2 \int_0^{l_e} b(x) (\rho_p H_p + \rho_r H_r) [N^w]^T [N^w] dx \right] \{u\} = 0 \quad (5)$$

In (5),  $[N^w]$  is the shape function matrix and  $[N^d]$  and  $[N^M]$  are the first and second derivatives of  $[N^w]$ , respectively.  $\rho_p$  is the density of the ply,  $\rho_r$  is the density of resin,  $l_e$  is the length of the element and  $H_p$  and  $H_r$  are the equivalent thicknesses of the resin and ply in each element, respectively. For example, if an element has a cross-sectional area of  $A = A_{Ply} + A_{Resin}$  and element length of  $l_e$ , therefore  $H_p = A_{Ply}/l_e$  and  $H_r = A_{Resin}/l_e$ .

Stiffness  $[k]$  and mass  $[m]$  matrices are defined for each element as:

$$[k] = \int_0^{l_e} b(x) [D_{11}(x) [N^M]^T [N^M] - N_x[N^d]^T [N^d]] dx \quad (6)$$

$$[m] = \int_0^{l_e} b(x) (\rho_p H_p + \rho_r H_r) [N^w]^T [N^w] dx \quad (7)$$

One can assemble global stiffness  $[K]$  and mass  $[M]$  matrices of the beam using element matrices by enforcing deflection and rotation continuity conditions. As a result, (5) transforms into:

$$[[K] - \omega^2 [M]] \{u\} = 0 \quad (8)$$

Equation (8) is an eigenvalue problem and can be solved to determine the natural frequencies and mode shapes of the beam.

### B. HFEM formulation

In the CFEM formulation, a cubical displacement function was assumed in Equation (4). In the Hierarchical Finite Element Method (HFEM) the displacement function is modified by adding trigonometric or polynomial functions [7]. In this study, the trigonometric hierarchical functions are used as:

$$W(x) = c_1 + c_2 x + c_3 x^2 + c_4 x^3 + \sum_{i=1}^N c_{i+4} \sin \frac{i \pi x}{l_e}, \quad i = 1, 2, 3, \dots \quad (9)$$

in which  $l_e$  is the length of the element and  $N$  is the number of hierarchical terms. Equation (9) can be expressed as:

$$W = [K_w][c] \quad (10)$$

$$K_w = \left[ 1 \ x \ x^2 \ x^3 \ \sin \frac{\pi x}{l_e} \ \dots \ \sin \frac{N \pi x}{l_e} \right] \quad (11)$$

$$[c] = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ c_4 \\ c_5 \\ \vdots \\ c_{N+4} \end{bmatrix} \quad (12)$$

In the same manner, rotation ( $\theta$ ) can be expressed as:

$$\theta = [K_\theta][c] \quad (13)$$

$$K_\theta = \frac{d(K_w)}{dx} = \left[ 0 \ 1 \ 2x \ 3x^2 \ \frac{\pi}{l_e} \cos \frac{\pi x}{l_e} \dots \frac{N\pi}{l_e} \cos \frac{N\pi x}{l_e} \right] \quad (14)$$

The displacement matrix in local coordinate system is:

$$\{u\} = \begin{bmatrix} w_1 \\ \theta_1 \\ w_2 \\ \theta_2 \\ A_1 \\ \vdots \\ A_N \end{bmatrix} = [K_u]\{c\} \quad (15)$$

in which  $A_i$  are the hierarchical degrees of freedom corresponding to hierarchical terms and  $[K_u]$  can be written as [21]:

$$[K_u] = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & \dots & 0 \\ 0 & 1 & 0 & 0 & \frac{\pi}{l_e} & \dots & \frac{N\pi}{l_e} \\ 1 & l_e & l_e^2 & l_e^3 & 0 & \dots & 0 \\ 0 & 1 & 2l_e & 3l_e^2 & -\frac{\pi}{l_e} & \dots & (-1)^N \frac{N\pi}{l_e} \\ 0 & 0 & 0 & 0 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & 0 & 0 & \dots & 1 \end{bmatrix} \quad (16)$$

The procedure to determine the stiffness [ $k$ ] and mass [ $m$ ] matrices for each element from the variational statement of equations of motion, (1), is analogous to that described for CFEM. The algorithm to assemble the global stiffness [ $K$ ] and global mass [ $M$ ] matrices is described in the Appendix.

Table I. Material Properties

Mechanical properties of ply		Mechanical properties of resin	
Longitudinal modulus ( $E_1$ )	113.9 GPa	Elastic Modulus (E)	3.93 GPa
Transverse modulus ( $E_2$ )	7.985 GPa	Shear modulus (G)	1.03 GPa
$E_3 = E_2$	7.985 GPa	Poisson's ratio ( $\nu$ )	0.37
In-plane shear modulus ( $G_{12}$ )	3.138 GPa	Density of resin ( $\rho_r$ )	1000 kg/m <sup>3</sup>
Major Poisson's ratio ( $\nu_{12}$ )	0.288		
Minor Poisson's ratio ( $\nu_{21}$ )	0.178		
Density of ply ( $\rho_p$ )	1480 kg/m <sup>3</sup>		

### III. FREE VIBRATION ANALYSIS AND DISCUSSION

#### A. Validation and convergence of HFEM solution

The material chosen in this study is NCT-301 graphite-epoxy prepreg which is available in the laboratory of Concordia Centre for Composites (CONCOM). The mechanical properties of the ply and the resin are given in the Table I. The beam has [0/90]<sub>9S</sub> laminate configuration unless specified otherwise.

In order to validate the HFEM formulation, a uniform-thickness uniform-width laminated composite beam is considered. The beam is composed of 36 plies. Individual ply thickness ( $t_k$ ) is 0.125 mm and the beam thickness ( $H$ ) is 4.5 mm. Free vibration analysis is carried out using both CFEM and HFEM for clamped-free boundary condition.

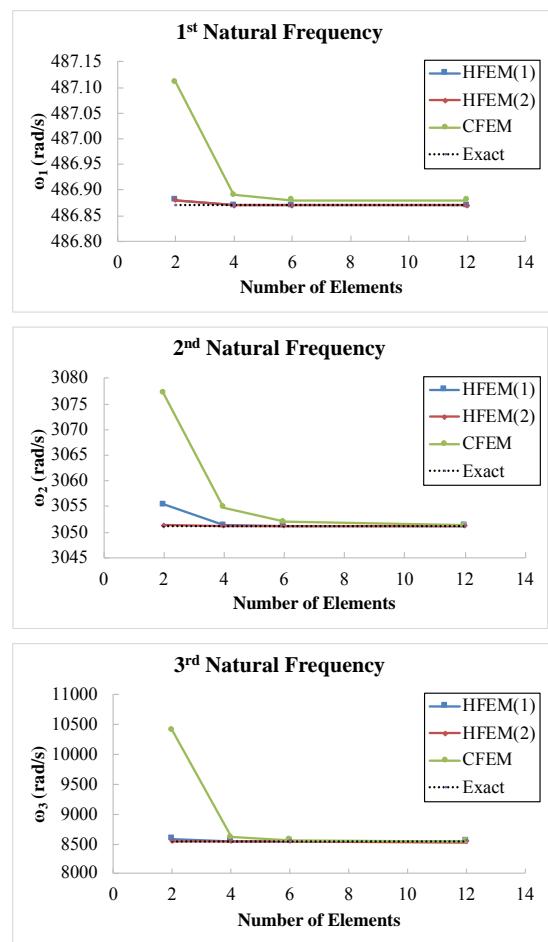

Figure 2. The comparison between results obtained using CFEM and HFEM

The first three natural frequencies are given in Fig. 2 for CFEM, HFEM with one hierarchical term (HFEM(1)) and HFEM with two hierarchical term (HFEM(2)) alongside the exact values of the natural frequencies [8].

As it is shown in Fig. 2, HFEM provides a better accuracy than CFEM with less number of elements that will significantly reduce the time required for the computations and reduce significantly the discontinuities in stress distributions across the nodes. In addition, there is no significant difference between the

results when the second hierarchical term is added. As a result, in this study HFEM with one trigonometric hierarchical term is considered.

In order to validate the accuracy of the HFEM model, a comparison with the results obtained using R-R (Rayleigh-Ritz method) [15] and a HOFEM (Higher-Order Finite Element Method) [17] is performed. The values of the first three natural frequencies using HFEM are presented alongside the results obtained using R-R and HOFEM methods in Table A.I in Appendix.

The comparison shows that HFEM provides accurate results within 0.2% of difference from the above-mentioned methods, which is very acceptable and appealing.

### B. Parametric Study

As shown in Figure 3 (not to scale), a thickness-and-width-tapered composite beam composed of 36 plies at the thick (left) side and 12 plies at the thin (right) side, is considered. Thickness of each ply is 0.125 mm and therefore the thick side beam thickness is 4.5 mm as opposed to 1.5 mm beam thickness at the thin side. The beam has a width of 15 mm at the wide section ( $b_L$ ) and 7.5 mm at the narrow section ( $b_R$ ), which leads to a width-taper-ratio ( $b_R/b_L$ ) of 0.5. The beam has a length of 25 cm and [0/90]<sub>9s</sub> laminate configuration. The material properties are given in Table I. The beam has a simply supported boundary condition.

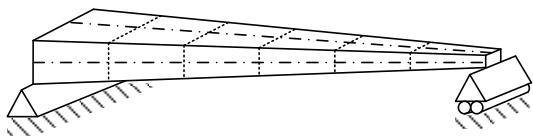

Figure 3. Doubly-tapered composite beam in simply-supported boundary condition

The following is a parametric study to determine the effect tapering on natural frequencies. In each section one variable is considered while all other variables remain constant with the values mentioned above as the base values.

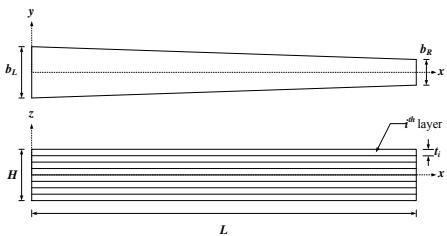

Figure 4. Uniform-thickness and width-tapered composite beam

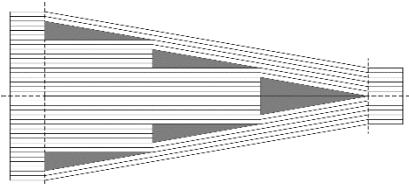

Figure 5. Thickness-taper configuration D

First, the effect of width-tapering, as shown in Figure 4 (not to scale), on the first three natural frequencies is considered. Then, the effect of thickness-tapering for taper configuration D, as shown in Figure 5 (not to scale), on the first three natural frequencies is investigated. Finally, the first three natural frequencies are calculated for a doubly-tapered composite beam.

### C. Discussion

Figure 6 shows the effect of width-taper-ratio on the natural frequency ratio of a uniform-thickness and width-tapered composite beam, for the first three natural frequencies. Natural frequency change is the ratio of the corresponding natural frequency for a given width-taper-ratio minus natural frequency of the uniform composite beam over the natural frequency of the uniform composite beam. As it is shown in Figure 6, The first natural frequency slightly decreases as the width-taper-ratio decreases. However, even by having a width-taper-ratio of 1/3, only 1.06% decrease is observed. However, For the second and third natural frequencies, by decreasing the width-taper-ratio, the natural frequencies slightly increase (less than 0.2 %).

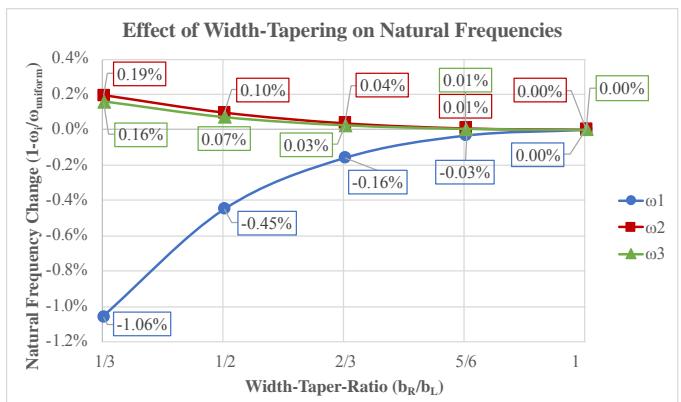

Figure 6. Effect of width-tapering on the first three natural frequencies

In Figure 7, the effect of thickness-tapering on the natural frequencies of thickness-tapered composite beams is plotted. Here, the natural frequency change is the ratio of the corresponding natural frequency for a given thickness-ratio minus natural frequency of the uniform composite beam over the natural frequency of the uniform composite beam. Thickness-ratio is the ratio of the thickness of the thin side over the thickness of the thick side. For this study thickness ratios of 1/3, 1/2, 2/3, 5/6 and 1 are considered which corresponds to thickness-taper angles of 0.344°, 0.258°, 0.172°, 0.086° and 0°, respectively. As it is shown in Figure 7, as the thickness ratio decreases, the first natural frequency decreases drastically. For a thickness ratio of 1/3 (or equivalently thickness-taper angle of 0.344°), the first natural frequency decreases by 39.82%. The second and the third natural frequencies show similar drastic reductions. This can be interpreted by the fact that by removing ply material along the thickness of the composite beam, the value of  $D_{11}$  decreases cubically, which results in the drastic reduction of stiffness of the beam. Moreover, thickness-tapering introduces packets of resin along the thickness of the beam which would also result in the decrease in stiffness of the beam and consequently the decrease of the natural frequencies.

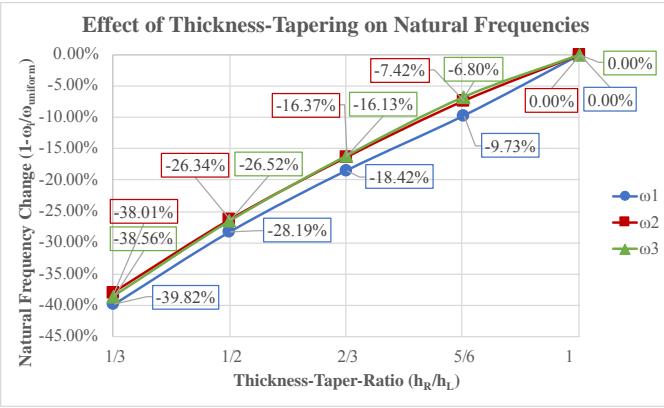

Figure 7. Effect of thickness-taper-ratio (or equivalently thickness-taper-angle) on the first three natural frequencies

Figure 8, shows the effect of width-tapering on a thickness-tapered composite beam with the thickness ratio of 1/3 (or equivalently thickness-taper angle of 0. 344°). It can be seen from Figure 8 that by having no width-tapering (width-tapering-ratio = 1) the reduction of 39.82% in the first natural frequency is present. By decreasing the width-tapering-ratio we see an additional decrease in natural frequencies (up to 3.27% for width-taper-ratio = 1/3). However, as it was observed before, the second and the third natural frequencies are slightly increased (less than 0.9 % compared to the case of thickness-tapered-only) by decreasing the width-taper-ratio.

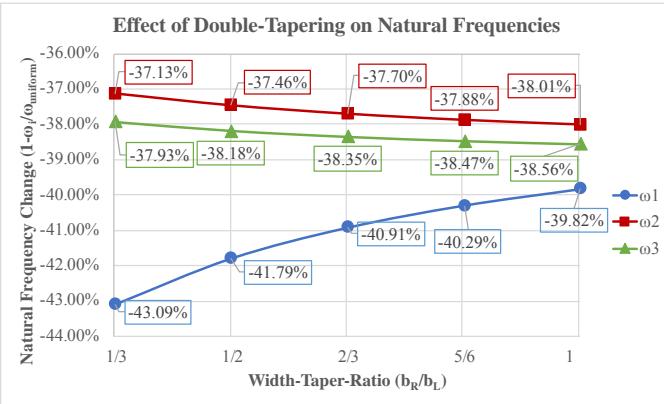

Figure 8. Effect of double-tapering on the first three natural frequencies – thickness-taper-ratio = 1/3

#### IV. CONCLUSION

Hierarchical Finite Element Method (HFEM) provides a better accuracy than Conventional Finite Element Method (CFEM) with less number of elements and this will significantly reduce especially the stress/strain discontinuities across nodes. In addition, there is no significant difference between the results when the second hierarchical term is added. Moreover, a comparison with other published results obtained using R-R (Rayleigh-Ritz method) and a HOFEM (Higher-Order Finite Element Method) shows that HFEM provides accurate results within 0.2% of difference from the above-mentioned methods, which is very acceptable.

A parametric study on the effect of boundary conditions, width-taper-ratio and thickness-taper-ratio (or equivalently

thickness-taper angle on the free vibration response of doubly-tapered laminated composite beams is conducted and the following are concluded:

- Width-tapering has a small effect (1% decrease for a width-taper-ratio of 1/3) on first natural frequency of a simply supported composite beam. This effect is even less significant for the second and the third natural frequencies (less than 0.2% increase).
- Thickness-tapering on the other hand has a significant effect (9.73% decrease for thickness-taper-ratio of 5/6 39.82% decrease for thickness-taper-ratio of 1/3) on the first natural frequency of a simply supported composite beam. This effect is similar for the second and the third natural frequencies.
- Addition of width-tapering to a thickness-tapered composite beam has a slight effect on its first natural frequency (1.97% decrease for width-taper-ratio of 1/2). However, this effect is insignificant on the second and the third natural frequencies (0.54% and 0.38% increase, respectively).

In HFEM with one trigonometric term, each element's stiffness (k) or mass (m) matrix is a 5x5 matrix. The fifth row and the fifth column are the hierarchical terms corresponding to hierarchical non-physical degree of freedom ( $A_i$ ) to complete the form of a square matrix. As it is shown in Table A.III, the global stiffness (K) and mass (M) matrices are assembled in the same manner as CFEM for the first four rows and columns and the hierarchical terms fill the rest of the matrix.

# Modeling of Magneto-Mechanical Response of Magnetorheological Elastomers having Different Arrangement of Magnetic Particles

Mostafa Asadi Khanouki and Ramin Sedaghati

Department of Mechanical, Industrial and Aerospace Engineering  
Concordia University  
Montreal, QC, Canada

**Abstract**—A model describing the magneto-mechanical properties of magnetorheological elastomers (MREs) under an external magnetic field and a mechanical shear deformation is presented. The main purpose of the present study is to demonstrate the effect of particle distribution and applied magnetic field on the MRE mechanical properties. Four types of rectangular lattice models are considered as the representation of spatial distribution of magnetic particles in the matrix. Using the energy method, shear modulus is obtained and numerically calculated as function of the strength of the external magnetic field and the shear strain. The results show a high sensitivity of shear modulus on the spatial distribution of particles. Depending on the lattice type, shear modulus exhibits an increasing or decreasing behavior with the increase of magnetic field intensity.

**Keywords-** *MR elastomers; microstructure modeling; magneto-mechanical properties; particle distribution*

## I. INTRODUCTION

Among different types of smart materials, those that are responsive to an external magnetic field are called magnetically activated smart materials or simply magneto-active materials. Basically, magneto-active materials are composed of two main components: magnetizable particles and nonmagnetic matrix. The host nonmagnetic matrix can be a solid or a liquid, which are then impregnated with micron-sized ferromagnetic particles. Once a magnetic field is applied, the rheology of the material will change as a result of magnetic interaction between particles. Therefore, a common name for the magneto-active materials is magnetorheological materials or in abbreviation, MR materials. Among the MR materials, those with a solid elastomeric matrix are called MR elastomer or simply MRE.

MREs can provide field-dependent elastic modulus making them ideal for many applications such as adaptive spring elements in seismic isolators, vibration absorbers, automotive suspension and artificial human body limbs to name a few [1]. Development of physic-based models capable of predicting the mechanical properties of MRES is of paramount importance for design of MRE-based adaptive devices and also development of control strategies. Many theoretical models have been presented

to predict magneto-mechanical properties of MREs [2-5]. One of the promising modeling approaches is based on the magneto-physical properties of components of the MREs. The method considers microstructure of the MRE and examines magnetic interaction between magnetic particles and their corresponding effect on elastomeric matrix that causes change of properties under an applied magnetic field [6-9]. Jolly et al. [6] presented a quasi-static dipole model to predict magneto-viscoelastic behavior of MREs with anisotropic (chain-like) distribution of particles. They only considered the interaction of two adjacent dipoles in a chain of particles in their model.

Based on the previous progresses in modeling mechanical behavior of MR fluids [10, 11], Davis [7] has also worked on a dipole model to predict the maximum possible increase of shear modulus (once saturation of MRE is occurred) as a function of saturation magnetization and volume fraction of filler particles. Later, some authors tried to present models to encircle the interactions of all particles in a chain [9] or in the whole structure [12]. As a recent progress in this field, Ivaneyko et al. [8] developed a model that can predict magneto-mechanical behavior of MREs under an applied magnetic field by considering interactions between all particles in the network. They discussed the case of a MRE with isotropic spatial distribution of magnetic particles and finally presented the MRE's modulus of elasticity as a function of magnetic field for tensile deformations.

In the present work, the model of Ivaneyko et al. [8] is extended for the case of static shear deformations in the framework of a nonlinear elasticity approach. Magnetic particles are supposed to be located on the sites of four lattice types namely simple cubic, body centered cubic, face centered cubic and edge centered cubic lattices. The two former lattices were also used in [8] but the two latter ones are utilized here for the first time. In the following, first, the mathematical formulation of the model is introduced. This is followed by the derivation of total potential energy of the deformed MRE in a simple shear test under an applied magnetic field. The field dependent shear modulus is then extracted from the derived energy function. The shear modulus depends on the strength of the magnetic field, shear strain, mechanical and magnetic properties of the matrix and particles and finally on the particles' lattice type. Finally,

numerical results for the shear modulus are provided and discussed.

## II. MATHEMATICAL FORMULATIONS

In order to model the mechanical response of a MRE that has a particular spatial distribution of the magnetic particles, the total energy of a MRE sample is obtained in this section. Total energy of the elastomer is a function of the external applied shear deformation, applied magnetic field intensity, lattice model of the magnetic particles and mechanical or magnetic properties of the material. In this study, a MRE sample under a simple shear loading in one direction (x-axis) which is normal to the direction of an applied magnetic field (y-axis) is considered. Fig. 1 illustrates this situation schematically that the simple shear happens in the x-y plane and the magnetic field ( $H$ ) is in the y direction. Magnetic particles inside the sample have magnetic dipoles in the direction of the external field.

### A. Total Potential Energy

Total potential energy of a deformed MRE in the presence of a magnetic field is composed of two parts. One is the elastic energy of the deformed MRE due to the entropic elasticity of polymer chains ( $e_{el}$ ) and the other is due to the potential energy of the magnetic particles placed in an external magnetic field ( $e_m$ ). Thus, the total potential energy of the deformed MRE ( $e_T$ ) under external magnetic field can be written as:

$$e_T = e_{el} + e_m \quad (1)$$

Here first, the elastic part of the energy ( $e_{el}$ ) is calculated for the case of a simple shear test on a continuous medium. Ogden strain potential is extensively used for such applications which is a nonlinear deformation model and valid for the large strain situations [13]. Here, a simplified form of the Ogden model with known coefficients is utilized. Based on this simplified model, the elastic energy of a MRE sample under nonlinear deformations can be presented with the Neo-Hooke law of the following general form [8]:

$$e_{el} = \frac{G_0}{2} (\lambda_x^2 + \lambda_y^2 + \lambda_z^2 - 3) \quad (2)$$

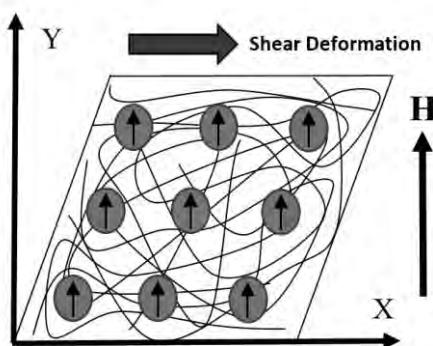

Figure 1. Schematic representation of a MRE sample under simple shear deformation normal to the applied magnetic field direction

where  $\lambda_x, \lambda_y, \lambda_z$  are the principal extension ratios, i.e. the ratio of the current length to original length, in the principal directions.  $G_0$  is the shear modulus of the MRE at zero field which is usually obtained experimentally. This material parameter introduces the effect of different complex phenomena into the elastic energy of the sample such as matrix reinforcement by the hard particles, adhesion of the matrix onto the surface of magnetic particles and so forth.

The magneto-mechanical response of the deformed MRE under the applied magnetic field is characterized based on the value of the shear strain  $\gamma$  in the x-y plane. For the case of large shear strains, the relation between the extension ratio in  $x$  direction and the shear strain is [14]:

$$\gamma = \lambda_x - \frac{1}{\lambda_x} \quad (3)$$

Assuming the material to be incompressible ( $\lambda_x \lambda_y \lambda_z = 1$ ), and considering a plane strain state ( $\lambda_y = 1$ ) the extension ratios are characterized based on the shear strain as:

$$\begin{aligned} \lambda_x &= \frac{\gamma + \sqrt{4 + \gamma^2}}{2}, \quad \lambda_y = 1, \\ \lambda_z &= \frac{1}{\lambda_x} = \frac{2}{\gamma + \sqrt{4 + \gamma^2}} \end{aligned} \quad (4)$$

Using relations (4) into (2), the elastic energy of the elastomer as a function of  $\gamma$  can be expressed as:

$$e_{el} = \frac{G_0}{2} \left( \left( \frac{\gamma + \sqrt{4 + \gamma^2}}{2} \right)^2 + \left( \frac{2}{\gamma + \sqrt{4 + \gamma^2}} \right)^2 - 2 \right) \quad (5)$$

The second part of the energy in (2) is due to the field-induced interaction of magnetic particles inside the elastomer. Applying a magnetic field on the MRE activates the elementary atomic magnetic dipoles in the magnetic particles. The induced dipole moment of each particle has an interaction with the other dipoles in the particle network and is known as the dipole-dipole interaction. The magnetic energy of the material which is the dipole-dipole interaction energy per unit volume can be expressed as [8, 15]:

$$e_m = -\frac{1}{V} \frac{\mu_r \mu_0}{4\pi} \sum_{ij} \left[ \frac{3(\vec{m}_i \cdot \vec{R}_{ij})(\vec{m}_j \cdot \vec{R}_{ij})}{|\vec{R}_{ij}|^5} - \frac{(\vec{m}_i \cdot \vec{m}_j)}{|\vec{R}_{ij}|^3} \right] \quad (6)$$

where  $V$  is the volume of the sample,  $\mu_0$  is vacuum permeability, and  $\mu_r$  is the relative permeability of the medium. Since we assume the elastomeric matrix to be non-magnetic, the relative permeability of the medium is unity ( $\mu_r = 1$ ). Here  $\vec{m}_i$  and  $\vec{m}_j$  are average induced dipole moments of the  $i$ -th and  $j$ -th magnetic particles,  $\vec{R}_{ij}$  is the radius vector between the  $i$ -th and  $j$ -th magnetic particles. The summation in (6) accounts for the superposition of mutual interaction between all pairs of

particles in the network. In order to simplify the calculation of the summation, we consider some lattice networks as the representation of the particle's distribution in the matrix. In this work, besides the two lattice models of simple cubic (SC) and body centered cubic (BCC) which have been used in the work of Ivaneyko et al. 2012 [8], face centered cubic (FCC) lattice and edge centered cubic (ECC) have also been investigated. A unit cell of these four lattice networks as models of spatial distribution of the particles is illustrated in Fig. 2.

For the sake of simplicity, all the particles are assumed to have the same spherical shape and with an average radius of  $r$ . The volume fraction of the magnetic particles dispersed in the matrix is given by:

$$\phi = \lambda \frac{v_0}{a^3} \quad (7)$$

where  $v_0 = \frac{4}{3}\pi r^3$  is a particle volume and  $\lambda$  is a factor depends on the lattice type which considering Fig. 2 are found to be:

$$\lambda_{SC} = 1, \quad \lambda_{BCC} = 2, \quad \lambda_{FCC} = 4, \quad \lambda_{ECC} = 4 \quad (8)$$

As stated before, application of a magnetic field on a MRE, causes each of the magnetic particles to have a magnetic dipole moment. The induced magnetic dipoles  $\vec{m}_i$  and  $\vec{m}_j$  in (6) are directed along the direction of applied magnetic field,  $\vec{H}$ , toward y-axis as shown in Fig. 1. Because of the symmetry of the lattice models with regard to the magnetic field, the absolute values of dipole moments are identical and related to the magnetization ( $M$ ) of each particle as  $m_i = m_j = v_0 M$ .

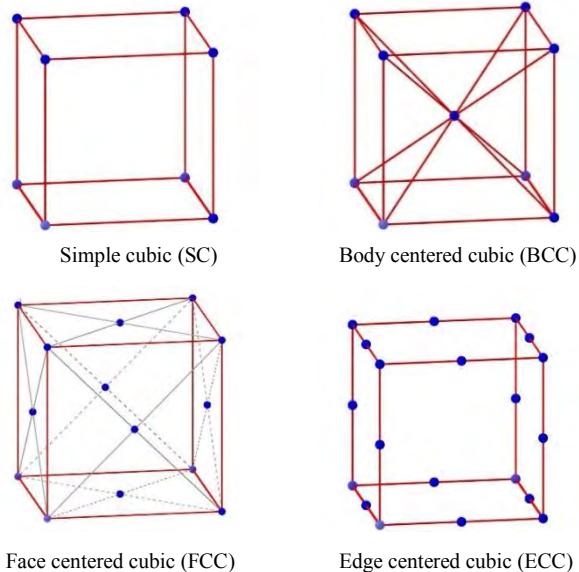

Figure 2. Schematic illustration of different lattice networks as representation for spatial distribution of magnetic particles in the elastomeric matrix

The relationship between the particle magnetization  $M$  and the applied field strength,  $H$ , can be approximated by the Frohlich-Kennelly equation as [8, 16]:

$$M = \frac{M_s(\mu_{ini} - 1)H}{M_s + (\mu_{ini} - 1)|H|} \quad (9)$$

where  $M_s$  is the saturation magnetization and  $\mu_{ini}$  is the initial magnetic permeability of the particles. To have more compact and simpler formulation, (9) can be transferred into a dimensionless form as:

$$\frac{M}{M_s} = \frac{h}{1 + |h|} \quad (10)$$

where  $h = (\mu_{ini} - 1)H/M_s$  is called reduced magnetic field and  $M/M_s$  the reduced magnetization. Equation (9) can predict saturation of a magnetic material. Indeed, the value of magnetization  $M$  increases with an increasing magnetic field and reaches to saturation magnetization,  $M_s$ , when  $H \rightarrow \infty$ .

By expressing the spatial distribution of particles with simplified arrangements as the lattice models presented in Fig. 2, the summation over indices  $i$  and  $j$  in (6) can be simplified. The  $j$ -th particle is taken and the summation is performed over index  $i$ . Since there is a translational symmetry in the infinite lattice with regards to the magnetic field, the dipole-dipole interaction of a given  $j$ -th particle with adjacent particles around it does not depend on the number  $j$ . Therefore, the double sum over indices  $i$  and  $j$  is reduced to a simple sum over index  $i$  multiplied by the number of particles  $N$ . Thus, (6) can be simplified as:

$$e_m = -u_0 v_0^2 c \left( \frac{M}{M_s} \right)^2 \sum_i \left[ \frac{3(\vec{R}_i)_x^2 - |\vec{R}_i|^2}{|\vec{R}_i|^5} \right] \quad (11)$$

where  $c = N/V$  is the concentration of particles. The vector  $\vec{R}_{ij}$  is replaced by  $\vec{R}_i$  for convenience, since the vector is calculated from the origin of a lattice. The parameter  $u_0$  is defined as

$$u_0 = \frac{\mu_0 M_s^2}{4\pi} \quad (12)$$

which is defined as the characteristic energy density for magnetic interaction [8]. The radius vector  $\vec{R}_i$  in (11) depends on the macroscopic shear strain  $\gamma$ . The components of the radius vector after deformation can be defined as

$$(R_i)_x = (R_i^0)_x \lambda_x = (R_i^0)_x \frac{(\gamma + \sqrt{4 + \gamma^2})}{2} \quad (13)$$

$$(R_i)_y = (R_i^0)_y \lambda_y = (R_i^0)_y \quad (14)$$

$$(R_i)_z = (R_i^0)_z \lambda_z = (R_i^0)_z \frac{2}{(\gamma + \sqrt{4 + \gamma^2})} \quad (15)$$

where  $(\vec{R}_i^0)_\xi$  are the components of the radius vectors before deformation, ( $\xi = x, y, z$ ). In a non-deformed MRE, the radius vector  $\vec{R}_i^0$  is defined based on the assumed lattice models in Fig. 2 and can be presented as,

$$\vec{R}_i^0 = \mathbf{a} \cdot \vec{r}_i \quad (16)$$

where the dimensionless vector  $\vec{r}_i$  runs over all particles on the sites of all lattices with the edge length  $a = 1$ . Using (10), and (13-16), the magnetic energy  $e_m$  as a function of a reduced magnetic field  $h$  and shear strain  $\gamma$  can be expressed as:

$$e_m = u_0 \phi^2 \left( \frac{h}{1+|h|} \right)^2 f(\gamma), \quad (17)$$

where the dimensionless function of strain  $f(\gamma)$  is in the following form:

$$f(\gamma) = -\frac{8}{\lambda} (\Gamma)^3 \sum_i \left[ \frac{2r_{ix}^2(\Gamma)^4 - 4r_{iy}^2(\Gamma)^2 - 16r_{iz}^2}{(r_{ix}^2(\Gamma)^4 + 4r_{iy}^2(\Gamma)^2 + 16r_{iz}^2)^{\frac{5}{2}}} \right] \quad (18)$$

and  $\Gamma = \gamma + \sqrt{4 + \gamma^2}$ .

The components of vector  $\vec{r}_i = (r_{ix}, r_{iy}, r_{iz})$  represent the location of all particles in the lattices which depend on the lattice type. Accordingly, the value of the function  $f(\gamma)$  also depends on the lattice type. In order to solve the problem numerically in the next section, vector  $\vec{r}_i$  should be programmed as such to locate the particles arranged in the four considered lattice networks. This would be done through nested loops in the coding for each of the lattice types. The number of loops depend on the configuration of particles in the lattice.

Finally, using (5) for elastic energy and (17) for magnetic energy, the total potential energy of the deformed MRE under application of the external magnetic field, can be obtained as:

$$e = \frac{G_0}{2} \left( \left( \frac{\Gamma}{2} \right)^2 + \left( \frac{2\gamma}{\Gamma} \right)^2 - 2 \right) + u_0 \phi^2 \left( \frac{h}{1+|h|} \right)^2 f(\gamma) \quad (19)$$

where the value of function  $f(\gamma)$  presented in (18) depends on the lattice types shown in Fig. 2. Having the total energy as a combination of elastic and magnetic contributions, the magneto-mechanical properties of the MRE can be investigated. In the next section, elastic shear modulus of the elastomer will be obtained from the energy function and will be presented on graphs as a function of the applied magnetic field intensity.

### B. Elastic Shear Modulus

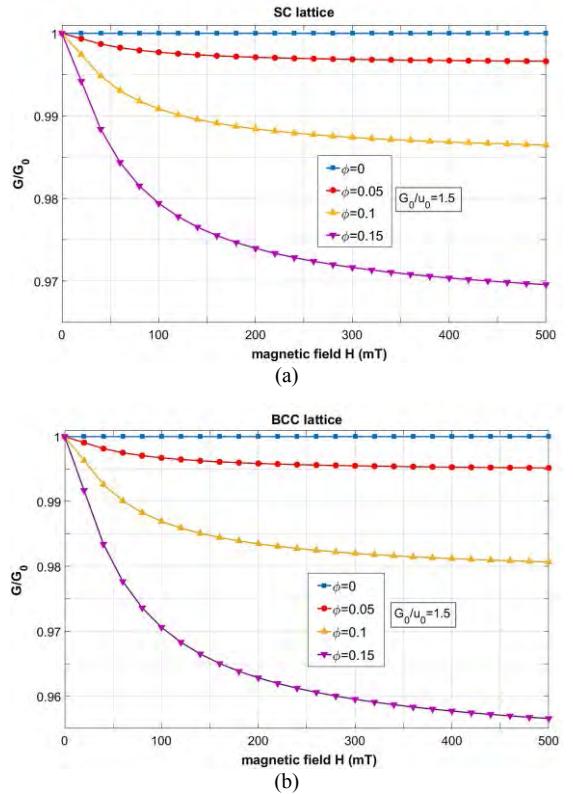

The interesting feature of magnetorheological elastomers is their adaptability and possibility of changing their modulus of elasticity by application of an external magnetic field. Shear modulus of a MRE sample having different idealized distribution of particles can be derived from the total potential energy of the material formulated in the previous section. Considering the case of a MRE sample under shear deformation normal to the direction of external magnetic field as shown in Fig. 1, the elastic shear modulus can be obtained as the second derivative of total energy with respect to  $\gamma$ , at equilibrium state as:

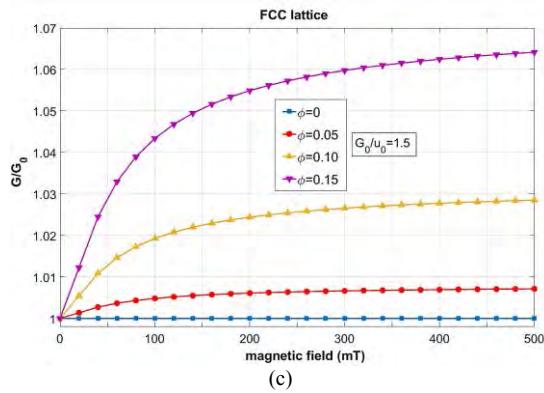

$$G = \frac{\partial^2 e}{\partial \gamma^2} \Big|_{\gamma=0}, \quad (20)$$

where  $G$  is the shear modulus of the MRE. Here, the ratio of modulus  $G/G_0$  is going to be depicted as a function of magnetic field magnitude  $H$  for each of the considered types of particle networks shown in Fig. 2. This dimensionless ratio also depends on the parameter  $\phi$  and the dimensionless ratio of  $G_0/u_0$ .

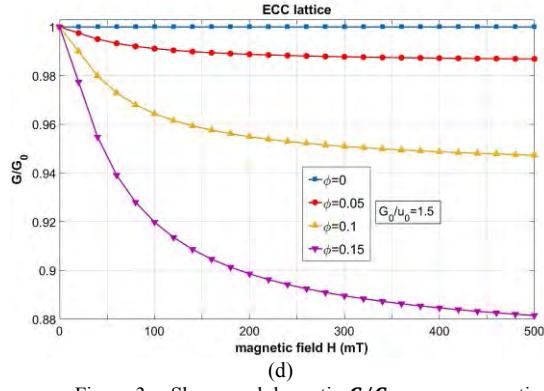

### III. RESULTS AND DISCUSSIONS

By programming in MATLAB® environment, shear modulus is calculated numerically. Fig. 3 shows the shear modulus ratio  $G/G_0$  as a function of the applied magnetic field,  $H$ , at different volume fractions  $\phi = 0, 0.05, 0.1, 0.15$  and constant value of  $G_0/u_0=1.5$  for all types of lattices considered in this work i.e. simple cubic, body centered cubic, face centered cubic, and edge centered cubic. Fig. 4 presents the same results at the fixed value of volume fraction  $\phi = 0.1$  but different values of parameter  $G_0/u_0=1, 1.5, 5, 10$ . It is noted that numerical values of  $M_s=1990$  kA/m, and  $\mu_{ini}=132$  as in [16] are utilized for obtaining numerical results.

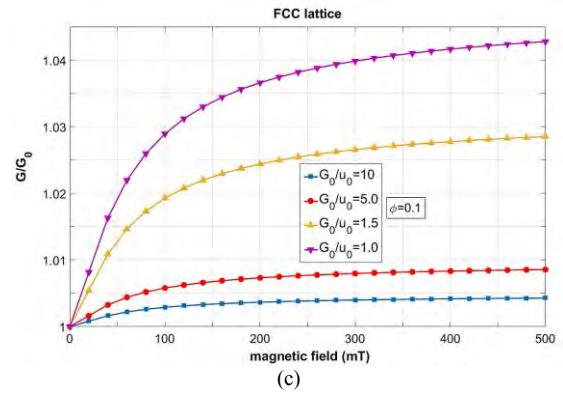

Figure 3. Shear modulus ratio  $G/G_0$  versus magnetic field intensity  $H$  (mT) at different volume fractions  $\phi$ , obtained for four different lattice networks: simple cubic lattice (a), body-centered cubic lattice (b), face centered cubic lattice (c), and edge centered cubic lattice (d).

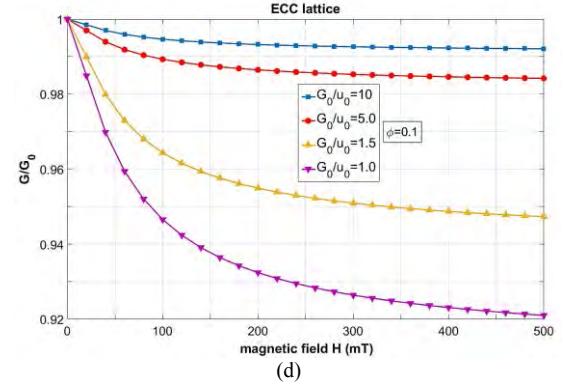

(a)

(b)

(c)

(d)

Figure 4. Shear modulus ratio  $G/G_0$  versus magnetic field intensity  $H$  (mT) at different values of  $G_0/u_0$  and fixed volume fraction  $\phi = 0.1$ , obtained for four types of lattice networks same as Fig. 3.

Examination of Figs. 3 and 4 reveals that, shear modulus of a magnetorheological elastomer decreases with magnetic field for the simple cubic, body centered cubic, and edge centered cubic lattices and increases for the face centered cubic lattice. These observations obviously show the impact of particles' network type on the magneto-mechanical behavior of MR elastomers. Different responses of lattice types to the applied magnetic field is due to the special arrangement of particles in each network which causes a different interaction between magnetic particles. Since the mutual interaction of all particles in the network is considered and summed for the calculation of magnetic energy and shear modulus, it is very difficult to evaluate the differences in reciprocal actions of particles for each lattice type. Among the considered lattices, edge centered cubic lattice has the largest change in the absolute value of the change of the shear modulus  $|G - G_0|$  with magnetic field. This may be due to the more compact arrangement of particles in this lattice type in comparison to the others.

In addition, it can be seen from Fig. 3 that an increase of the volume fraction  $\phi$  results in the increase of the absolute value of the change of the modulus  $|G - G_0|$  for all lattice types. That means the more number of particles participated in the material, the bigger the contribution of magnetic energy in the shear modulus by the application of a magnetic field. Furthermore, according to Fig. 4, increase of the parameter  $G_0/u_0$  decreases the absolute value of the change of the modulus  $|G - G_0|$  for all distributions of particles. Considering that the parameter  $G_0/u_0$

is in fact the ratio of the characteristic values of the elastic energy to the magnetic energy, increase of this parameter decreases the contribution of magnetic interaction on the shear modulus of the material. The results of this paper are compatible with those reported in [8] for the Young's modulus of a magneto-sensitive elastomer.

#### IV. CONCLUSIONS

In this work, a microstructure model of mechanical properties of MR elastomer materials was employed and extended to predict the static shear modulus of a MRE under an external applied magnetic field. To identify the effect of magnetic particles distribution on the magneto-mechanical behavior of a MRE, four idealized homogeneous arrangements of particles called lattice networks were considered. The utilized lattice types are simple cubic, body centered cubic, face centered cubic, and edge centered cubic. First the mathematical formulation of the total potential energy of a MRE sample under a shear deformation and also an external magnetic field was derived. The total energy has two parts of the elastic energy and the magnetic energy. The latter one depends on the interaction of magnetic particles and so on the lattice type. Second the shear modulus of the MR elastomer was extracted from the total energy. Then, using numerical calculations, the shear modulus was obtained as a function of magnetic field and presented for samples having different content of particles and initial properties.

According to the results presented in this work, the shear modulus decreases with increase of the magnetic field for three of the considered lattice types including simple cubic, body centered cubic, and edge centered cubic. However, the shear modulus increases with the magnetic field for the face centered cubic lattice. The variety of the results of the lattice types to the magnetic field is an obvious indication for the impact of magnetic particles distribution on the magneto-mechanical properties of the material. Besides, the effect of volume fraction of particles  $\phi$  and the ratio  $G_0/u_0$  on the shear modulus is also investigated. The absolute value of the change of shear modulus from the initial modulus  $|G - G_0|$  increases with an increase of volume fraction and decreases with an increase of the ratio  $G_0/u_0$ .

In order to know which of the assumed particle networks can be a more realistic model of particles distribution in homogeneous MRE materials, these theoretical results should be compared with experimental tests. Looking through the literature, the static shear modulus of a MR elastomer normally should increase under an applied magnetic field [7, 9, 17]. Accordingly, the results of the face centered cubic (FCC) lattice can be of higher validity. Comparing the theoretical results of the investigated model in the present work with the results of experimental tests can be an objective of another work in this subject.

**Abstract**—The formulation, tuning and performance of a signal prediction algorithm as applied to the determination of a Go-NoGo state are discussed. Simulations were used to tune and assess the performance of the signal prediction algorithm. The paper describes the development of useful criteria, based on the mean and standard deviation of the predicted signal, used for producing the Go-NoGo state. A latching algorithm was used to improve the output of the Go-NoGo state.

**Keywords**-Signal prediction; Go-NoGo state; control system state estimation

## I. INTRODUCTION

In marine applications, the determination of the ship motion and the relative motion between two independent bodies is a challenging task. The motion of the mothership often defines the availability for load transfer, aircraft landing opportunities and the launch and recovery of marine craft. Sophisticated and established methods do exist that determine the motion of a ship in a seaway through panel or finite element methods [1],[2]; however, these methods do not lend themselves to real-time estimation. Moreover, these methods cannot be extrapolated to determine any generalized signal or motion. Kuchler et al. [3] presented an implementation of a wave-prediction algorithm, which combats transport delays between actual ship motion and measurement of ship motion. Woodacre et al. [4] was able to build upon Kuchler et al. [3] and use a version of the prediction algorithm as a previewing function for a Model-Predictive Control scheme (MPC). The current authors are building upon these works to generalize a signal prediction algorithm (SPA) so that it can predict any sinusoidal signal and, given a set of criteria, determine if a process has a high likelihood of success.

This paper presents the formulation of the signal prediction algorithm (SPA) in the following section, followed by an investigation of the tuning parameters used for detecting the modes of the signal. Simulation results are analyzed in Section III and useful criteria for defining a “GO” scenario are developed for the purpose of producing a Go-NoGo command

signal. In Section IV, a latching algorithm is proposed to remove fluctuations in the Go-NoGo command signal. The paper ends with concluding remarks and future work. In general, the methods proposed can be used for fault detection and avoidance of unmanned systems.

## II. SIGNAL PREDICTION ALGORITHM

### A. Signal Prediction Formulation

The signal prediction method based on the work of Kuchler et al [3] and Woodacre et al. [4],[5] is composed of three distinct parts: mode detection, estimation, and prediction. To predict the wave motion, the periodic components, or modes, must be identified. These modes are determined by decomposing the measured signal  $s(t)$  into a set of  $N$  sine waves expressed as

$$s(t) = \sum_{i=1}^N A_i \sin(2\pi f_i t + \varphi_i) + v(t) \quad (1)$$

where the amplitude  $A$ , frequency  $f$ , and phase  $\varphi$  of each mode  $i$  are obtained by taking the Fast Fourier Transform (FFT) of past measured data over a specified time interval. Additionally, the static signal offset is denoted by  $v(t)$ . The specified time window for the FFT, referred to as  $T_{FFT}$ , and sampling frequency are set depending on the frequency content of the known wave spectrum. The time window  $T_{FFT}$  is chosen such that the highest frequency of the wave spectrum can be detected, while also preventing aliasing. The sampling frequency of the FFT is selected such that a desired resolution in the frequency domain is achieved.

As conditions change, the number of modes  $N$  and associated frequencies  $f$  change with time; therefore, to predict the periodic motion, a peak detection algorithm is performed at every  $T_{FFT}$  interval on the latest set of measured data. This peak detection algorithm determines the amplitude  $A_{FFT}$  and frequency  $f_{FFT}$  of each mode based on the dominant peaks in the FFT spectrum. A peak in the FFT spectrum is determined to be

dominate when it exceeds a peak detection sensitivity,  $\eta$ , which is set by the user. When a new set of modes is identified, it is used to initialize an observer model with a new set of parameters:  $A_{FFT}$ ,  $f_{FFT}$ ,  $\varphi_{FFT}$ , and  $N$ .

The observer model is used to continuously estimate the mode parameters  $A_{FFT}$  and  $\varphi_{FFT}$  such that the latest signal measurements are used to adapt  $A_{FFT}$  and  $\varphi_{FFT}$  at each time step. For the prediction algorithm, a discrete Kalman filter is implemented to estimate the system states and has the form

$$\begin{aligned}\hat{x}_{k+1} &= \Phi \hat{x}_k + L(w_k - \hat{w}_k), \quad \hat{x}_0 = x_0 \\ \hat{w}_k &= C \hat{x}_k\end{aligned}\quad (2)$$

where  $k$  is the current time step,  $\Phi$  is the discrete system matrix,  $\hat{x}$  is the vector of observed states,  $L$  is the observer gains matrix,  $\hat{w}$  and  $w$  are the estimated motion and measured motion respectively, and  $C$  is the system output matrix. The discrete system matrix, observed states and system output matrix were derived following the work of Kuchler et al. [3].

For the current study, a static observer gain matrix was selected via manual tuning and has the form

$$L = [0.2 \quad 3 \quad 0.2 \quad 3 \quad \dots \quad 0.2 \quad 3 \quad 0.1] \quad (3)$$

From each detected mode, two observer states  $x_{i,1}$  and  $x_{i,2}$  are estimated and then rearranged to solve for the adapted observer parameters  $\varphi_{obs}$  and  $A_{obs}$  at the current time  $t_k$ , such that:

$$\begin{aligned}\varphi_{obs} &= \arctan\left(\frac{2\pi f_i \hat{x}_{i,1}}{\hat{x}_{i,2}}\right) - 2\pi f_i t_k \\ A_{obs} &= \frac{\hat{x}_{i,1}}{\sin(2\pi f_i t_k + \varphi_{obs})}\end{aligned}\quad (4)$$

Finally, the prediction algorithm can be used to forecast the motion sequence over a prediction horizon  $T_{Pred}$ , i.e. at the time  $t_k + T_{Pred}$ . Referring to Equation 1, the predicted motion at  $t_k + T_{Pred}$  is

$$s_{Pred}(t) = \sum_i^N A_{obs,i,k} \sin(2\pi f_i(t_k + T_{Pred}) + \varphi_{obs,k,i}) + v(t) \quad (5)$$

To test the SPA and develop the Go-NoGo discriminator, a benchmark data set was used.

### B. Benchmark Data

Figure 1 shows the benchmark test case used as the input signal  $s(t)$  throughout this paper. This test case originates from a set of digitized ship motion data from the Australian DSTO report [6]. The signal  $s(t)$  is the resolved roll motion of the data, in degrees.

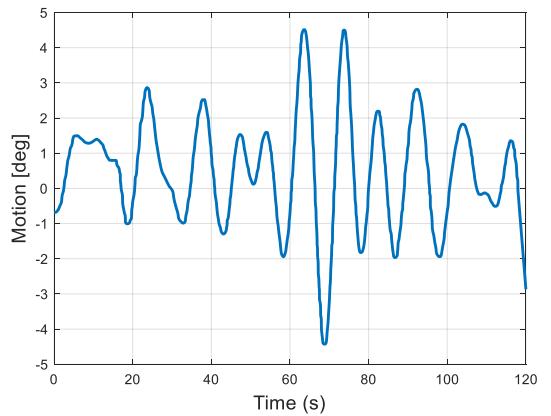

Figure 1. Benchmark test case of resolved roll motion from the Australian DSTO report [6].

### C. Mode Detection Tuning

In the SPA formulation section above, it was discussed that to detect the dominant modes of the incoming signal it is necessary to select an appropriate  $T_{FFT}$  and peak detection sensitivity,  $\eta$ . The selection of an inappropriate  $T_{FFT}$  can result in two undesirable scenarios: the first being too short an interval that results in no modes detected, and the second being too long an interval that results in modes detected at a rate that does not keep up with changing conditions, yielding aliasing. To examine these issues, Figure 2 plots the input signal  $s(t)$ , as a solid blue line, and the prediction  $s_{Pred}(t)$ , as a dashed red line, at 0.25 s into the future.  $s_{Pred}(t)$  is shifted back 0.25 seconds, i.e. 25 time steps, to place both the input signal and the prediction in the same time frame. The dotted green line between 70 s and 80 s in Figure 2 depicts the scenario where there is no predicted signal due to no modes detected during the previous  $T_{FFT}$  interval.

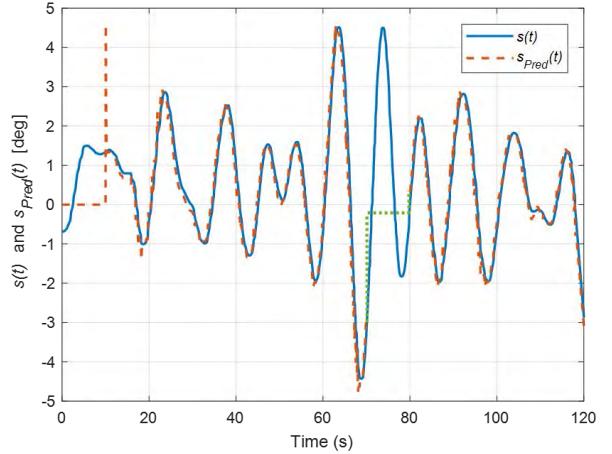

Figure 2. Measured and predicted signal together, with prediction signal time shifted to the input signal timeframe. The prediction discontinuity due to no modes detected is shown in green.

To address the issue of discontinuities in mode detection, the detection algorithm was amended such that in the case where zero modes are detected, the set of data over which the

FFT is performed is expanded every time step until at least one new mode is detected. The next mode detection is then performed after another  $T_{FFT}$  window, starting where the new set of modes was detected. In this way, the mode detection algorithm can handle slower than expected modes that may exist in the signal  $s(t)$ . In addition to the latter, the proposed amendments stated above also eliminate the second undesirable scenario, as the user can set a shorter  $T_{FFT}$  to avoid aliasing, without needing to consider the  $T_{FFT}$  length required to ensure continuous mode detection.

The peak sensitivity  $\eta$  describes the minimum peak height; a threshold value used by the peak detection algorithm to determine the dominant peaks in the FFT spectrum. Figure 3 shows the amplitude-frequency spectrum of the first 10 s of the benchmark test case in Figure 1 with  $\eta = 0.01$ , indicated by a dashed red line. For this  $\eta$ , the number of peaks detected is 6, denoted by the triangle markers. By inspection of the first 10 s of the benchmark test case in Figure 1, to capture the dominate motion at most two peaks should be detected. Any other peaks in the FFT spectrum is attributed to sensor noise. By increasing the value of  $\eta$ , the sensor noise can be rejected. Shown as a dashed red line in Figure 4,  $\eta$  has been increased by a factor of 10 ( $\eta = 0.1$ ) and the number of peaks detected is two. The selection of peak detection sensitivity  $\eta$  must therefore be set based on sensor noise and is case specific. Future work could examine a recursive methodology to determine if a peak is valid or estimate how many peaks should be identified.

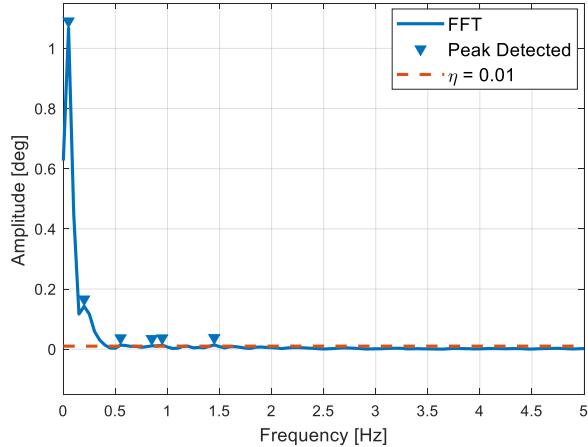

Figure 3. Dominant peaks detected from the FFT spectrum of the first 10 s of the benchmark case for  $\eta = 0.01$

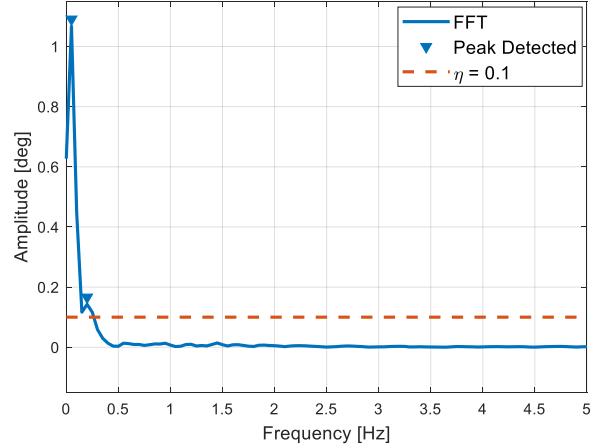

Figure 4. Dominant peaks detected from the FFT spectrum of the first 10 s of the benchmark case for  $\eta = 0.1$

### III. RESULTS

#### A. Simulation

The SPA detailed in Section II was implemented in MATLAB and simulated in the Simulink environment. Figure 5 depicts the Simulink block that calls on the SPA function. The input variables include input signal  $s(t)$ ; the GO criteria; tuning parameters  $T_{FFT}$  and  $\eta$ ; and the prediction horizon  $T_{Pred}$ . The SPA block outputs the predicted signal  $s(t+T_{Pred})$  and the Go/NoGo command signal. A fixed step, discrete solver was used with fixed step  $dt = 0.01$  s. For the benchmark case in Figure 1, the simulation runtime is approximately 11 s for the full 118 s of the benchmark signal.

Figure 5. SPA function block implemented in the Simulink environment

#### B. Prediction Assessment

Figure 6 displays the predicted signal, solid red line, over a continuous prediction horizon of 10 s for the benchmark input signal, solid blue line, at time  $t = 38$  s. The parameters used for the prediction were:  $T_{FFT} = 10$  s and  $\eta = 0.1$ . In Figure 6, good accordance is observed between the input signal and predicted curve until  $T_{Pred} \approx 3$  s. To investigate this further, the predicted signal is examined for 1 s, 3 s and 10 s prediction horizons.

Figure 7a depicts the prediction error for the prediction at 1 s into the future at every point in time. Similarly, Figure 7b and c respectively depict the prediction error at 3 s and 10 s into the future at every point in time. Note that the first 11 s are omitted to ignore the initialization period of the SPA. The maximum, minimum, mean and standard deviation of the error for each case are tabulated in Table I for  $t = 11$  s to 110 s. From Table I, both the mean and standard deviation of the absolute error are significantly larger, by an order of magnitude, for the longest

prediction horizon of 10 s. The latter is consistent with what was qualitatively observed in Figure 6 at  $t = 38$  s. The results in Table I suggest that determining the likelihood of success of a process to produce a Go-NoGo command becomes less accurate for longer prediction horizons as the mean error increases significantly over this time interval. Furthermore, defining the GO scenario based on the maximum error observed over  $T_{Pred}$  alone is not representative of true future events for longer predictions. The following section will develop useful GO criteria that considers the error that exists in the prediction.

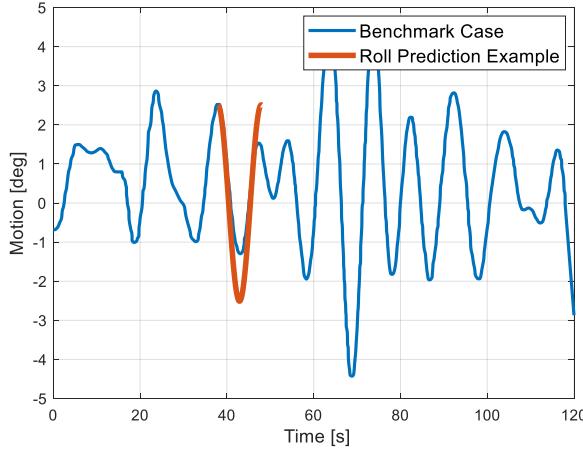

Figure 6. Benchmark data with prediction curve at  $t = 38$  s plotted over a continuous time horizon of 10 s into the future.

TABLE I. ERROR METRICS FOR VARIOUS PREDICTION HORIZONS

Error  [deg]	Prediction Horizon, $T_{Pred}$		
	$T_{Pred} = 1$ s	$T_{Pred} = 3$ s	$T_{Pred} = 10$ s
Maximum	1.74	3.72	3.88
Minimum	$4.57 \times 10^{-6}$	$4.41 \times 10^{-4}$	$2.93 \times 10^{-4}$
Mean	0.29	0.89	1.41
Standard Deviation	0.35	0.92	1.69

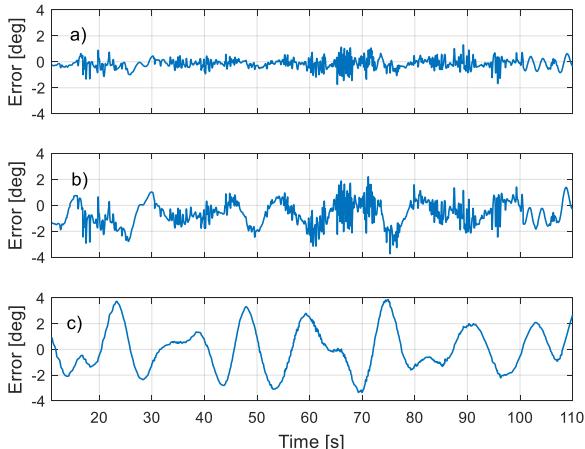

Figure 7. Error between benchmark data and prediction at a) 1 s into the future, b) 3 s into the future and c) 10 s into the future.

### C. Developing the Go/NoGo Criteria

For the purposes of this paper, the SPA is used to output a Go-NoGo command based on given GO criteria. The GO criteria could be one or several parameters used to define the acceptable conditions for a GO scenario. The criteria are compared with the predicted signal over the continuous prediction horizon  $T_{Pred}$  at each time step. If over the prediction horizon, the predicted signal meets the GO criteria, a GO command is output. Conversely, if the GO criteria are not met by the predicted signal over the prediction horizon, a NoGo command is output. In this section, the development of useful definitions of the GO scenario, to be identified based on the GO criteria, are investigated.

The first definition of the GO scenario to be investigated is the simple Maximum Prediction Threshold (MPT) approach. This approach identifies a GO scenario if over the entire prediction horizon, the maximum value of the predicted signal is below the given threshold value. In other words, only one point of the predicted signal must be above the threshold to output a NoGo command. The results in Table I suggest that this simple Maximum Prediction Threshold approach would not provide a useful definition of the GO scenario for longer  $T_{Pred}$ , as there exists more error with the predicted signal as the prediction horizon increases. Two more GO criteria are suggested below that are defined such that the error that exists in the prediction is considered.

If instead, the GO scenario is defined based on the statistical spread of the predicted signal, it is possible to relax how the GO criteria identify a GO scenario. The spread of 1 Standard Deviation (1-SD) approach outputs a GO command when the prediction mean, evaluated over the prediction horizon, plus 1 standard deviation of the prediction is below a threshold value. The 1-SD approach is expressed empirically in Equation 6 as

$$\text{Go Criteria} > \bar{s}_{\text{Pred},k} + \sigma_k \quad (6)$$

where  $\bar{s}_{\text{Pred}}$  is the prediction mean over  $T_{Pred}$  at time step  $k$ , and  $\sigma$  is the standard deviation of the prediction over  $T_{Pred}$  at time step  $k$ . Equation 6 is equivalent to stating that for any randomly selected sample of the predicted signal over  $T_{Pred}$ , a GO command is output if 68% of the sampled points fall below the threshold.

The spread of 1.645 Standard Deviations (1.645-SD) approach defines the GO scenario to occur when the prediction mean plus 1.645 standard deviations is below the threshold value. The 1.645-SD approach is expressed empirically in Equation 7 as

$$\text{Go Criteria} > \bar{s}_{\text{Pred},k} + 1.645 \sigma_k \quad (7)$$

Equation 7 is equivalent to stating that for any randomly selected sample of the predicted signal over  $T_{Pred}$ , a GO command is output if 90% of the sampled points fall below the threshold. Both methods described in Equations 6 and 7 are based on the same principle but differ in how conservatively they evaluate the predicted signal.

To evaluate the three definitions of the GO scenario MPT, 1-SD and 1.645-SD, the SPA was run for each case with the benchmark data and compared with the desired Go-NoGo command signal. The desired command signal was determined by setting the command as GO when the benchmark case is below the threshold value and setting the command as NoGo when the benchmark case is above the threshold value. Figure 8a shows the input signal, left axis, as a solid blue line with the GO criteria threshold, set as  $2.5^\circ$ , as a dashed red line. In Figure 8a, the desired Go-NoGo command signal, right axis, is also shown for  $t = 50$  s to  $t = 90$  s of the simulation. Here GO = 1 and NoGo = 0. Figure 8 part b, c and d depict the Go-NoGo command signal for the MPT, 1-SD and 1.645-SD approaches respectively. The three GO scenario definitions were evaluated based on the number of seconds that a GO command is output compared to the amount of GO time registered by the desired command signal. When obtaining the GO time, the first 11 s of data are omitted to ignore the SPA initialization period. In Table II, the GO time for the benchmark case from  $t = 11$  s to  $t = 118$  s is tabulated for each approach.

TABLE II. EVALUATION OF GO SCENARIO DEFINITIONS

“GO” metric	“GO” scenario definition [11 s – 118 s]			
	Desired	MPT	1-SD	1.645-SD
“GO” time [s]	98.98	87.71	94.78	77.94
Error [s]		11.27	4.20	21.04

Due to its close agreement with the desired command signal, the best definition of the GO scenario, based on a given threshold value, is the 1-SD method. Moreover, with the least amount of GO time, the 1.645-SD method was found to be the most conservative method for defining the GO scenario.

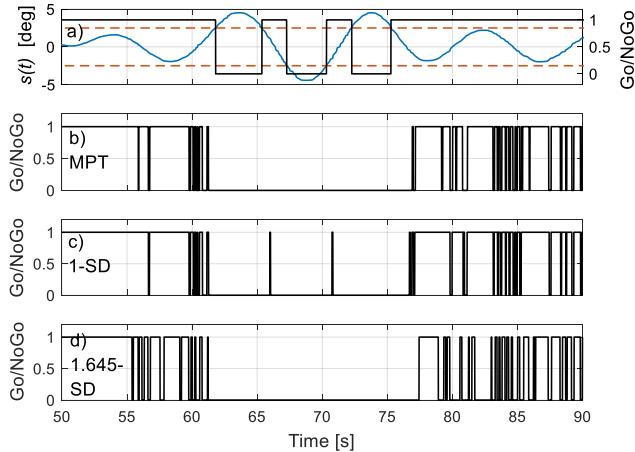

Figure 8. Go-NoGo command signals with desired command signal in a), and resulting command outputs for approaches b) MPT, c) 1-SD and d) 1.645-SD. For display purposes, the results are shown for  $t = 50$  s to  $t = 90$  s.

#### D. Go-NoGo Command Latching

Observing the Go-NoGo signals in Figure 8b, c and d at 60 s, 80 s and 90 s, there is rapid fluctuation in the command signal.

For a physical implementation of the SPA, it is desired that the SPA latches on to a GO or NoGo command to meet the responsivity of the physical system components. A method for Go-NoGo command latching is proposed below to limit this undesirable fluctuation.

Figure 9 shows the logic flowchart for the latching algorithm. To start, the latching algorithm receives the Go-NoGo state determined from the predicted signal. Next, the algorithm looks to see if a target state has been set. If no target state has been set, the current Go-NoGo state is set as the target state. The algorithm must then determine whether it will commit to this target by watching the incoming Go-NoGo state over an evaluation period  $T_{eval}$ . During this evaluation period, if at any point the incoming Go-NoGo state differs from the target state, the current Go-NoGo state is set as a new target state and  $T_{eval}$  is reset. However, if all Go-NoGo states received during the evaluation period match the target state, the algorithm will “latch” onto the target state and output this command over the runtime interval  $T_{run}$ . After  $T_{run}$  is complete, a new evaluation period begins.

Figure 10 shows the results of the latching algorithm where the Go-NoGo command signal without latching is shown in 10a, and the Go-NoGo command signal with latching is shown in 10b. For illustrative purposes,  $T_{eval}$  was set as 0.1 s and  $T_{run}$  was set as 2 s, i.e. if a GO condition is sustained for 0.1 s the system will latch in a GO condition for at least 2 seconds. The command signals are output for the benchmark test case for  $t = 50$  s to  $t = 90$  s. It is observed that for the selected  $T_{eval}$  and  $T_{run}$ , all fluctuation was removed from the original command signal in Figure 10 a.  $T_{eval}$  and  $T_{run}$  are case specific and should be based on the physical systems involved.

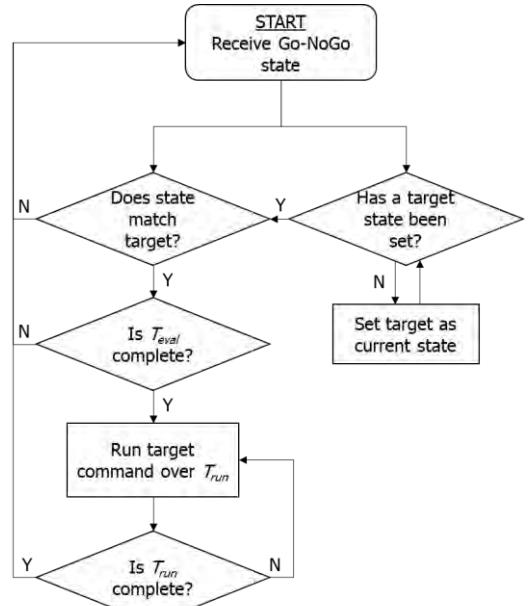

Figure 9. Flow chart of the logic used in the command signal latching algorithm.

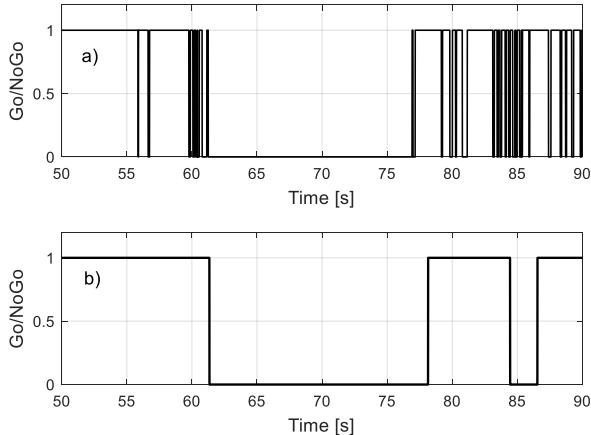

Figure 10. Go-NoGo command signals for the benchmark test case without latching in a) and with command latching in b). For display purposes, the results are shown for  $t = 50$  s to  $t = 90$  s.

#### IV. CONCLUSIONS

This paper describes the generalized formulation and tuning of a signal prediction algorithm as it applies to the determination of a Go-NoGo state. A key modification made to the SPA was the implementation of continuous mode detection that enables the algorithm to dynamically handle changing conditions of the input signal. Tuning the SPA also included setting a peak height sensitivity parameter that is used for determining the dominant peaks in the FFT spectrum during mode detection. By investigating the FFT spectrum of one identification period of the input signal, it was determined that the peak height sensitivity should be set such that it ignores sensor noise in the measured signal and is therefore case specific.

The paper also described the development of useful GO criteria used for producing the Go-NoGo state. Because prediction error increases over the prediction horizon, it was determined that a GO scenario identified by the maximum point of the prediction should not be used, as this approach can lead to erroneous conclusions regarding the Go-NoGo state. Instead, a GO scenario defined by the mean and one standard deviation of the predicted signal over the prediction horizon was found to

produce a Go-NoGo signal that agreed the most with the desired Go-NoGo signal.

Performance of the SPA was further improved with the implementation of a latching algorithm that successfully removed undesirable fluctuation in the Go-NoGo signal.

It is anticipated that several practical industrial applications can benefit from the proposed methods of determining a Go-NoGo state. In general, the methods proposed can be used for fault detection and avoidance of unmanned systems. Specifically, with UAV ship landing operations the SPA can be employed to estimate the ‘quiescent period’, where the roll and pitch angles of the ship are below critical threshold values. From the estimated quiescent period, a Go-NoGo state is inferred that can be used to increase the effectiveness of autonomous vertical landings on transient platforms.

#### ACKNOWLEDGEMENT

Waterloo, Canada

**Abstract**— Notches are inevitable in many components and structures due to design limitations. In addition, they are the locations for stress concentration and are susceptible to fatigue failure. As a result, the cyclic stress/strain response at a notch is of key importance. Fiber Bragg Grating (FBG) sensors have been successfully utilized for mechanical and thermo-mechanical strain measurement in many cases; nevertheless, their capability of measuring strain at spots with intensive stress/strain has not yet been explored. In this research, FBG sensors are employed for strain measurement at the notch tip. A verification test was designed to substantiate the FBG measurements. The test involves a rectangular magnesium sheet with a center hole, subjected to uniaxial cyclic loading while the strain was measured at the notch tip using three different methods: strain gage, digital image correlation (DIC), and FBG. There were good agreements between the three measurements.

**Keywords-** Notch; strain measurement; FBG; DIC

## I. INTRODUCTION

Fatigue is the dominant failure mode for components under cyclic loading, particularly in notched members [1]. To assess fatigue life, the cyclic stress/strain response at the notch tip is of key importance; however, strain measurement at this location has been challenging due to the high gradient of strain over a small area in the vicinity of the notch.

The common experimental approaches for notch stress/strain assessment are photoelasticity, thermoelasticity, brittle coatings, strain gages, and digital image correlation (DIC). Photoelasticity was initially devised by Brewster [2]. More than a century later, Coker and Filon developed this method as a tool for stress distribution assessment [3]. In this technique, a transparent material is utilized for fabricating a specimen with geometry similar to that of the notched member, and stress distribution is obtained by monitoring changes in the optical properties of the loaded transparent specimen via a polariscope. Photoelasticity can be adapted to both static and dynamic loading scenarios, even though doing so requires model preparation, and sometimes, tedious post-calculation [4].

The thermoelastic effect in metals was first recognized by Weber [5]. Belgen developed the first thermoelasticity application for contactless experimental stress analysis [6]. In thermoelasticity, local small temperature alterations of the loaded specimen indicate the stress distribution, allowing full-field stress map to be made of the surface. In this method, the minimum detectable stress is restricted by the sensitivity of the employed apparatus; therefore, high precision requires costly experimental setup [7].

The brittle coating method begins with spraying a brittle coating on the surface of the notched member and letting it dry. The applied load will form crack patterns in the coating. The region and magnitude of stress concentrations can be indicated by comparing the crack patterns with the intact surface of the calibration coating. The coating's vulnerability to humidity and temperature, and the qualitative rather than quantitative results are two disadvantages of this method [8].

The strain gage technique is the most common experimental method for local strain measurement. The strain gage consists of a metallic foil pattern that acts as electrical resistance, supported by an insulating backing. It is attached to a prepared surface in the region of interest by a suitable adhesive. The dimensional change caused by the applied load results in electrical resistance alternation of the foil, which is used for strain measurement [9]. Initial calibration, non-linearity, and pointwise measurement are among strain gage's main drawbacks [7].

Digital image correlation (DIC), is a non-contact optical technique for strain measurement, employs image tracking and registration techniques [10]. One of the first applications of DIC for deformation quantification was suggested by Peters and Ranson [11]. The DIC's accuracy has been widely substantiated through comparison with finite element and other verified methods [12]–[17]. Two DIC algorithms were used by González and co-workers [10] for elastoplastic strain distribution measurement in shallow and deep notches. They verified their results with finite element method (FEM). Kotousov et al. [18] employed DIC for displacement- and strain-fields quantification near a sharp notch and compared the measurements with analytical and numerical solutions.

The Fiber Bragg grating sensor is another advanced optical method for gauging external stimulants like strain. The Bragg gratings are written into the germanium-doped core of an optical fiber by periodic ultraviolet exposure leading to peculiar wavelengths reflection [19]. Any externally applied load and/or change in temperature increases or decreases the initial wavelength that is recorded by an interrogator during the experiment. The magnitude of this alternation can be converted into strain values by means of the mathematical expressions [19]. Even though the merit of FBG sensors for mechanical strain quantification has been verified extensively in the literature [20]–[24], its capability for intense notch tip strain measurement is still not well understood.

Because of the high resolution of the grating in the FBG sensor, it could be a proper candidate for mechanical strain measurement at spots with an intensive stress/strain gradient, e.g., at notches. To explore the applicability of the FBG, they are employed in this work for strain measurements at the notch tip. Variable amplitude cyclic loading was applied to the specimen, and the strain was measured utilizing three different measurement methods: strain gage, DIC, and FBG.

## II. MEASUREMENT AND TEST PROCEDURES

### A. Material and Experimental Setup

The material under investigation was 4mm thick AZ31B-H24 hot-rolled magnesium sheet, provided by Magnesium Elektron of North America (MENA). Wrought magnesium has different yields in tension and compression [25] similar to the strength-differential effect seen in high strength steels [26]. The specimen was machined along the rolling direction with the dimensions shown in Fig. 1.

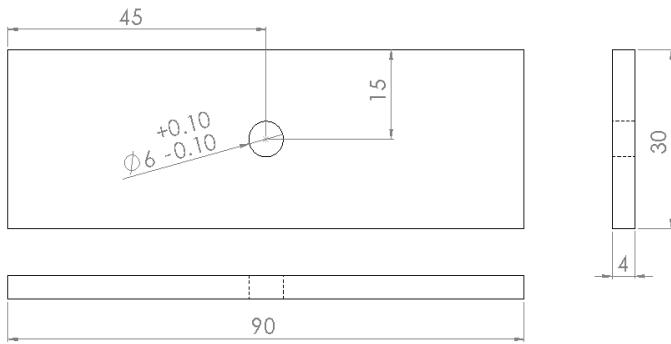

Figure 1. Notched specimen geometry (dimensions in millimeters)

Miniature strain gage C2A-06-015LW-120 from Micro Measurement Co. was selected for parallel strain measurement. The geometry of the strain gage is shown in Fig. 2. DAQ-DQ430 data-acquisition was employed, and one dummy gage was linked to the device to support quarter bridge gage configuration.

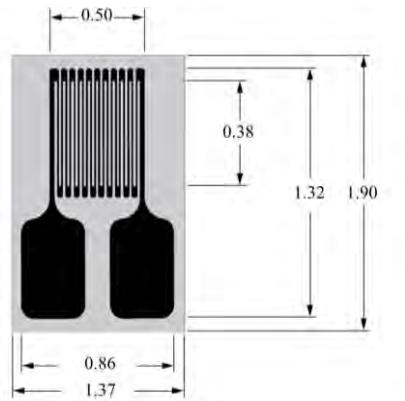

Figure 2. C2A-06-015LW-120 Strain Gage

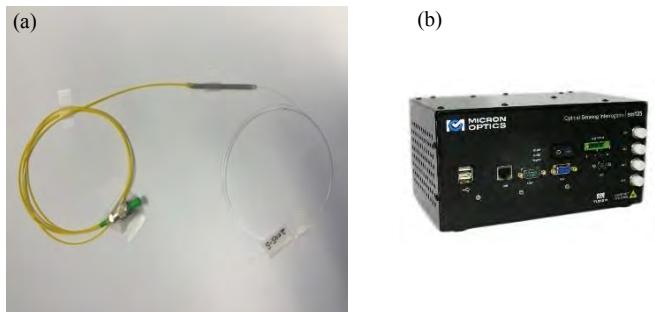

Figure 3. FBG equipment a) Corning SMF-28 with Bragg Grating b) Micron Optic SM125-200 Interrogator

Corning SMF-28 FBG with 5 mm effective length and 125  $\mu\text{m}$  diameter were used in this research. The fiber optic sensor is illustrated in Fig. 3 (a). The initial wavelength was measured to be 1550 nm. The grating modulation is Gaussian-apodized for this sensor, and the Bragg grating (1 mm length) had been written on a single mode of the optical fiber. The utilized optical interrogator is a Micron Optic SM125-200 with 5 pm resolution and an accuracy specification of 10 pm, as shown in Fig. 3 (b). It was connected to one side of the fiber optic cable by a FC/APC fiber connector.

For DIC strain measurement, the ARAMIS 3D System with two 5 megapixels CCD cameras, capable of 15 fps readout at full resolution has been employed. This stereo system delivers precise 3D coordinates by using stochastic patterns or reference point markers.

Three different methods- DIC, strain gage, and FBG- were utilized for notch tip strain measurement. The schematic configuration indicating the devoted area to each technique is illustrated in Fig. 4 (a). To obtain comparable results from the different techniques, measurement was performed at the same distance from the notch tip. Due to the installation limitations enforced by the strain gage dimensions, the strain gage was attached to the specimen as close to the notch tip as was technically possible. Then, its location was used as a reference for the FBG sensor and DIC measurements. The FBG sensor was connected to the other side of the notch, as shown in Fig. 4 (b). For simultaneous strain measurement, LabVIEW was used.

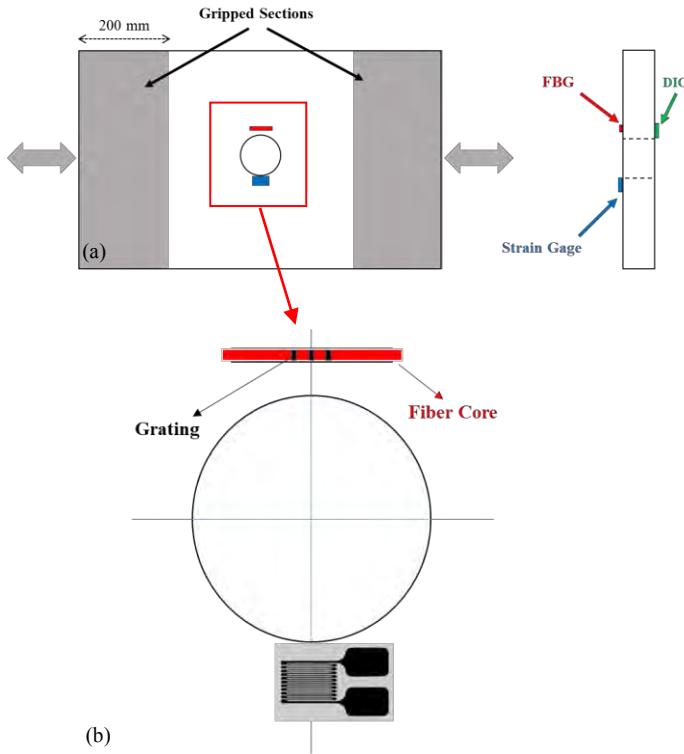

Figure 4. Schematic configurations of a) techniques used for notch tip strain measurement b) FBG and strain gage positions relative to the notch

### B. Test Procedures

The specimen was loaded using the 8874 Instron servohydraulic test frame with 25kN load capacity and 100N.m torque capacity. The test was run in load-control mode, and a variable amplitude load (VAL) pattern was applied. The peak force was 13 KN in accordance with the notch tip stress concentration to compel plastic deformation at the notch tip, while the far field remained elastic. Given the specimen geometry, shown in Fig.1, and the mode of loading, Fig. 4 (a), the stress concentration factor is equal to 2.5 [27]. The VAL loading scenario is depicted in Fig. 5.

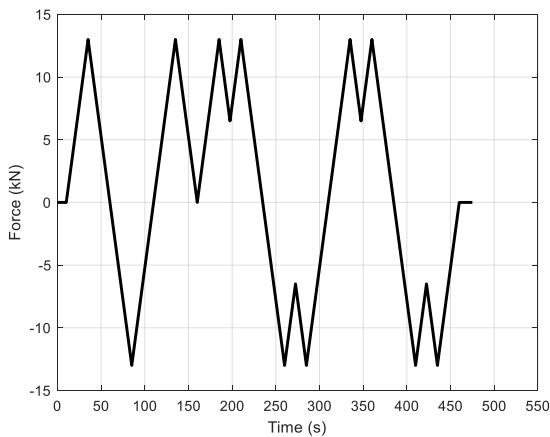

Figure 5. VAL scenario for FBG evaluation

### III. RESULTS AND DISCUSSION

Fig. 6 shows the test setup. Measured Peak and valley strains are tabulated in Table. I, and the engineering strain as a function of time is plotted in Fig. 7. All three methods follow the VAL pattern closely, with DIC having more noise in the measurements. This issue can possibly be resolved by utilizing higher resolution cameras. Fig 8. manifests the strain distribution around the notch tip for the first peak of loading captured by DIC.

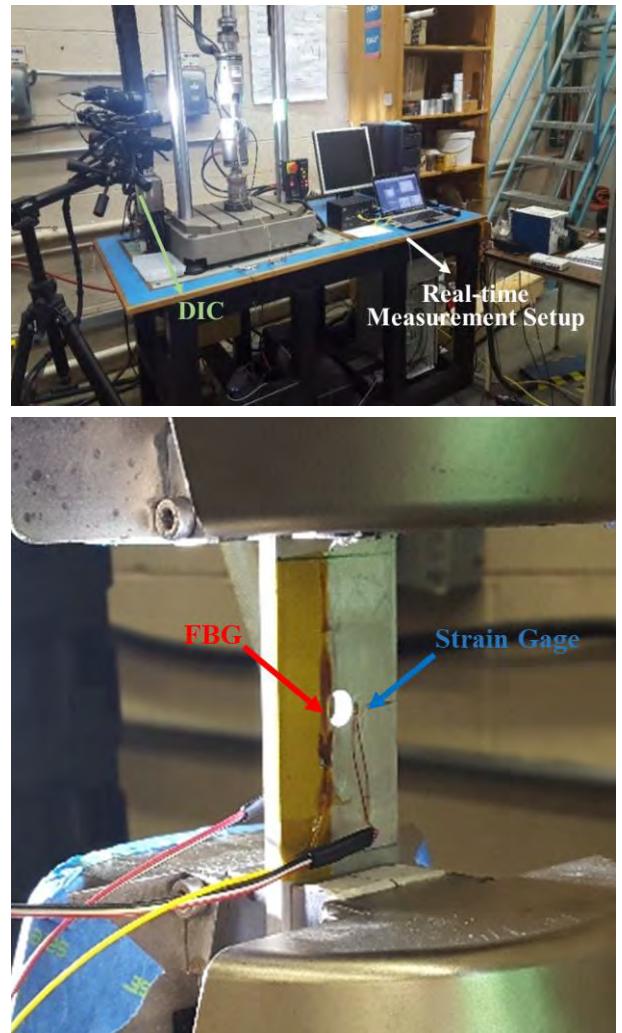

Figure 6. Final setup for simultaneous strain measurement

TABLE I. FIRST PEAK AND VALLEY OF STRAIN (%) MEASURED BY THREE DIFFERENT TECHNIQUES

Techniques	Peak	Valley
Strain Gage	0.587	-0.497
FBG	0.601	-0.575
DIC	0.599	-0.523

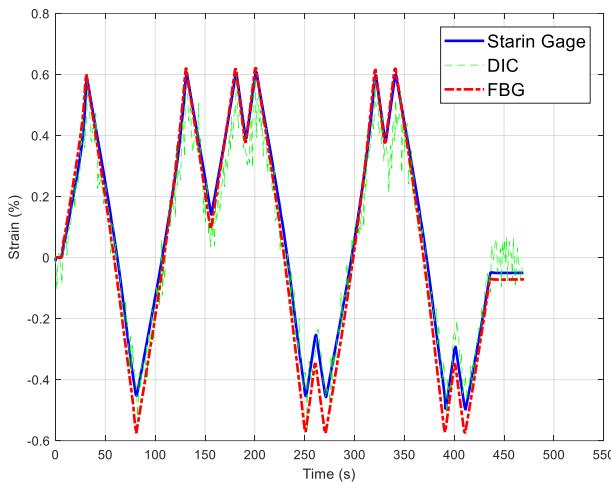

Figure 7. Notch strain measured by three experimental approaches

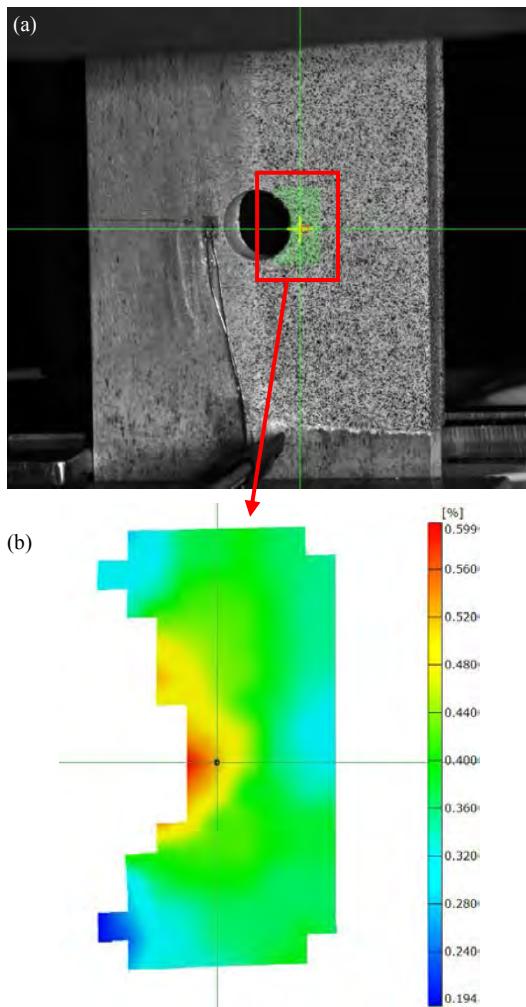

Figure 8. Peak strain distribution at the notch tip captured by DIC a) sample with speckle pattern b) strain map

The FBG sensor was capable of monitoring real-time strain during the experiment, whereas for DIC, the obtained images had to be analyzed after the test. In addition, the FBG pointwise resolution was higher compared to the strain gage. Overall, this study demonstrates the promising capability of FBG for fine strain measurement at the notch tip. Major sources for the slight difference in results are attributed to the following:

- Due to the very high strain gradient in the area near the notch root, even a few microns difference in the measurement position can affect the results significantly.
- All the implemented techniques average the strain over a specific area, e.g., the resistor area ( $0.38 \times 0.5 \text{ mm}^2$ ) of the strain gage, although efforts have been made to keep it as small as possible.

# Evaluation of Energy Efficient Propulsion Technologies for Unmanned Aerial Vehicles

Jay Matlock, Stephen Warwick, Phillip Sharikov, Jenner Richards, Afzal Suleman

Mechanical Engineering  
University of Victoria  
Victoria, Canada

**Abstract**— The transition to cleaner, more efficient and longer-endurance aircraft is at the forefront of current research and development in air transportation systems. The focus of this research is to experimentally evaluate Hybrid Propulsion and Energy Harvesting Systems in Unmanned Aerial Vehicles (UAV). Hybrid systems offer several potential benefits over more conventional gasoline and electric systems including lower environmental impacts, reduced fuel consumption, longer endurance, redundancy and distributed propulsion. Additional energy efficiency can be achieved by harvesting some of the thermal energy of the exhaust gases. By using the Seebeck effect, the temperature gradient between ambient air and the exhaust can be used to generate electric power, making it possible to eliminate costly mechanical systems such as alternators and reduce fuel consumption.

The development and experimental evaluation of a hybrid-propulsion UAV was carried out at the University of Victoria Center for Aerospace Research (UVIC-CfAR) in the framework of the Green Aviation Research & Development Network (GARDN) grant. The work involved the development of a framework to evaluate UAV hybrid propulsion efficiency, as well as to predict the amount of power harvestable from thermoelectric generators (TEG). The hybrid propulsion framework was used to investigate the trade-offs between different hybrid architectures against conventional electric and internal combustion propulsion systems. The energy harvesting module was designed to evaluate the trade-off between energy harvested, implementation costs and weight.

In order to validate the computational results, experimental testing was performed. First, an apparatus was designed to collect performance data of a triple-TEG system connected to a 4-stroke Saito internal combustion engine. Thermal performance of the system was evaluated at eleven different test points, and a number of variables were modified to simulate real flight profiles. Next, another apparatus was designed to characterize the performance of a parallel hybrid-electric propulsion system in a UAV. This apparatus allows for different mission profiles that closely match the flight test data from other propulsion types.

**Keywords:** *hybrid propulsion, series and parallel architecture; energy harvesting; thermoelectric generators*

## I. INTRODUCTION

Conventional aircraft are powered by fossil fuels used in different types of internal combustion engines, which produce a substantial amount of pollutants in the form of carbon dioxide. With new regulations and increase of public interest there has been an effort to transition to green transportation. Hybrid-electric propulsion and energy harvesting technologies are potential solutions to mitigate some of the issues identified. There is substantial pressure on the industry to maximize the efficiency of propulsion systems and minimize environmental impact. Gasoline internal combustion engines and electric motors are the two main architectures for UAVs, but each system has disadvantages.

Internal combustion engines tend to have higher endurance than electric systems, but this comes at the cost of high vibration and noise pollution, as well as high levels of emissions. Typically, gasoline engines are oversized for cruise in order to satisfy climb requirements. Electric propulsion systems have the benefit of lower noise, vibration and emissions and can supply a high torque across their operating range. However, the power density of battery packs is much lower than that of hydrocarbons, and the additional weight means that electric propulsion systems suffer from low endurance. A hybrid propulsion system that offers the benefits from both gasoline and electric configurations could prove to be a viable candidate for UAVs. The potential advantages of a hybrid propulsion system include the reduction in fuel burn and emissions, lower acoustic signature when operating in electric-only mode, lower-vibration operations, and the possibility of novel configurations through distributed propulsion. The efficiency of the overall system could be increased even further if some energy harvesting techniques are applied to the exhaust gas using thermoelectric generators. A hybrid propulsion system could also include some intangible benefits such as redundancy in the case of engine failure.

The two types of hybrid-electric configurations used in this project are series and parallel, as shown in Fig. 1. In a series configuration, the combustion engine and electric motor are not mechanically coupled. Instead, the combustion engine generates power using a separate generator which can be used to drive the electric motor or charge the battery packs. In a parallel

configuration, the combustion engine and electric motor are connected using some sort of mechanical coupling, and together drive the propeller. In a parallel configuration, a clutch is required to disconnect either the electric motor or combustion engine to operate in isolated modes.

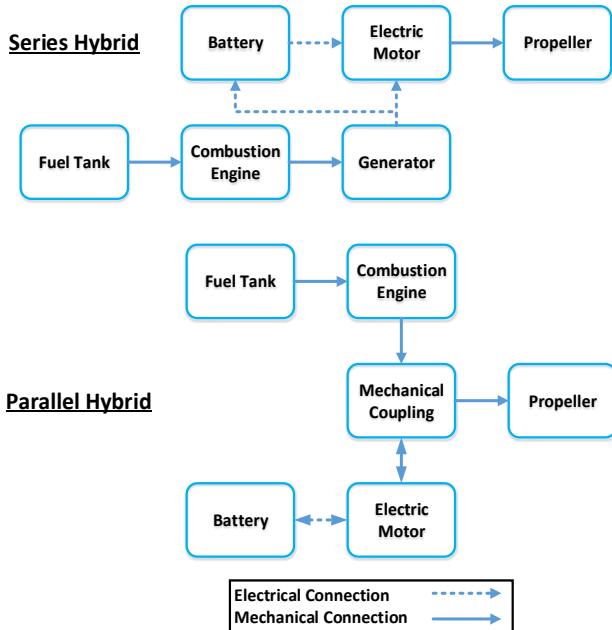

Figure 1. Series and Parallel hybrid-electric configurations.

One of the first major hybrid-electric propulsion UAV projects began in 2010 with the Air Force Institute of Technology's 'Project Condor'[1], [2]. This design involved conceptual design work, simulation, and control strategy development by several groups and predicted efficiencies of 94% [3]–[5]. The University of Colorado has shown success with their project HELIOS which also made use of a parallel hybrid architecture in their UAV [6]. Further, parallel hybrid research by Glasscock, Hung, Gonzalez and Walker at Queensland University have suggested that an increase of power of 35% can be achieved with only a 5% weight penalty for a UAV [7].

In a study conducted by Harmon, Frank and Joshi [4] it was estimated that a parallel configuration on a small UAV would be approximately 8% lighter than a series configuration. This estimate is due to the large electric motor and generator requirement of the series configuration. Although series hybrid configurations suffer substantial energy-conversion losses, they are simpler to control and offer features that are suitable for intelligence, surveillance and reconnaissance (ISR) missions such as distributed propulsion or electric-only operation. These features are possible for a series configuration because the internal combustion engine is decoupled from the electric motor that provides the propulsion.

Energy harvesting is the practice of generating energy from ambient energy sources, such as solar, vibrational, acoustic or thermal energy. Many applications for energy harvesting can be found in aviation, from structural health monitoring (SHM) systems requiring in-situ power production to electric-based

systems harvesting energy to increase endurance. Research into energy harvesting at UVIC CfAR has focused on recovering thermal energy to provide auxiliary power to an aircraft's electrical systems.

Thermoelectric generators utilize the Seebeck effect to convert thermal energy to electrical power when subjected to a temperature gradient. TEG efficiency depends on both the materials used and the temperature difference between the two sides of the module, as TEGs commonly operate at approximately 20% Carnot efficiency [8]. Commercial units have up to 12% conversion efficiency, with a 5% efficiency being common.

As mentioned previously, reciprocating internal combustion engines are a popular choice for UAV propulsion due to the fuel high energy density; however, this comes with a tradeoff of low thermal efficiency. Only 30–45% of the fuel energy is utilized to produce mechanical power, and this figure is even lower for small-scale engines [9]. The remaining energy is lost to the environment, with 40% of the total energy lost as exhaust gas kinetic and thermal energy [10]. Exhaust temperatures commonly reach as high as 800 degrees Celsius. Therefore, the high temperature of the exhaust relative to the environment makes the exhaust system a potential candidate for thermoelectric energy harvesting.

Thus far, thermoelectric energy harvesting research has largely been concentrated in the automotive sector. Generally, TEGs are placed on a specially designed exhaust pipe and are cooled with engine coolant; systems using heat pipes have been explored but are limited to low-temperature applications [8]. As weight is a secondary concern in the industry compared to aviation, a number of high-power energy recovery systems have thus been created and tested by companies such as BMW, Ford and Honda. Research has indicated that thermoelectric systems are capable of meeting the electrical requirements of vehicles, with experimental systems exceeding 700W power generation during bench testing [10]. An increase in fuel efficiency of up to 10% has been claimed, [11] though real-world efficiency gains were closer to 3% [9].

In contrast, thermoelectric energy harvesting for UAV applications has only received limited attention. Fleming, Ng and Ghamaty investigated thermoelectric power systems for micro air vehicle applications, [12] and Langley, Taylor, Wagner and Morris conducted theoretical modelling, design and optimization, and subsequent flight testing of a thermoelectric power system [13]. As system weight is of much higher concern in aerospace, thermoelectric energy harvesting is largely prevented from employing the liquid-cooled heat exchangers prevalent in automotive research; ambient air becomes a much more feasible option for cooling. Previous research on the subject has largely been limited to low-temperature, small-gradient applications [14].

## II. HYBRID PROPULSION SYSTEM

The purpose of the framework is to compare conventional electric and gasoline UAV propulsion systems against various hybrid-electric and energy efficient systems. As new hybrid UAV projects emerge, it is difficult to quantify their performance against other designs as there is a wide range of

designs and applications. This framework was developed using MathWorks MATLAB and includes all of the aircraft dynamics independent of the propulsion module so that propulsion systems can be used interchangeably. Once the models are validated with real flight test data, this framework can be used to compare theoretical systems or prototype systems still in development. Since all of the aircraft components are modelled parametrically, the design space can be thoroughly explored and optimized through various component sweeps and trade studies. The results from this exercise can be used to observe tradeoffs and impacts between different propulsion architectures and will drive design decisions for future UAVs.

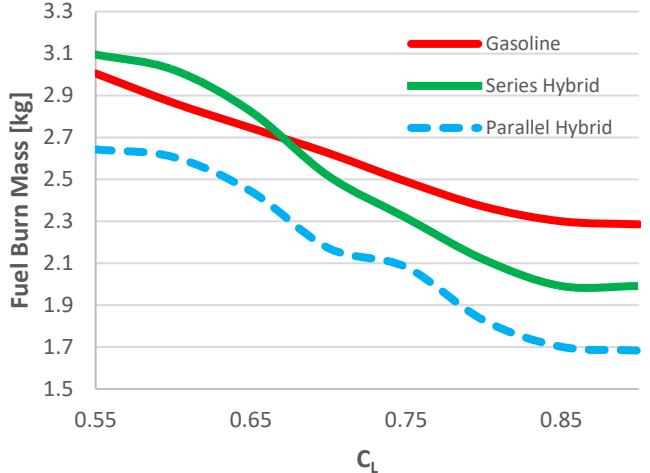

The series and parallel hybrid architectures were evaluated for several mission profiles. These missions provide a variety of different operating points that UAVs are typically used for, rather than steady-state comparison between propulsion systems. These profiles include a high-speed Interception Mission, a maximum-endurance Communications Relay Mission, a terrain following Pipeline Inspection Mission, and finally a flight path optimization mission for LIDAR Data Collection. These missions are depicted in Fig. 2.

**Figure 2.** Interceptor Mission (top left), Communications Relay Mission (top right), Pipeline Inspection Mission (bottom left), and LIDAR Data Collection (bottom right) profiles.

Several of the individual components of the aircraft, such as the propeller, lithium polymer (LiPo) batteries, electric motors and the internal combustion engines were modelled from existing architectures and combined in the framework. The propeller model includes a parametric model to morph measured geometry for a range of sizes. For the LiPo batteries, an equivalent circuit was used to model both the discharge and charge characteristics of a battery in order to accurately estimate the voltage drop. This model was used in combination with experimental data of voltage curves collected by discharging a LiPo battery at different rates. A thrust test stand was developed to determine the performance of these LiPo batteries with several electric motors. This thrust test stand allowed for any combination of batteries, electronic speed controller and motor to be tested together to collect experimental data, and included safety cut-offs for thermal, voltage or current thresholds. In order to validate these models, component-level bench tests were conducted.

Fig. 3 depicts the results of an example exercise using the framework. Here, the coefficient of lift parameter was swept from 0.55 to 0.90 to observe the trade-offs of fuel burn between the gasoline configuration, and both series and parallel hybrid configurations for a sample aircraft. As can be seen, the series hybrid architecture will burn less fuel than the gasoline-only configuration at higher  $C_L$  values, and the parallel hybrid is the most efficient with the lowest fuel burn for the full  $C_L$  range. The ability to observe these trends and analyze the tradeoffs between different propulsion systems attests to the power and novelty of this framework.

**Figure 3.** Framework design study example: Pipeline Inspection Mission  $C_L$  versus Fuel Consumption.

In future work, all of the components will be combined for system-level bench tests for both series and parallel hybrid architectures. The system-level bench tests will provide the opportunity to observe the performance of the propulsion system in a controlled environment and provide repeatable results. As with the component level testing, the results from the hybrid bench tests will be updated back into the framework to increase the accuracy of the theoretical models and lead to the design and integration into an airframe.

### III. THERMOELECTRIC ENERGY HARVESTING

To validate the theoretical model of an exhaust energy harvester, a test apparatus was designed and built. The energy harvester was designed to use the exhaust flow from a commercial-grade 50cm<sup>3</sup> 4-stroke Saito FG36 gas engine to provide heat to 3 Marlow Industries 30mm x 30mm TG12-4 thermoelectric generators. The cooling was provided by forced air. An Advanced Thermal Solutions ATS-EXL68-300-R0 heat sink was modified to provide two 15cm-long profiles, and the TEG modules were fixed between them using Arctic Silver Ceramique 2 thermal paste to maximize thermal contact. The heat sinks were enclosed in aluminum shrouds and the two sides were clamped together. To simulate external airflow, an electric ducted fan unit was integrated to simulate an aircraft speed of up to approximately 200 km/hr at ground level. The cold air

flow and the exhaust flow were counter-current to each other. The system was connected to the engine exhaust using a corrugated metal hose. Removable fiberglass insulation was also installed to control heat loss from the apparatus.

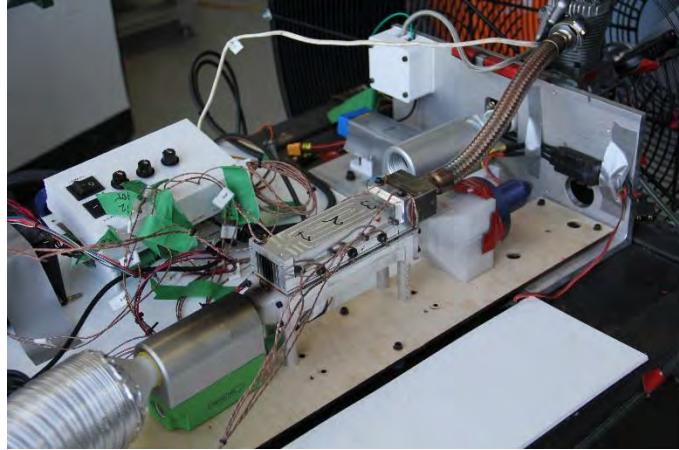

Figure 4. Energy Harvesting Apparatus Setup.

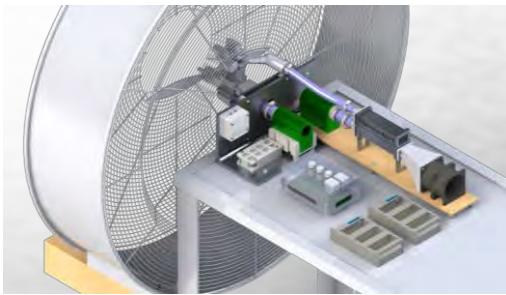

Figure 5. Energy Harvesting Apparatus.

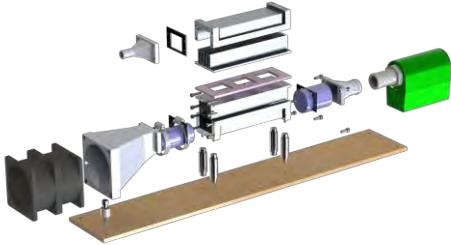

Figure 6. TEG module exploded view.

The system was instrumented to record 5 design variables (engine throttle control, cold air flow rate control, and resistive load control for each of the 3 TEGs). The temperature gradient across each TEG was measured using two Digilent K-type thermocouples, and the exhaust temperature was recorded at both the exhaust manifold and the entrance to the heat exchanger. Ambient air flow temperature was tracked at the inlet and the outlet of the heat exchanger, and ambient air flow rate was measured at the heat exchanger inlet using an E+E Elektronik EE741 flow meter. For the engine control, air flow was tracked at the carburetor inlet and fuel mass was tracked using a load cell. Data collection and system control was accomplished using LabVIEW software.

An energy harvesting module for the MATLAB framework was developed to predict thermoelectric power generation

based on the operational state of the aircraft. Engine parameters were used as inputs to predict exhaust temperature, and the aircraft's speed is used to determine the cold air flow. Load resistance was set to optimize power production throughout the mission, simulating the overall power generation. This power was directly applied to a battery module in the framework, and can be used to recharge the flight packs or supply power to a payload. Due to the relatively low operating temperature range, the energy harvesting module makes the assumption that the TEG material properties are temperature independent.

Extensive component and system-level testing was performed. The performance of TEG modules was quantified experimentally as shown in Fig. 7. TEG power generation was changed by sweeping load resistance at constant airspeed and engine power. The ability to control load resistance ensures optimal power generation at any flight profile. The relationship between engine power, flight speed, and TEG temperatures was defined empirically and used to refine the energy harvesting module.

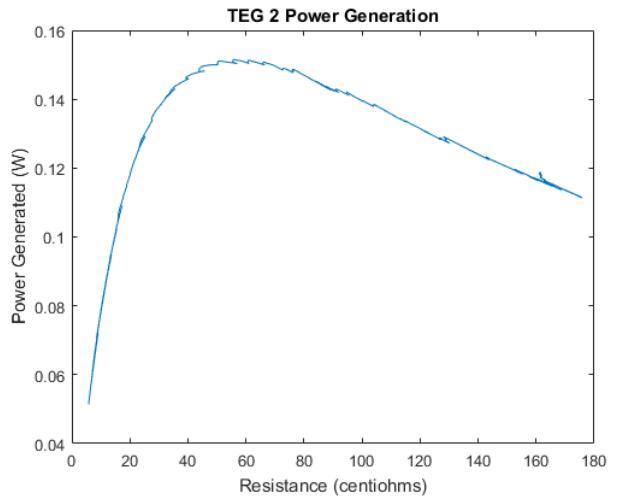

Figure 7. TEG power generation for a given resistance.

#### IV. CONCLUSION/RECOMMENDATIONS

A hybrid propulsion system framework has been implemented and evaluated for multiple mission scenarios. This framework allows the user to define component information and sizing, aircraft parameters, and complex mission profiles. From this setup, design trade-offs between UAV propulsion systems were identified and quantified to drive engineering design decisions. Specific experiments can be conducted to observe very precise and slight changes to the overall performance of an aircraft. As hybrid-electric aircraft increase in popularity, the aeronautical industry will benefit from such an analysis tool to optimize designs. As new and more efficient propulsion technologies are created, this framework will allow users to benchmark new designs.

Using the framework, mission profiles were designed to simulate realistic missions such as Interceptor, Communications Relay, Pipeline Inspection and LIDAR Data Collection. Since UAVs are used in a variety of applications, it is a useful exercise

to test the designs across multiple mission profiles to determine the optimal design. Together with the energy harvesting module, design decisions can be made on the trade-offs between different component sizes and optimized.

Future work will include the construction of more detailed and complex mission profiles to further test the performance of aircraft. The ability to test the designs in real-world missions will not only allow for realistic performance estimates, but also open the opportunity in future work to tune the model using actual flight test results. Furthermore, experimental data from the component bench testing and the energy harvesting apparatus will be used to validate the framework and produce more accurate results.

This project clearly demonstrates the need and novelty of the hybrid propulsion design tool to compare the performance of UAV propulsion types, and proves that hybrid UAVs are viable candidates for a variety of missions. Green aviation will likely be achieved by hybrid technology, and the framework provides valuable insight into engineering design decisions. Results from this project will be used to optimize the hybrid propulsion system for UAVs.

**Abstract**— Rocks may be subjected to dynamic disturbances while under high in situ stresses. When disturbed by dynamic loads from blasting, seismicity or rockbursts, the underground structures would be vulnerable to failure. Depending on the distance from the underground opening, the in situ stress states change from hydrostatic in the far-field, to triaxial in the intermediate distance, and to the pre-tension nearby the opening. Thus, SHPB testing system is further adjusted with confining pressure system into dynamic testing system of rocks under different in situ states. In the experiment with this dynamic testing system, the Brazilian disc rock specimens are first subjected to pre-stresses simulating in-situ stresses underground (including pre-tension, hydrostatic confinement, and triaxial confinement) and then loaded dynamically using the modified SHPB system. The dependence of dynamic tensile strength of the rock material on the static pre-stress and loading rate is investigated. These experimental results will be of great importance in the design and safety of underground rock engineering projects.

**Keywords-SHPB; Pre-stress; Hydrostatic Confinement; Triaxial Stress; Rate dependence**

## I. INTRODUCTION

With the development of underground space, it is necessary to study the mechanical properties of underground rocks, which are subjected to high lithostatic and tectonic stress. Problems involving underground rocks are common in many important economic fields including hydropower, transportation, mining and defense infrastructure. Deep rock structures are prone to dynamic loads such as blast mining, rock burst and small seismic events, so it is necessary to simulate the underground stress state and conduct designed dynamic experiments to investigate the dynamic properties of underground rocks. Depending on the distance from the underground opening, the in situ stress states change from hydrostatic in the far-field, to triaxial in the intermediate distance, and to the pre-tension nearby the opening, as shown in Fig. 1.

Dynamic mechanical properties of engineering materials have been investigated for many years and various devices are used to conduct experiments on these materials. One of the

most frequently used techniques is the split Hopkinson pressure bar (SHPB) system. Using the SHPB technique, dynamic mechanical properties such as compressive strength, tensile strength and fracture toughness have been studied on engineering materials, mostly under uniaxial loading conditions [1]. However, underground rocks are subjected to in situ stresses and occasional dynamic loadings. Most research on axial compression properties of rock-like materials under the preloading situations are conducted on ceramics and concretes under lateral confinement, either passive or active [2]. Gong and Malvern [3] proposed a way to provide passive confinement on concrete specimens in the SHPB system. Chen and Ravichandran [4] adopted the passive confinement method to investigate the dynamic properties of ceramics. Song and Chen et al. [5] studied confinement effects on the dynamic compressive properties of an epoxy syntactic foam, considering the effect of both the loading rate and passive lateral confinement. Christen and Swanson et al. [6] designed dynamic mechanical experiments under active confinement. Gary and Baily [7] adopted the technique and found the confining pressure more stable with air as the medium. They conducted experiments on concrete and proposed a meso-mechanical model. Lindholm and Yeakley et al. [8] proposed the experimental method under hydrostatic confining pressure in 1974. Li and Zhou et al. [9] and Zuo and Li et al. [10] investigated the dynamic response of rocks under both axial and active lateral confinement. Frew and Akers et al. [11] improved Lindholm's device and developed a hydrostatic apparatus based on SHPB system.

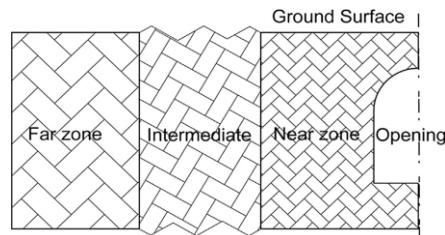

Figure 1. Zoning of the confining stress states around an underground opening

It is worth noting that, in previous research, there are not many results of tensile experiments on pre-stressed rocks, and

if so, all of them are under quasi-static stress states. Some researchers conducted Brazilian disc (BD), shear and torsion tests on rocks under hydrostatic pressure [12, 13] and they found that the strength of rock increases with the hydrostatic pressure. Vasarhelyi [14] investigated the influence of confinement on the mode I fracture of Gneiss. Al-Shayea and Khan et al. [15] tested straight notched Brazilian disk (SNBD) specimens under diametrical compression to study the influence of confinement on fracture toughness of limestone. Chen and Zhang [16] studied the influence of confinement on rock fracture toughness using notch-hole combined Brazilian disc specimens and Funatsu and Seto et al. [17] did the same tests on notched semi-circular bend (NSCB) specimens and they found the same increasing trend with confining pressure.

Therefore, there have been many improvements in dynamic testing of rocks with the static stress states; however, the research and testing system concerning various dynamic response (e.g. compression and tension strength, fracture toughness) of rocks subjected to different pre-stresses (i.e. pre-tension, hydrostatic confinement, and triaxial confinement) are still deficient. In this paper, a SHPB testing system is adjusted with confining pressure system for dynamic response of rocks under different pre-stress states. To calibrate this testing system, the Brazilian disc rock specimens are first subjected to simulating in-situ stresses underground (including pre-tension, hydrostatic confinement, and triaxial confinement) and then loaded dynamically using the modified SHPB system. The dependence of dynamic tensile strength of the rock material on the static pre-stress and loading rate is investigated. The calibrated testing system will be importantly applied to the design and safety of underground rock engineering projects.

## II. SHPB SYSTEM FOR ROCKS UNDER PRE-TENSION

### A. The Pre-tension SHPB System

The modified SHPB system for pre-tension test includes three bars (a striker bar, an incident bar, and a transmitted bar) [18] and the pre-tension system (Fig. 2). The elastic bars are made of high strength maraging steel. The pre-tension system is mainly composed of a pressure chamber that provides axial preload to the bars and specimen, and a rigid mass at the incident bar end that is connected to the chamber by tie-rods. The pre-tension system is similar to that innovated by Frew et al. [11], who developed a modified SHPB system for dynamic tests under hydrostatic confinement. However, there is a main difference between the current design and those of Few et al. [11] and Zhou et al. [19]. In their designs, the bars are connected by the tie-rods from the impact end of the incident bar to the free end of the transmitted bar, while in the current design, the bars are connected near the other end of the incident bar through a flange (Fig. 2). The total length of the compressed bars in the current design is much shorter and thus is less prone to buckling.

The recording system consists of the foil strain gauges, a signal conditioner, and an oscilloscope. There are two strains gauges on each bar attached at the symmetrical position, and they are connected to a signal conditioner through a Wheatstone bridge. The oscilloscope is connected to the signal

conditioner using two channels, one for the signal on the incident bar and the other for the signal on the transmitted bar.

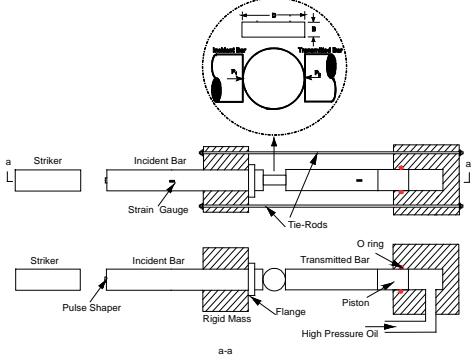

Figure 2. Schematics of the pre-tension SHPB system

### B. The Validity of Dynamic Test with Pre-tension

During the tests, the static pre-tension is applied to the specimen by the pressure loading unit attached to the end of the transmitted bar through the elastic bars and flange supported by a rigid mass. When the desired pre-tension is achieved, dynamic loading is applied from the impact of the striker bar on the free end of the incident bar. The incident pulse propagates along the incident bar before it hits the specimen, leading to a reflected stress wave and a transmitted stress wave that are recorded by the strain gauges attached on the incident and transmitted bar surfaces. The motion induced by the incident wave is to the right and thus the flange has no effect on the wave propagation. The strains of incident wave, reflected wave and transmitted wave are denoted by  $\varepsilon_i$ ,  $\varepsilon_r$  and  $\varepsilon_t$ , respectively.

Based on the one dimensional stress wave theory, and assuming stress equilibrium during loading [18] (i.e.,  $\varepsilon_i + \varepsilon_r = \varepsilon_t$ ), the history of the force on the specimen is:

$$P(t) = P_0 + P_d(t). \quad (1)$$

where  $P_0$  is the static preload on the bars,  $P_d(t)$  is the dynamic force history on the bars after the impact. The tensile stress history at the center of the disc specimen can be determined as:

$$\sigma(t) = \sigma_0 + \sigma_d(t) = \frac{A_0 E_0 \varepsilon_t(t)}{\pi R B}. \quad (2)$$

where  $\sigma_0$  is the pre-tension at the center of the disc, and

$$\sigma_0 = \frac{P_0}{\pi R B}. \quad (3)$$

where  $\sigma_d(t)$  is the dynamic tensile stress,  $E_0$  is the Young's Modulus of the bars,  $A_0$  is the cross-sectional area of the bars;  $R$  is the radius of the specimen and  $B$  is the thickness of the specimen. The tensile strength is the maximum value of the tensile stress when the rock specimen is damaged. There is an

approximately linear region in  $\sigma_d(t)$  (Fig. 3), and its slope is taken as the loading rate.

Similar to the traditional dynamic rock tension experiments in the SHPB system, the validity of dynamic test with pre-tension is achieved by the force balance in the specimen during the experiments. This can be researched by using pulse shaper technique [18]. Fig. 3 shows the force history according to the strain gauges attached on the incident bar and the transmitted bar. The force on one side of the specimen is the sum of forces by the incident and reflected stress waves (marked as In.+Re), and the force on the other side of the specimen is by the transmitted stress wave (marked as Tr). The initial force on the transmitted bar corresponds to the preload on the specimen, which is  $P_0$  as in Eq. (1). It can be seen from Fig. 3 that the dynamic forces on both sides of the specimens are almost identical during 80  $\mu$ s to 160  $\mu$ s, which is the main dynamic loading period. It is also noted that the forces on the two ends of the specimen are different before 80  $\mu$ s. The reason is that before the dynamic impact, the specimen is subject to the static preload through the transmitted bar, which is already compressed and thus the strain gauge on the transmitted bar measured the preload. However, the incident bar is free before impact loading and thus there is no deformation measured by the strain gauge on the incident bar at the beginning. The force difference at time zero in Fig. 3 is the static preload applied on the rock specimen, which is 10.07 KN in this case, corresponding to the pre-tension of 10 MPa at the specimen center.

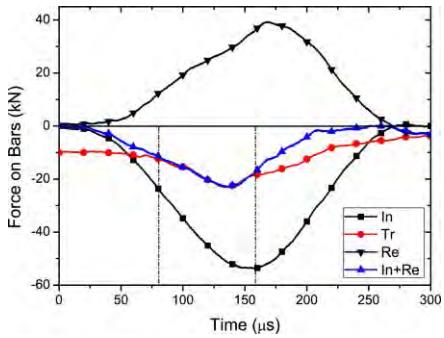

Figure 3. Dynamic force balance in a typical pre-tension SHPB test

### C. Dynamic Brazilian Test with Pre-tension

Five groups of BD rock specimens (with static tensile strength of 12.8 MPa) under the pre-tension of 0 MPa, 2 MPa, 4 MPa, 8 MPa, and 10 MPa are tested under different loading rates.

During each test, the tensile strength is the maximum value of the tensile stress history. Fig. 4 illustrates the dynamic tensile strength versus loading rate. It is obvious that the dynamic strength increases with the loading rate, revealing the phenomenon of rate dependency that is common for engineering materials, such as rock [20], concrete [21, 22], ceramic [23, 24].

Apart from the rate dependency mentioned above, what can be seen from Fig. 4 is that the dynamic tensile strength of the rock decreases with the increase of the pre-tension when

subjected to the same loading rate. For example, when the loading rate is approximately 190 GPa/s, the dynamic tensile strength is 19.8 MPa when the specimen is loaded stress-free being subjected to dynamic loading. However, the dynamic tensile strength of the one with 10 MPa pre-tension is 11.7 MPa, which is 8.1 MPa lower than the former. The decrease of dynamic tensile strength is caused by the opening of microcracks when the specimen bears the pre-tension stress, which is consistent to the results reported by Xia et al. that the microstructures affect the dynamic stress of rock specimens [2].

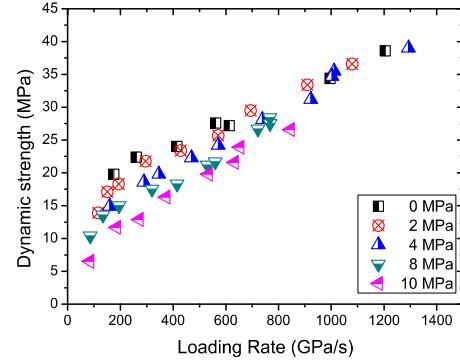

Figure 4. The dynamic strength versus loading rate for different pre-tensions

## III. SHPB SYSTEM FOR ROCKS UNDER HYDROSTATIC STRESS

### A. The SHPB System with Hydrostatic Confinement

The modified SHPB apparatus for tri-axial stress state includes the three bars (a striker bar, an incident bar, and a transmitted bar) [18] and a hydraulic system, as shown in Fig. 5. The elastic bars are made of the same material as that for the pre-tension test. The hydraulic system is mainly composed of a cylinder that applies lateral confinement to the rock specimens (Cylinder 1), and a pressure chamber that provides axial preload (Cylinder 2) to the bars and specimen. The only difference between the apparatus in Fig. 2 and the apparatus in Fig. 5 is Cylinder 1 that provides the lateral confining pressure. The recording system is same as the pre-tension SHPB system (Fig. 5).

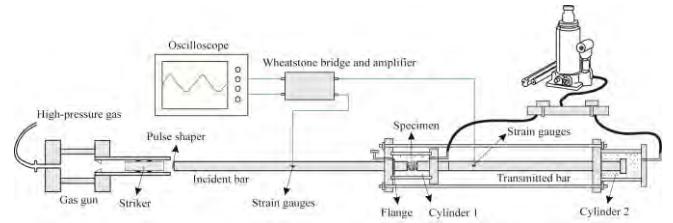

Figure 5. Schematics of the modified SHPB system for Tri-axial test

As shown in Fig. 6, the two cylinders are connected to the same hydraulic press by separate valves. When the two valves are open at the same time, the rock specimen would be in hydrostatic stress state, regardless of the shape of the rock specimen. Denote  $A_b$  as the cross area of the bars,  $A_s$  as the

contact area between the specimen and the transmitted bar; denote  $\sigma_0$  as the oil pressure provided by the pump,  $\sigma_1$  and  $\sigma_2$  as the stresses of the specimen at the transmitted bar end and the incident bar end, respectively.

When the two valves are open at the same time, both the lateral confining stress on the specimen and the stress on the transmitted bar are equal to the oil pressure  $\sigma_0$ . Since the transmitted bar is force balanced, the force on the transmitted bar at the specimen end equals that at the pump end. The force at the specimen end is composed of two parts, the one by the pressure oil  $\sigma_0(A_b - A_s)$  and the one by the specimen  $\sigma_1A_s$ ; the force at the pump end is  $\sigma_0A_b$ . So, the force balance of the transmitted bar leads to:

$$\sigma_0(A_b - A_s) + \sigma_1A_s = \sigma_0A_b. \quad (4)$$

solve Eq. (4) we can get

$$\sigma_1 = \sigma_0. \quad (5)$$

similarly, we can get

$$\sigma_0 = \sigma_1 = \sigma_2. \quad (6)$$

Hence the specimen is in hydrostatic stress state when the two valves are both open at the same time. It can be shown in the similar way that for a specimen with arbitrary shape, as long as it is symmetric with respect to the loading axis, the specimen is under hydrostatic confinement if the pressure in both cylinders is identical.

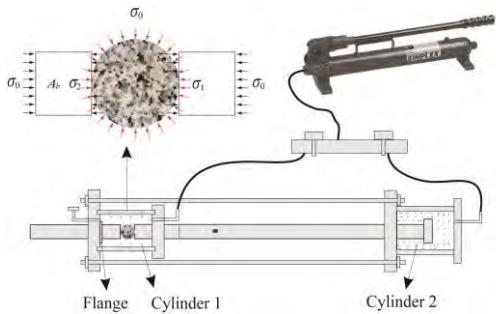

Figure 6. Hydrostatic stress of rock materials in a SHPB test

#### B. The Validity of Dynamic Test with Hydrostatic Confinement

Similar to the dynamic test with pre-tension in SHPB system, the dynamic test with hydrostatic confinement in SHPB system is valid when the force balance in the specimen during the experiments is achieved. This is also facilitated by using pulse shaper technique. In addition, enough loads are required to break the confined specimen so the striker is launched with sufficient air pressure every time with different pulse shapers. Different dimensions of the shapers made of

different materials lead to different loading rates on the rock specimens.

Fig. 7 shows a typical force history of the two loading ends of the specimen measured by the strain gauges. On one side of the specimen is the sum of forces by the incident and reflected stress waves, which is marked as In.+Re. in the figure, and on the other side is the force by the transmitted stress wave, marked as Tr. It can be seen that the dynamic forces on both sides of the specimens are identical during the loading and unloading period, demonstrating the validity of the test. It also shows that although the incident force is as high as about 200 KN, the force on the specimen is only about 50 KN, which is 25 percent of the incident force, and this is why the striker is launched at high air pressure every time to make sure the load is high enough to break the confined specimens.

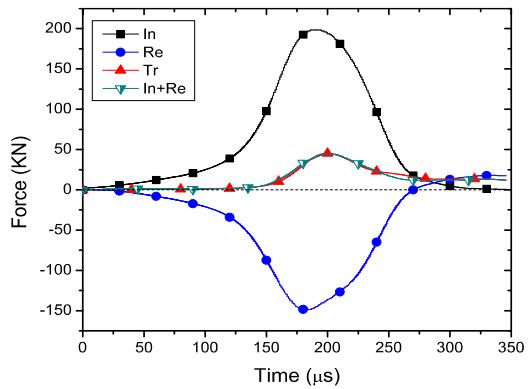

Figure 7. Dynamic force balance in a typical SHPB test with confined Brazilian disc specimen

#### C. Dynamic Brazilian Test with Hydrostatic Confinement

Five groups of specimens are tested under the hydrostatic confinements of 0 MPa, 5 MPa, 10 MPa, 15 MPa, and 20 MPa. The tensile stress history at the center can be determined as:

$$\sigma(t) = \frac{2A_b E_b \varepsilon_t(t)}{\pi BD}. \quad (7)$$

where  $E_b$  is the Young's Modulus of the bars,  $A_b$  is the cross-sectional area of the bars;  $B$  and  $D$  are the thickness and the diameter of the specimen, respectively. The tensile strength is the maximum value of the tensile stress when the confined rock specimen is damaged.

Fig. 8 illustrates the dynamic tensile strength versus loading rate. It is obvious that the dynamic strength increases with the loading rate.

Based on the fitted curves in Fig. 8. It is obvious that the dynamic tensile strength increases with both the hydrostatic stress and the loading rate. It can be also seen that the increment of the dynamic tensile strength decreases with the loading rate and the hydrostatic stress. This indicates that when the confining pressure reaches a certain value, or at a certain underground depth, the dynamic tensile strength of rock materials would mainly depend on the loading rate, it does not

change much as the confinement increases further under the same loading rate.

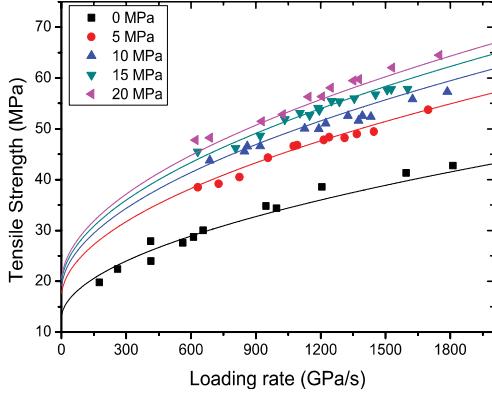

Figure 8. Dynamic tensile testing results under different loading rates and hydrostatic pre-stress, and data fitting of the results

#### IV. SHPB SYSTEM FOR ROCKS UNDER TRI-AXIAL STRESS STATES

##### A. The SHPB System for Tri-axial Stress State

The modified SHPB apparatus for tri-axial stress state is the same as that for hydrostatic confinement test, as shown in Fig. 5. The experimental design is that we first exert a hydrostatic stress to the BD specimen through the cylinders and the press, by opening the two valves at the same time. When the hydrostatic stress is achieved, the valve controlling the lateral confinement is closed, and the cylinder at the transmitted bar end is used to provide more axial load to the specimen for pretension so that the specimen is under triaxial stress conditions (Fig. 9).

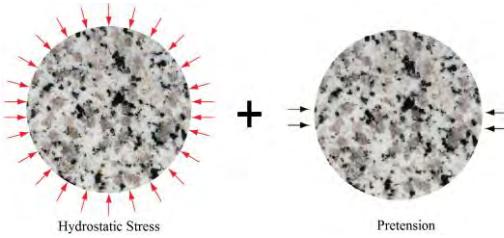

Figure 9. Experimental design with different hydrostatic stress and pretension

After the calculation of the stress on the specimen, the stress exerted on the bar is then determined to achieve the pre-stress conditions before the impact is launched. For example, when the hydrostatic stress is 5 MPa, then the Brazilian tensile strength of the specimen is 17.8 MPa, which is the sum of the hydrostatic stress and the BD strength without any confinement. Then with the design that the pretension is 20% of the strength, which is 3.56 MPa on the specimen. Through the correlation between the tensile stress on the specimen and the stress at the bar specimen interface, the load needed on the bar can be determined.

Denote  $\sigma_t$  as the tensile stress at the specimen center, through the correlation between the tensile stress at the specimen center and the stress at the specimen-bar interface,

$$\Delta\sigma_t = \frac{2P}{\pi BD} = \frac{1}{2} \frac{\pi D_b^2 \sigma_b}{\pi BD} = \frac{D_b^2 \sigma_b}{2BD}. \quad (8)$$

where  $P$  is the force on the bar,  $B$  and  $D$  are the thickness and diameter of the specimen, while  $\sigma_b$  is the stress on the bar, and  $D_b$  is the diameter of the bars. So, the stress on the bar should be calculated from Eq. (9) to achieve the desired pre-stress conditions.

$$\sigma_b = \frac{2BD\sigma_t}{D_b^2}. \quad (9)$$

With hydrostatic confinement, the axial stress applied on transmitted bar is:

$$\sigma_b = \frac{2BD\sigma_t}{D_b^2} + \sigma_0. \quad (10)$$

where  $\sigma_0$  is the hydrostatic stress on the specimen.

##### B. Dynamic Brazilian Test under Tri-axial Stress State

Similar to the dynamic test with hydrostatic confinement in SHPB system, the dynamic test for the tri-axial stress state is valid by using the achievement of the force balance in the specimen during the experiments. This is also facilitated by using pulse shaper technique.

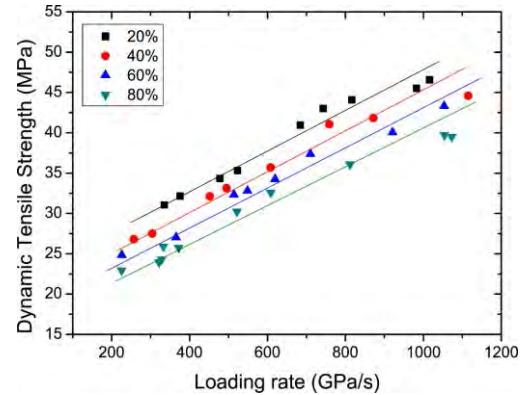

Figure 10. Total strength of rock specimen under 5MPa hydrostatic stress and pre-tension

The tensile stress history at the center can be determined as:

$$\sigma(t) = \frac{2A_b E_b \varepsilon_t(t)}{\pi BD}. \quad (11)$$

where  $E_b$  is the Young's Modulus of the bars,  $A_b$  is the cross-sectional area of the bars;  $B$  and  $D$  are the thickness and the diameter of the specimen, respectively. The tensile strength is the maximum value of the tensile stress when the confined rock specimen is damaged.

Four groups of specimens are tested under the hydrostatic confinements of 5 MPa and the pretensions are 20%, 40%, 60% and 80% of the tensile strength under the corresponding hydrostatic stress state, as shown in Fig. 10. Fig. 10 illustrates the correlation between tensile strength and the loading rate when the rock specimens are under 5 MPa hydrostatic stress and various pretensions, respectively. It can be observed that the tensile strength increases with the loading rate almost linearly, revealing the phenomenon of rate dependency that is common for engineering materials. Besides the rate dependency mentioned above, it is also obvious from Fig. 10 that the dynamic tensile strength of the rock decreases with triaxial stress states, which is also observed from the pre-tension tests in Section II.

## V. CONCLUSIONS

When the underground rocks under high in situ stresses are disturbed by dynamic loads from blasting, seismicity or rockbursts, the underground structures would be vulnerable to failure. In situ stress states of the underground openings change from hydrostatic in the far-field, to triaxial in the intermediate distance, and to the pre-tension nearby the opening. In order to investigate the dynamic behaviors (e.g. compression and tension strength, fracture toughness) of rocks under in situ states, a dynamic testing system of rocks under different in situ states (i.e. pre-tension, hydrostatic confinement, and triaxial confinement) is modified with the SHPB testing system and confining pressure system.

To calibrate the dynamic testing system of rocks under in situ states, the Brazilian disc rock specimens are first subjected to simulating in-situ stresses underground (including pre-tension, hydrostatic confinement, and triaxial confinement) and then loaded dynamically through the modified SHPB system. The advantages of the design for the dynamic testing system is given and the validity of dynamic BD rock tests performed in this dynamic testing system was discussed. Based on this system, the dependence of dynamic tensile strength of the rock material on the static pre-stress and loading rate is investigated. The calibrated testing system will be importantly applied to the design and safety of underground rock engineering projects.

**Abstract**— Permanganate phosphate coating is considered as one of the most promising alternative coatings to chromate conversion coating because of the similarity between permanganate and chromate. However, the permanganate phosphate coating always has net-work cracks. In this paper, a thick and crack-free permanganate phosphate coating was developed by a two-stage conversion process. Results of scanning electron microscope (SEM) with X-ray diffraction (XRD) analysis showed that some more corrosion resistant compounds appeared in the coating after a two-stage conversion treatment, which were not found in the single conversion coating. Moreover, the two-stage conversion coating has a higher thickness with few cracks. Furthermore, electrochemical tests and salt spray test further exhibited that the two-stage conversion coating had a better corrosion performance than either of the two single conversion coatings.

## I. INTRODUCTION

Two major obstacles have limited the expansion of Mg alloy use in transportation industry. The limited slip systems at room temperature leads to activation of deformation twinning which causes different yield strengths in tension and compression [1-2] (which is different from hydrostatic stress dependent strength different effect [3] seen in high strength steel). The high corrosion susceptibility of magnesium alloys extremely restricts their further application in automotive, aerospace industries and electronics [4]. Presently, the most widely used method in industries to provide the protection on magnesium and its alloys is generally the chromate conversion coating. However, the inevitable environmental and health

problems caused by hexavalent chromate leads to a real necessity of developing alternative conversion coatings. During the past 20 years, a few environmental friendly conversion coatings were proposed to be aimed at replacing chromate conversion coating, including metal phosphate coatings, rare earth coating, stannate coating, etc [5-8].

Compared to chromate conversion coating, permanganate phosphate coatings are more environmental friendly and could provide equivalent corrosion resistance and paint adhesion. In recent years, varieties of research related to phosphate permanganate coating have been made on magnesium alloys. Hawke et al. [9] developed a coating consisting of an agglomerate of well-formed crystals with the coating thickness of 4-6 $\mu$ m using a conversion bath containing KMnO<sub>4</sub> and NH<sub>4</sub>H<sub>2</sub>PO<sub>4</sub>, which showed good corrosion resistance and paint base performance. Typically, permanganate phosphate coatings have severe cracks, through which corrosive species could readily reach the Mg substrate. Jian, etc. [10] reported that a phosphate-permanganate conversion coating without cracks was able to be fabricated in a strongly acidic solution which exhibited excellent corrosion resistance. However, this coating is too thin and too weak. To date, there are no work on magnesium alloys reporting a permanganate phosphate conversion coating that is both thick and crack-free.

In the present study, a two-stage conversion process is proposed to form a dense and thick phosphate-permanganate coating. The microstructure and corrosion resistance of this two-stage conversion coating was evaluated by SEM-EDS, electrochemical testing. Results showed that this two-stage conversion coating were both dense and thick that the corrosion resistance was improved compared to the single-step conversion coating.

## II. MATERIALS AND EXPERIMENTS

### A. Materials and surface preparation

Specimens of AZ31B [11-12] cast alloy with a size of 3×25.4×50.8 mm taken from a cylindrical ingot were utilized as the test material. These coupons were mechanically grinded to 1200# using emery paper, ultrasonic degreased in acetone, washed in ethanol and dried in air stream.

### B. Conversion coating treatment and characterization methods

Potassium permanganate (15g/L KMnO<sub>4</sub>), potassium dihydrogen phosphate (3g/L KH<sub>2</sub>PO<sub>4</sub>), manganese sulfate (4g/L MnSO<sub>4</sub>) and ethylenediaminetetraacetic acid, namely EDTA (1g/L C<sub>10</sub>H<sub>16</sub>N<sub>2</sub>O<sub>8</sub>) were used to prepare the aqueous conversion bath. The two-stage conversion process was firstly conducted in a low pH bath and then was immediately treated by a high pH solution. Another two single stage coatings were also separately obtained as a comparison by a single low pH solution treatment (marked as LP treatment) and a single high pH solution treatment (marked as HP treatment).

The surface morphology, microstructure and chemical composition of the conversion coating were characterized using scanning electron microscopy (SEM) and energy-dispersive spectrometry (EDS). The potentiodynamic polarization and electrochemical impedance spectroscopy (EIS) measurements were performed in 3.5% sodium chloride (NaCl) using a potentiostat/galvanostat electrochemical system (Solartron SI 1287 and 1255B). Prior to the polarization scan and EIS measurement, each sample was immersed in the testing solution for 30min to reach a steady open circuit potential (OCP). The potentiodynamic polarization measurement was conducted by sweeping the potential from -100mV to +500mV vs the OCP at a scan rate of 1 mV/s. For EIS analysis, each spectrum was recorded at the OCP in frequencies ranging from 100 kHz to 10 mHz, with a sinusoidal signal amplitude of 10mV. All experimental data were presented in the form of the average± the standard deviation of three measurements.

The salt spray chamber test was performed according to the SAE J2334 standard. In this test, the coupons were placed at an angle of 15°-30° from the vertical direction in a chamber. One 24-hour cycle includes a 6 hours exposure in 100% condensing humidity at around 50°C, a 15 minutes exposure at 25°C to a fog containing 0.5 wt. % NaCl, 0.1%CaCl<sub>2</sub>, 0.075% NaHCO<sub>3</sub> and a 17.75 hours exposure in a dry environment at 60°C (50% relative humidity).

## III. RESULTS AND DISCUSSION

### A. Surface morphology and coating composition analysis

Figure 1.1 shows the surface morphology of the coating obtained by the two-stage conversion process described above. Another two coatings, i.e. the most corrosion resistant from the low pH treatment and the most corrosion resistant from the high pH treatment, are also presented in the figure together with the bare alloy for comparison. In general, all the coatings displayed similar surface morphology with networks of shallow cracks except that some cracks in the two-stage

coating was slightly widened. The ESD analysis suggested that the second phase particles in the bare alloy were oxidized after the conversion process, as shown in the Table . And it can be seen from Figure that more oxidized second phase particles were seen in the coating from the high pH treatment (HP coating) than that from the low pH bath (LP coating). The fact that the second phase particles can be seen on the coating surface indicates that the coating was quite thin. The most interesting aspect of EDS results is that some manganese oxides were also detected in the two-stage conversion coating, as shown by the spot D in Figure (d). Manganese oxides (MnO/MnO<sub>2</sub>/Mn<sub>2</sub>O<sub>3</sub>) are generally more corrosion resistant than MgO and Al<sub>2</sub>O<sub>3</sub>. Therefore, this two-stage conversion process has the potential to further improve corrosion resistance of the Mn-P coating, as compared to a single conversion process. Additionally, the thickness of each coating could be evaluated from the weight gain of the coated samples, as presented in Figure . It distinctly demonstrated that the two-stage conversion coating had the highest thickness and the HP coating film was the thinnest, indicating that the two-stage conversion process can be used to grow thick and corrosion resistant Mn-P coating on Mg alloys.

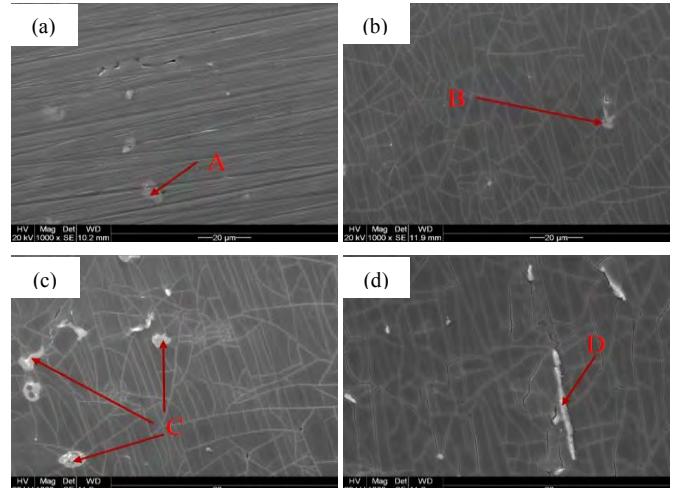

Figure 1.1 The surface morphology of (a) the bare alloy; (b) the coating obtained by low pH treatment (LP coating); (c) the coating obtained by high pH treatment (HP coating); (d) Two-stage coating.

Table 1 Chemical composition (atm.%) of the compounds as indicated in Figure 1.1

Spot	Mg	Al	Zn	Mn	O
A	90.65	6.88	2.47		
B	90.50	3.69	3.81		2.00
C	67.64	19.01	12.18		1.16
D	50.45	9.45	2.31	25.04	9.79

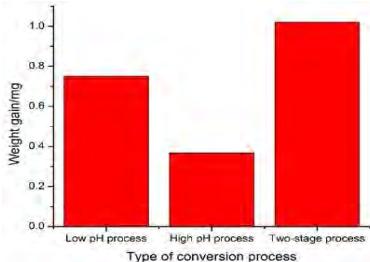

Figure 1.2 Weight gain of the samples after being treated by different conversion process

### B. Electrochemical test

Figure shows the potentiodynamic polarization curves of the various conversion coated AZ31B in 3.5% NaCl solution. Generally, the cathodic polarization curve is related to the evolution of hydrogen and the anodic polarization curve represents the corrosion resistance of the coating. As can be seen in the figure below, both the anodic and cathodic polarization curves of the conversion coatings shifted toward the lower current direction (left) significantly compared to those of the bare alloy, indicating that both the anodic reaction and cathodic reactions were inhibited and hence the corrosion resistance of the AZ31B was effectively improved by the conversion coating. Moreover, it can be observed that a passive region (defined as the potential difference between the corrosion potential  $E_{corr}$  and the breakdown potential  $E_{break}$ ) occurred in the anodic polarization branch of the coated samples. Among all coated samples, the HP coating exhibited the largest passive region of 432.2mV. From the polarization test results we can see that the HP coating and two-stage coating showed similar corrosion behavior and both were more corrosion resistant than the LP coating.

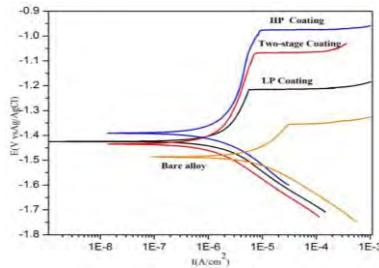

Figure 1.3 Polarization curves of the bare alloy and different conversion coated samples

Electrochemical impedance spectroscopy (EIS) was then used to further study the corrosion resistance of the coated samples. As can be clearly observed from the Bode plots (Figure ) of various conversion coatings and the bare alloy, the two-stage conversion coating exhibited the highest impedance values in the low frequency range. The impedance generally represents the ability of the coating to resist the flow of electrical current. Higher impedance suggests a lower anodic dissolution rate. Therefore, from the point of view of EIS results, the two-stage conversion coating shows the highest corrosion resistance.

From the results of the electrochemical tests, it can be concluded that the two-stage conversion process resulted in a thick and dense coating with better corrosion resistance than

the coating obtained by a single conversion process (LP coating and HP coating).

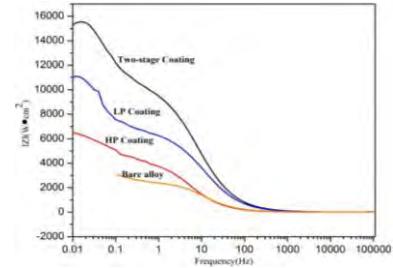

Figure 1.4 Bode plots of the bare alloy and different conversion coated samples

### C. Salt spray test

To characterize long-term corrosion performances of the coated specimens, salt spray chamber test according to SAE J2334 standard was conducted for up to 168 hours. The edge of the examined samples were all sealed with epoxy to avoid the edge effect in the corrosion process. By visual examination of the conversion coated samples as shown in Figure 1.5, we observed that a few corrosion pits were seen on the surface of LP coated and HP coated samples after a test duration of 96 hours. In contrast, only several small corrosion pits were found on the surface of the two-stage conversion coated specimen. Furthermore, as the testing duration went up to 168 h, corrosion pitting on the LP coated and HP coated coupons became more severe with an increased number of pits. However, the corrosion of two-stage conversion coated coupon did not deteriorate so much with the increasing testing time.

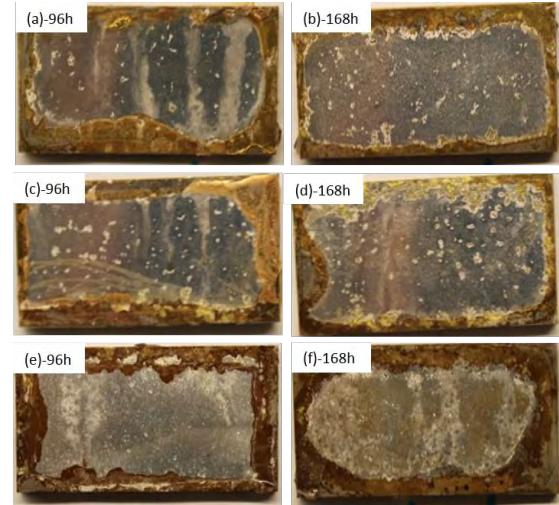

Figure 1.5 Salt spray test results conversion coated samples: (a)(b) LP coating; (c)(d) HP coating; (e)(f) Two-stage coating

## IV. CONCLUSIONS

A two-stage conversion process, namely, the treatment in a low pH solution followed by an immediate treatment in a high pH solution, was developed to deposit a thick and dense protective surface coating on Mg alloy AZ31B. Results of SEM analysis, electrochemical tests and salt spray test exhibited that the two-stage conversion coating had better

corrosion performance than either of the two single conversion coatings.

**Abstract**— This paper discusses the development of a ground based experimental environment that can mimic the libration dynamics of tethered satellite systems. The setup consists of an Air-Bearing Inclinable Turntable (A-BIT), whose inclination and rotation rate can be adjusted independently. Appropriate scaling factors help compare the tethered system in the experiment to that in orbit, both of which experience vastly different magnitudes of forces. The two scenarios also differ in their physical parameters including the length of the tether, the mass of the satellite, and the tension along the tether. The scaling factors are used to compare the behavior of these two tethered satellite systems.

**Keywords-** space tethers; air bearing table; inclinable turntable; ground based testing; tether deployment; scaling tether deployment; tether dynamics.

## I. INTRODUCTION

Tethers are long ropes or tapes that connect two satellites orbiting at different altitudes in space. They are usually constructed using a bare metal like aluminum, however, depending on their application they may have a part or the entire tether covered with insulating material. Tethers have numerous applications in space including power generation, attitude stabilization, momentum transfer, and de-orbiting the satellite at the end of its mission [1] [2] [3] [4]. When a tethered satellite is launched, the tether is folded and stowed inside of the satellites. Once the satellites are in orbit, the tether is deployed and stabilized in the desired orientation. In fact, all successful tethered satellites rely on the successful deployment and stabilization of the tether, while the missions that fail to achieve this struggle to complete their objectives. This fact is evidenced by missions such as the Tethered Payload Experiment (TPE) I & II, launched in 1980 and 1981, respectively. The TPE I mission deployed only 38 m, instead of the planned 400 m tether deployment, while the TPE II fared marginally better, deploying 103 m out of its 500m long tether [2] [4]. Onboard cameras showed that the under-deployed tether wasn't under tension all the time, which resulted in the tether coiling up. Similarly, the Small Expendable Deployer System (SEDS-I), launched in 1993, failed to slow down the deployment of the tether, which caused the satellites to recoil at the end of deployment [1] [2] [3]. The unsuccessful deployment of the

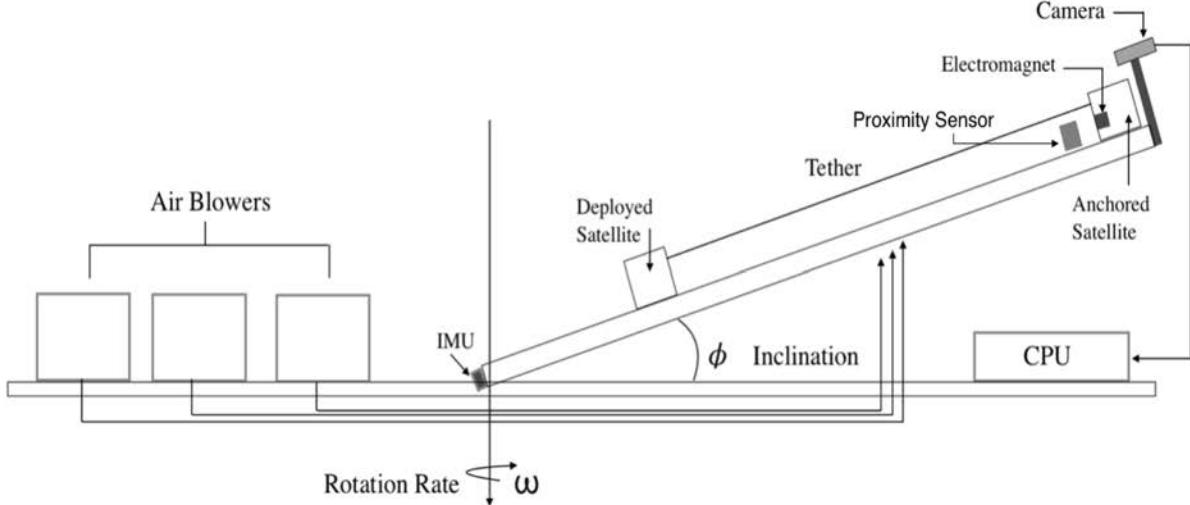

tether in all such missions inhibited the payload onboard from completing the mission objectives. This presents a serious challenge for tethered satellite missions, as a tremendous amount of resources are wasted if the tether does not deploy properly. Although it is not possible to completely eliminate the possibility of mechanical failure of the deployment and stabilization mechanism, an experimental verification of the behavior of the satellite, given the mission parameters, can help fine-tune the deployment process in order to ensure a smooth and complete deployment of the tether.

This research focuses on the development of a testbed that is capable of imitating the behavior of a tethered satellite system orbiting in a circular Low Earth Orbit. The testbed utilizes an Air-Bearing Inclinable Turntable or *A-BIT*, whose inclination and rotation rate can be adjusted independently. A similar experimental technique was employed by [5] [6], focusing on the dynamics of a climber attached to a pre-deployed tether. The *A-BIT* aims to provide insight into the libration dynamics of a tethered satellite and provide a platform to test control strategies that stabilize the libration of the tethered satellite system.

## II. EXPERIMENTAL SETUP

The proposed experimental setup of the *A-BIT* is shown in Fig. (1). The table is 2m long and 1 m wide. There are two dummy CubeSats on the table. The mother satellite is anchored near the edge of the table furthest from the rotation axis, while the daughter satellite is free to move across the table. There are three air blowers mounted on the rotating frame that allow the satellite to float on the testbed. The mother and daughter satellite are connected by an aluminum tape tether which has a width of 1cm and a thickness of 50  $\mu\text{m}$ .

Prior to deployment, the tether is folded and stored in a stowage box placed above the daughter satellite [7], and both satellites are held together by an electromagnet mounted on the mother satellite. The electromagnet latches on to a threaded steel rod which passes through a spring mounted on the daughter satellite. As the daughter satellite is pushed together with the mother satellite, this spring get compressed between the two satellites. To deploy the daughter satellite, the electromagnet is remotely deactivated, converting the potential energy of the spring into the kinetic energy of the daughter satellite. The stowage box of the tether includes a passive braking mechanism

**Figure 1: An Overview of the Experimental Setup**

which uses friction to slow down the deployment process and avoid recoil. There are two cameras mounted on the table, one on either side of the mother satellite in order to track the motion of the daughter satellite. A proximity sensor is placed on the table near the mother satellite to measure the deployment speed of the daughter satellite.

The inclination of the *A-BIT* with respect to the local horizontal  $\Phi$ , and its rotation rate  $\omega$  can both be adjusted independently. An Inertial Measurement Unit (IMU) is mounted on the turntable to measure the values of  $\Phi$  and  $\omega$ . The inclination of the table emulates the gravity gradient along the tether, while the table's rotation emulates the centrifugal and Coriolis forces acting on the daughter satellite.

### III. SCALING EXPERIMENTAL PARAMETERS

In order to emulate the behavior of an orbiting tether using the *A-BIT* experiment properly, the forces acting on the daughter satellite in the experiment should be similar to those in orbit, namely, the gravitational gradient, the centrifugal force and the Coriolis force. Since the magnitude of these forces are not the same as those in orbit, they need to be appropriately scaled. This can be achieved by equating the net torque and the net angular momentum of the two systems. This provides a relationship between the libration angle of the tether in the experiment to the same in orbit, as expressed in Eq. (1)

$$\sin \theta_e = \frac{3L^2\Omega^2 M}{2ml(g \sin \phi - \omega^2 r \cos^2 \phi)} \sin 2\theta_o \quad (1)$$

where  $\theta_e$  is the libration angle of the tether on the *A-BIT*,  $\theta_o$  is the libration angle of tether in orbit,  $g$  is the acceleration due to gravity,  $r$  is the distance of the mother satellite to the rotation axis, and  $\Phi$  is the inclination of the *A-BIT* as defined before. The terms  $M$ ,  $L$ , and  $\Omega$  represent the mass of the daughter satellite, the length of the tether and orbital rate of the tethered satellite system respectively in orbit, while the terms  $m$ ,  $l$ , and  $\omega$  represent the same, but in the experiment.

Similarly, the relation between the tension along the tether in orbit and the tension along tether in the experiment, is expressed in Eq. (2) [8]:

$$T_o = \frac{ML}{I_o^2} [\Omega^2 + f \pm 2\Omega\sqrt{f} + 2\Omega^2 I_o^2] \quad (2a)$$

$$f = \frac{I_e^2}{ml} [T_e - mg \sin \Phi + m k \omega^2 \cos^2 \Phi (r - l)] \quad (2b)$$

where  $T_e$  and  $T_o$  are the tensions along the tether in the experiment and in orbit respectively, while  $I_e$  and  $I_o$  are the moments of inertia of the system in the experiment and in orbit respectively. The moment of inertia is measured about the center of mass of the mother satellite.

The following expression is introduced in order to relate the orbital rate of the tethered satellite system with the rotation rate of the air-bearing table [6] [8]:

$$\omega = \sqrt{\frac{ML^2\Omega^2}{kml^2}} \quad (3)$$

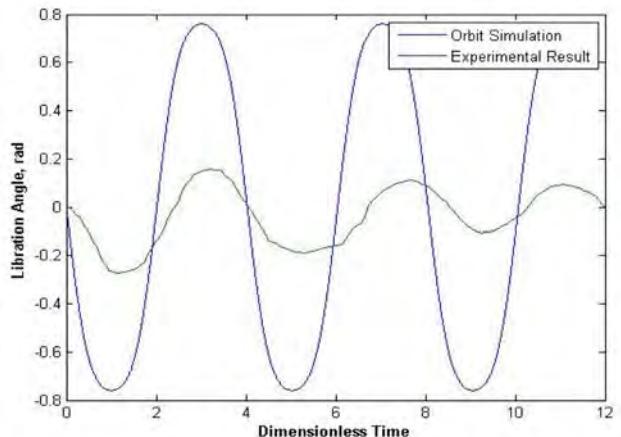

where  $k$  is a dimensionless constant used to limit the inclination and rotation rate of the *A-BIT*. It should be noted that this expression holds true for small libration angles only.

As with the forces, the timescale of the tether libration in orbit and in the experiment, is not the comparable. In order to overcome this, both timescales can be resolved into dimensionless time by using the orbital rates as a normalizing factor.

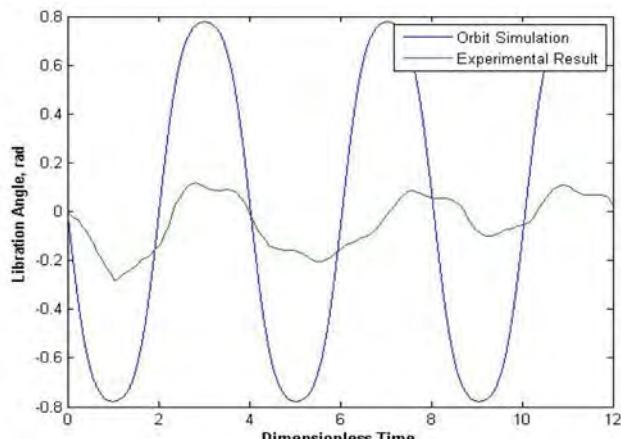

### IV. EXPERIMENTAL RESULTS AND ANALYSIS

Once the orbital parameters to be simulated have been decided, the experiment is setup using the parameters developed in the previous section. Figures (2a) and (2b) show the experimental results along with the numerical simulation of an 800m long tether orbiting at 1440 Km and 1450 Km above the Earth's surface, respectively. The results show that the time periods of libration, in orbit and in the experimental setup, are comparable. The results of the experiment show a 3% longer time period than the simulation. This is most likely caused by

the damping experienced by the system in the experiment, but not in orbit. However, this damping can be measured and its effects can be accounted for. As mentioned in the previous section, the scaling factors have been developed such that the amplitude of libration matches only for small libration angles. Since no control law has been applied to the simulation of the tether in the orbit, the amplitude of libration is very high and thus does not match up to that in the experiment.

(a)

(b)

**Figure 2: Tether Libration Dynamics. Emulated orbital height**  
(a) 1440 Km (b) 1450 Km

## V. CONCLUSION

The results serve as a preliminary indicator that the *A-BIT* can be utilized to study the behavior of the tethered satellites in orbit. They show that the scaling factors have been implemented effectively and that these factors can be used to scale up the libration dynamics measured in the experiment to those expected to be observed in orbit. Future work on the experimental setup would include measurement of the extent of damping experienced by the system and model it out of the resultant motion observed. Sensors would be put in place to measure the tension along the tether. A wide-angle camera would be mounted on top of the table. This would provide better position estimation and reduce the drag experienced by the daughter satellite due to the change in orientation of the mounted target that is being tracked. The experimental setup will be modified to include various control strategies, whose behavior in orbit is known. Implementing these control laws will reduce the libration angle of the tether. Comparing the behavior of the tethered satellites in the experiment to that in orbit should provide details about the effectiveness of the experimental setup to measure amplitude of the libration as well, instead of just its time period. A successful imitation of both these parameters in the experiment will allow this setup to be used for validating the effectiveness of new control strategies to stabilize tethers in orbit.

# Anisotropic Fatigue Modeling of Wrought Magnesium Alloys

Amirhossein Pahlevanpour, Seyed Behzad Behravesh, Hamid Jahed  
Mechanical and Mechatronics Engineering Department, University of Waterloo  
Waterloo, Canada

**Abstract**— The merit of Jahed-Varvani (JV) as an energy-based model and Smith-Watson-Toper (SWT) as a critical plane fatigue model are assessed for three wrought magnesium alloys. The raw data, including the stabilized strain-stress hysteresis loops and strain-life curves, was collected from the literature. The SWT model provided more scattered predictions than the JV model, which suggests that the JV model is more appropriate for fatigue modeling of wrought magnesium alloys, that exhibit anisotropic and asymmetric behavior. A discussion justifies the differences between the predictions of the two models. Eventually, the life of the materials in different directions is predicted by one set of JV parameters, which was previously extracted for AM30 in the transverse direction. The promising results provide supplementary support for the auspicious capability of strain energy density as a damage parameter for wrought magnesium alloys.

**Keywords-** *Magnesium; wrought; anisotropy; fatigue; modeling*

## I. INTRODUCTION

The profound impact of the automotive industries on greenhouse gas emission and global warming has led them into light-weighting of their products [1]. Magnesium (Mg) alloys with roughly 35% and 75% less density than aluminum and steel, respectively are the lightest available structural metals. This low density and high specific strength of the Mg alloys have made them highly attractive for the transportation industries.

Load-bearing components in vehicles undergo cyclic loadings; therefore, fatigue analysis is inevitable in their design process. However, finding a reliable model to mimic the fatigue behavior of wrought Mg alloys has been a challenge due to their asymmetric and anisotropic characteristics.

Numerous approaches have been developed and evaluated for the life prediction of wrought Mg alloys including, the energy-, strain-, stress-, and fracture-mechanic-based models. These efforts can be categorized into either model that consider just one material direction [2]–[6] or the ones that account for the anisotropic characteristic of wrought Mg alloys [7]–[11].

Lugo et. al [3] developed a microstructure-sensitive model that successfully imitates strain-controlled fatigue experimental observations along the working direction. The model is based on the crack initiation and growth stage constitution, and was justified for three AZ31 initial conditions, i.e., extrusion, rolled

plate, and rolled sheet. Castro and Jiang [5] assessed three critical plane approaches: Smith-Watson-Toper (SWT) [12], Fatemi-Socie , and Jiang [14] models, during tension-compression, torsion, and combined axial-torsion loading on AZ31B along the extrusion direction. The Fatemi-Socie damage parameter provided reasonable fatigue life prediction, but the SWT failed to follow torsion and tension-compression experimental data. The mixed mode cracking was suggested as the source of inaccurate crack orientation prediction for both the SWT and Fatemi-Socie models. The results of Jiang's model were substantiated for all loading conditions, predicting both the fatigue life and the cracking orientation. Xiong and Jiang [2] noticed the SWT parameter's inability to correlate the fatigue life of ZK60 extrusion while scrutinizing its cyclic behavior with intense texture under high strain amplitudes up to 6 % and also stress-controlled condition. Specimen failure under compression for strain amplitudes larger than or equal to 3.5% was implied to be the cause of the inaccurate SWT predictions, based on the fact that SWT is founded on tensile cracking as the failure mechanism. In contrast, SWT exhibits promising life prediction in the range of 0.2% to 1.5% strain amplitudes [6].

Concerning anisotropic fatigue modeling, Lin et al. [4], [8] modified the conventional Basquin's model to account for the mean stress effect and applied the model to hot-rolled AZ91 under cyclic asymmetric stress-controlled loading for rolling and transverse directions. Park et al. [10] evaluated the fatigue life prediction capability of the Ellyin energy-based model [15] in conjunction with stress and plastic strain amplitudes as two damage parameters for rolled AZ31. Loads were applied parallel and perpendicular to the rolling direction. This study concluded that the energy model performs better than the other two models. By employing the modified total strain energy density model proposed by Jahed and Varvani (JV) [16], Roostaei and Jahed [9] achieved satisfactory fatigue life prediction for AM30 extrusion independent of material orientation. They reported that the predicted lives by the SWT model are more scattered and more conservative than the JV model. This behavior was attributed to intricate maximum stress variation at different strain amplitudes [9].

In spite of several attempts to model the fatigue behavior of Mg alloys, a phenomenological study in search of suitable fatigue criterion capable of capturing the asymmetric and anisotropic behavior of wrought Mg alloys is still lacking. This paper examines SWT and JV models for anisotropic life

prediction of wrought Mg alloys using data available in the literature. Then, the idea of employing a single set of parameters for life estimation of wrought Mg alloys in various loading directions is evaluated. For this study, the set of parameters for the JV model, already been extracted for AM30 extrusion in the transverse direction, was utilized to predict the fatigue life of AZ31B and AZ80 in different directions.

## II. EXPERIMENTAL SETUP

Only a few published works present the strain-life curves and stabilized hysteresis loops for wrought Mg alloys in different directions. The studies conducted by L. Wu et al. on rolled AZ31B-H24 [17], F. Lv et al. on rolled AZ31B [11], Xiong and Jiang on rolled AZ80 [7] and Roostaei and Jahed on AM30 extrusion [9] are among those few published results. The details of the investigated materials are presented in Table I. In what follows, rolling direction (RD) will be assigned as the reference direction for AZ31-H24, AZ31B, and AZ80 in two fatigue models and the life in the other directions will be predicted based on the reference parameters.

TABLE I. INVESTIGATED WROUGHT MG ALLOYS

Material	Process	Directions	Strain ratio	Environment	Reference
AZ31B-H24	Rolled	Rolling (RD) Transverse (TD) Normal (ND)	-1	Ambient	[17]
AZ31B	Rolled	Rolling (RD) Normal (ND)	-1	Ambient	[11]
AZ80	Hot-rolled	Rolling (RD) Normal (ND) 30° to normal (ND30) 60° to normal (ND60)	-1	Ambient	[7]
AM30	Extrusion	Extrusion (ED) Transverse (TD)	-1	Ambient	[9]

## III. MODELING

### A. Smith-Watson-Topper (SWT)

SWT is a critical plane fatigue model, that takes into account mean stress effect through the maximum stress term as shown in J1([12]):

$$SWT = \sigma_{n,max} \frac{\Delta\epsilon_1}{2} \quad (1)$$

where  $\sigma_{n,max}$  and  $\Delta\epsilon_1$  are the maximum normal stress and the principal strain range on the principal strain plane, respectively. The SWT parameter has been correlated to the fatigue life of Mg alloys by either [2], [6],

$$(SWT - FP_0)^v N_f = D \quad (2)$$

where  $FP_0$ ,  $v$ , and  $D$  are fitting coefficients; or by Coffin-Manson parameters [9], [18]–[20] employed in this study as well,

$$\sigma_{n,max} \frac{\Delta\epsilon_1}{2} = \frac{\sigma'_f}{E} (2N_f)^{2b} + \sigma'_f \epsilon'_f (2N_f)^{b+c} \quad (3)$$

where:

- $\sigma'_f$ : Fatigue strength coefficient
- $\epsilon'_f$ : Fatigue toughness coefficient
- $b$ : Fatigue strength exponent
- $c$ : Fatigue toughness exponent

and  $E$  is the modulus of elasticity. The parameters in the SWT model are essentially the same as those in the Coffin-Manson model [21], [22],

$$\frac{\Delta\epsilon}{2} = \frac{\sigma'_f}{E} (2N_f)^b + \epsilon'_f (2N_f)^c \quad (4)$$

Therefore, the parameters are obtained by the decomposition of strain range into elastic and plastic strain ranges, as shown in Fig. 1.

The Coffin-Manson parameters for the three different materials were extracted in the reference direction, RD, and are tabulated in Table II. Adopting the SWT criteria and using the Coffin-Manson parameters, fatigue lives in all directions were calculated using a single set of parameters per material. Fig. 2 depicts the predicted life versus the experimental life for the three materials in various directions. The solid line denotes the perfect estimation, whereas the dashed and dashed-dot lines enclose the factor of 2 and 3 boundaries, respectively.

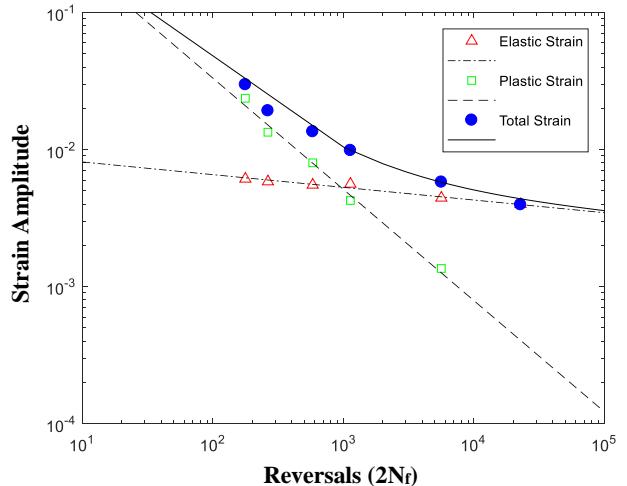

Figure 1. Strain range decomposition for the Coffin-Manson model; the typical result for AZ31B-H24 along RD

TABLE II. COFFIN-MANSON PARAMETERS ALONG RD FOR INVESTIGATED MG ALLOYS

	AZ31-H24	AZ31B	AZ80
$\sigma'_f$ (MPa)	442.49	749.75	422.07
$\epsilon'_f$	1.393	0.185	0.103
$b$	-0.092	-0.179	-0.071
$c$	-0.811	-0.604	-0.545

As expected, the life estimation for RD in all materials is satisfactory, demonstrating that the mathematical fitting was conducted correctly. However, the fatigue lives in other directions were overpredicted for AZ31B-H24 and AZ80, and underpredicted in AZ31B. In particular, the predicted life deviated from the factor of 3 bound for ND samples of AZ80 and AZ31-H24. This deviation is more intense for AZ80 in ND30 specimens, which will be discussed later. In contrast, the predicted lives for AZ31B, being conservative, fall within the factor of 2 bound lines.

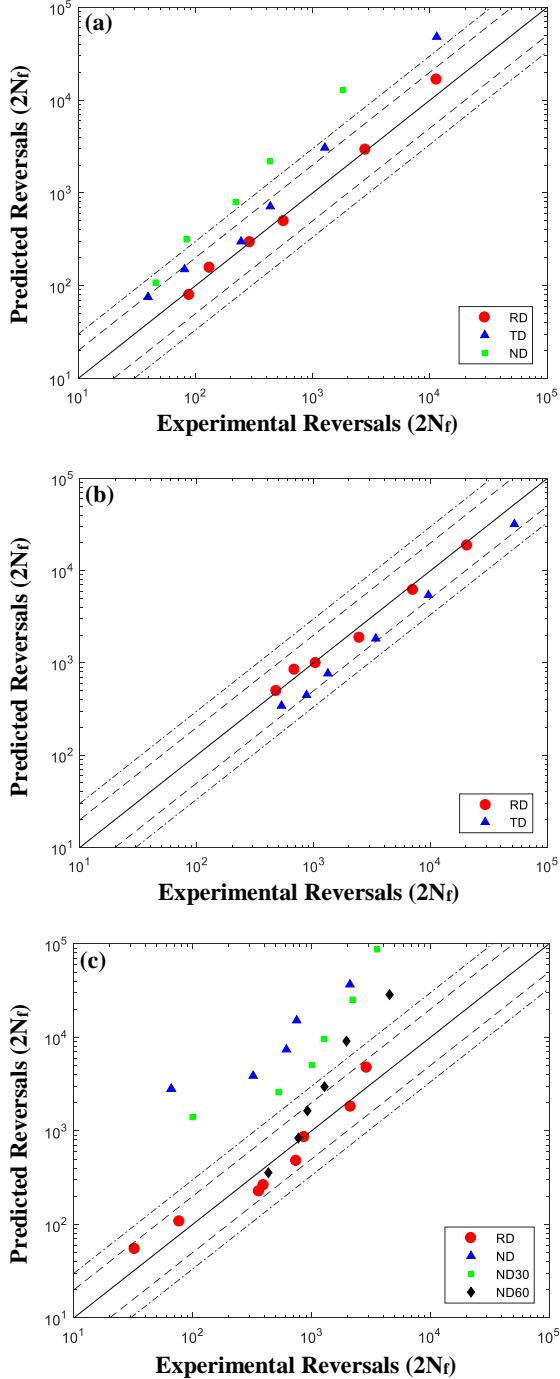

Figure 2. SWT fatigue life prediction for a) AZ31B-H24, b) AZ31B, and c) AZ80

### B. Jahed-Varvani (JV)

The invariant nature of energy makes energy-based fatigue models appropriate candidates for Mg alloys with asymmetric and anisotropic characteristics, and they have been employed for the life estimation of many Mg alloys [5], [9], [10], [18], [20], [23]–[27]. Jahed and Varvani [16] employed total strain energy density as the damage parameter by incorporating energy-based fatigue properties,

$$\Delta E = \Delta E_e^+ + \Delta E_p \quad (5)$$

*JV parameter*

where  $\Delta E_p$  is plastic strain energy density and defined as the area enveloped by the stabilized hysteresis loops and  $\Delta E_e^+$  is the positive elastic strain energy density, and is calculated as follows:

$$\Delta E_e^+ = \frac{\sigma_{max}^2}{2E} \quad (6)$$

where  $\sigma_{max}$  is the maximum tensile stress of the stabilized hysteresis loop. The JV parameter is correlated to the life through:

$$JV = E'_e(2N_f)^B + E'_f(2N_f)^C \quad (7)$$

where

$E'_e$ : Fatigue strength coefficient

$E'_f$ : Fatigue toughness coefficient

$B$ : Fatigue strength exponent

$C$ : Fatigue toughness exponent

are the material constants extracted from the curves fitted to the elastic and plastic strain energy versus life, as depicted in Fig. 3. This figure presents the typical strain energy decomposition for AZ31B-H24 along the reference direction, RD. The JV model parameters for the three different materials along RD are summarized in Table. III.

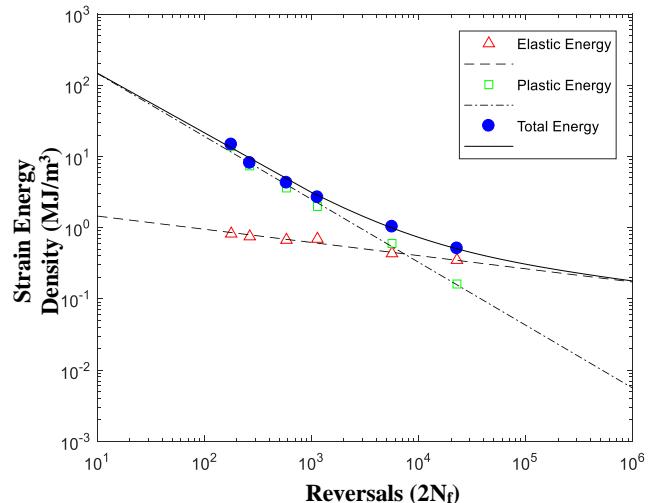

Figure 3. Decomposition of strain energy for the JV model; the typical result for AZ31B-H24 along RD

TABLE III. JV MODEL PARAMETERS ALONG RD FOR DIFFERENT MG ALLOYS

	AZ31-H24	AZ31B	AZ80
$E'_e$ (MJ/m <sup>3</sup> )	2.225	6.387	2.024
$E'_f$ (MJ/m <sup>3</sup> )	1115.85	746.37	64.26
$B$	-0.185	0.357	-0.142
$C$	-0.884	0.911	-0.598

By employing the JV model in conjunction with a single set of parameters per material, fatigue lives in different directions were predicted and plotted against the experimental lives in Fig. 4. The vast majority of data points for all subject materials are bounded within the factor of 3, independent of loading direction. Modest overprediction is perceived for AZ31-H24; in contrast, the lives congregate tightly about the ideal estimation with slight conservative predictions for AZ31B. The life of AZ80 samples in ND is highly overpredicted at the two extremes of the experimental life range, whereas estimated life is almost uniformly distributed over and under the ideal prediction in RD, ND30, and ND60 directions, besides laying within the bounds of  $\pm 3$  factor. The observed results demonstrate the competency of the JV model for anisotropic and asymmetric wrought Mg alloys.

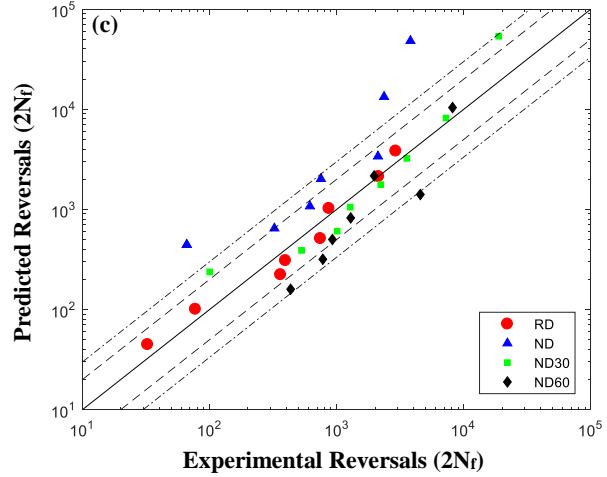

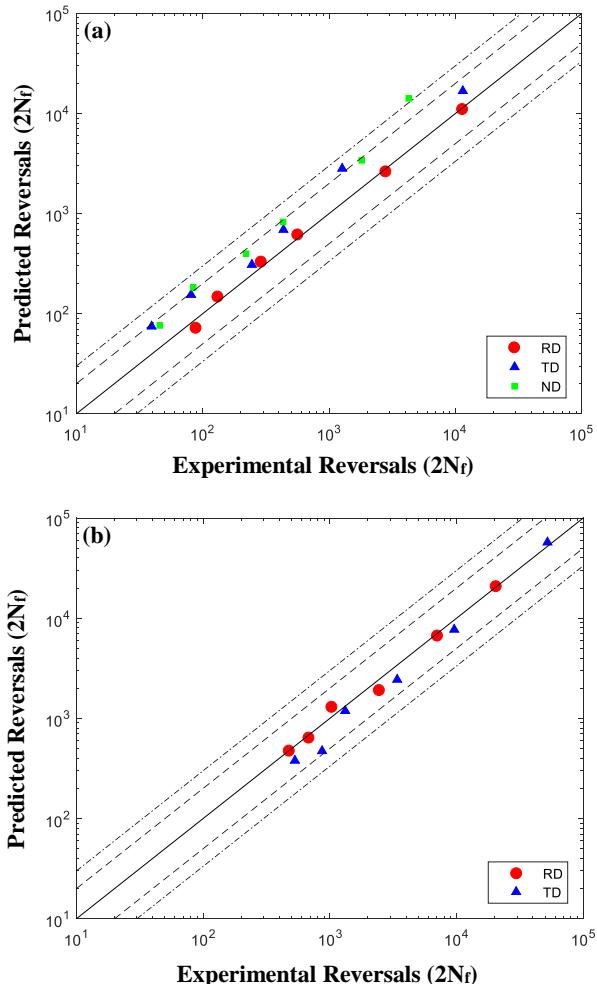

Figure 4. JV fatigue life prediction for a) AZ31B-H24, b) AZ31B, and c) AZ80

#### 4. Discussion

In general, the two models provide a good fatigue-life prediction performance. The SWT model's shortcomings for some of the fatigue data are attributed to two factors [2]:

1. Many wrought Mg alloys show nonlinear elastoplastic strain responses in the strain amplitudes higher than 1 % which could not be captured by linear Coffin-Manson fitting embedded in the employed SWT method [2], [7], [11].
2. Deformation mechanism alternation from slip to twinning/detwinning at some certain strain level introduces a kink point in the strain-life curve [2], [5], [6], which can considerably affect the fatigue resistance. Also, the change in the deformation mechanism is reflected in the hysteresis-loop shape and the enclosed area, which is not accounted for in the SWT model.

To further investigate the life prediction of SWT under large strain amplitudes, the stabilized hysteresis loops for AZ31B-H24 under  $\epsilon_a=1.4\%$  in different directions are provided in Fig. 5. The life reported for these tests in all directions are roughly the same and equal to 250 cycles [17]; however, their hysteresis loops are substantially different. Also, a significant mean stress is developed that is not accounted for, in the life model parameters of SWT. Table. IV compares the JV and its components in addition to SWT damage parameter for RD and ND. In spite of the fact that both RD and ND samples had nearly the same life, the SWT parameter values in these directions differ by 42%, whereas the difference for the JV parameter is 14%. The pronounced elastic strain divergence in comparison with plastic strain could explain the SWT's unsatisfactory life prediction in HCF where the elastic energy is dominant. The minimum difference belongs to the plastic portion of the strain energy density, which has been proven to be a robust damage parameter for the LCF regime [7], although its precision will

decrease in the HCF regime, where less energy is dissipated in each cycle.

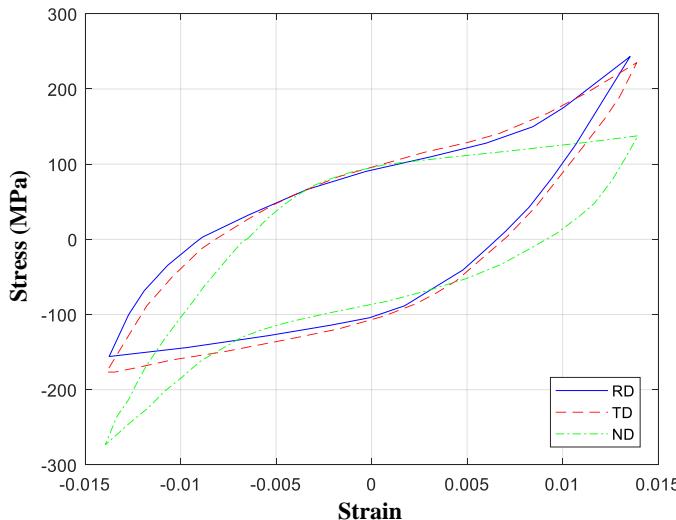

Figure 5. AZ31B-H24 stabilized hysteresis loops for 1.4 % strain

TABLE IV. AZ31B-H24 FATIGUE MODEL PARAMETERS FOR AZ31B-H24 UNDER  $\epsilon_a = 1.4\%$

	<b>RD</b>	<b>ND</b>	<b>Difference (%)</b>
<b>Elastic Energy Density</b>	0.672	0.215	68.0
<b>Plastic Energy Density</b>	3.612	3.475	3.8
<b>JV</b>	4.284	3.690	13.9
$\epsilon_{elastic}$	0.0055	0.0031	43.6
$\epsilon_{plastic}$	0.0085	0.0109	28.2
<b>SWT</b>	3.292	1.921	41.6

In order to evaluate JV as a universal fatigue model for Mg alloys, the JV parameters extracted for AM30 in TD, which are tabulated in Table. V [9], were employed to predict the life of the three materials under investigation. Fig. 6 shows predicted versus experimental fatigue lives, where most of the points are condensed within the factor of 3 boundaries. The present research further supports the findings of previous studies [5], [9], [10], [18], [20], [23]–[26] in which the strain energy density with its corresponding life model is an appropriate damage parameter for wrought Mg alloys with asymmetric and anisotropic behavior.

TABLE V. JV PARAMETERS FOR AM30 EXTRUSION ALONG TD [9]

$E'_e$ (MJ/m <sup>3</sup> )	2.995
$E'_f$ (MJ/m <sup>3</sup> )	1710.690
$B$	-0.281
$C$	-0.975

kchallagulla@laurentian.ca

**Abstract** — Axisymmetric finite element models are developed to simulate static pull test and dynamic drop test of MCB33 (modified conebolt with full debonding) using ABAQUS. Results from the numerical models are in reasonable agreement with the test results. A parametric study is performed considering various variables (i.e. friction, cone angle, material strength, etc.) to analyze the performance of MCB33. The results demonstrate that friction between the steel and resin, cone angle, and the Poisson's ratio of the resin affect the static and dynamic behaviors of the rockbolt. These parameters can be modified to improve the current design and enhance the overall performance of the rockbolt.

**Keywords:** finite element analysis; rockbolt; modified conebolt; static pull test; dynamic drop test

## I. INTRODUCTION

As depth of mining and underground construction increases, stress-induced rock fracturing is inevitable due to high in-situ stress and complex geological and geometrical conditions in underground hard rock mines. In some cases, rock can fail violently, leading to seismic events and rockbursts [1, 3, 6, 7 and 8].

Rockbursts can cause fatalities and injuries to workers, damage mine infrastructures and equipment, disrupt production, thus increase investment risk. To minimize the rockburst risk, design measures will be required. As an important line of defense, ground control support systems are used to prevent or minimize rockburst damage to excavation and enhance workplace safety.

In some deep hard rock mines, the modified conebolt (MCB) [2] are used for dynamic rock support. To further improve the performance of the MCB, design modification and subsequent static and dynamic testing is required. However, laboratory and field-testing of a new product is time-consuming and costly. To complete one design modification, several iterations of prototype manufacturing and testing are required. Hence computer-aided product design and testing is required to reduce the product development cycle and cost.

### A. Modified conebolt

The modified conebolt shown in Fig. 1 is a long slender steel bar (17.3 mm diameter) with a cone-shaped anchorage, resin mixing blade and a plastic sleeve on the shank to fully debond the bolt from the resin grout and apply all loads to the bolt to facilitate cone plough. As the cone ploughs through grout in a controlled fashion, the bolt absorbs energy. The MCB33 (modified conebolt with 33 mm borehole size) attributes mostly to cone resistance in resin without the frictional forces of the shank. As a result, the cone plough is more predictable.

Once a borehole (e.g. diameter 33 mm) is drilled deep into the stable hard rock, resin packs are inserted. The MCB33 is then drilled into the borehole while the resin-mixing blade mixes the resin, thus the bolt is encapsulated with resin. The plastic sleeve on the shank fully debonds the shank from the resin. When the resin is cured in a few minutes, the MCB33 is ready to take load and deform. If a rockburst is significant and impose a large dynamic loading to the rock, the cone will plough through the resin and aid in dissipating energy. The act of cone ploughing creates displacement without significant yielding of the bolt.

Figure 1. Schematic of a MCB33 [2].

## II. TESTING METHODS

### A. Static pull test

The static pull test is used to determine the load-displacement curve of a bolt. A hydraulic jack is used to apply a force on the end plate. The applied force on the bolt plate will deform the bolt and if load and displacement are measured, the load-displacement curve can be obtained.

### B. Dynamic drop test

The dynamic drop test is used to evaluate energy absorbing capacities of rockbolts. A rockbolt is encapsulated in a thick wall steel pipe with the use of grout – resin or cement. A weight free falls onto the end plate to load the rockbolt dynamically at a pre-determined impact energy. Monitor systems are used to measure load and displacements at both ends of the rockbolt so that strains can be calculated. Fig. 2 shows the drop test facility at CANMET, Canada.

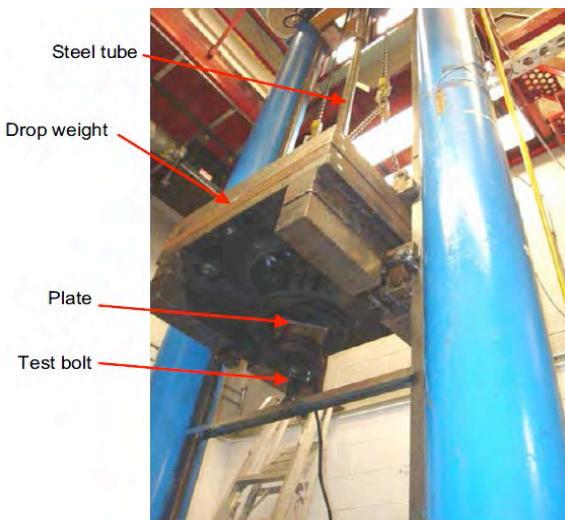

Figure 2. Drop test setup for MCB rockbolt testing at CANMET, Canada.

## III. MODELLING METHODOLOGY

### A. Static pull test

An axisymmetric finite element model of MCB33 (Fig. 3) is developed to simulate the in-situ pull test. The conebolt is fully encapsulated in resin in a 33 mm borehole in hard rock. Model dimensions of the rockbolt follow typical dimension of the modified conebolt for borehole sizes of 33 mm, and the rock surrounding the borehole is large enough for using a fixed boundary condition. The axisymmetric model has four components: (a) modified conebolt for borehole size 33 mm, (b) resin bonding the modified conebolt to the surround hard rock, (c) surrounding hard rock, and (d) interface between the bolt and the resin.

The following assumptions are considered to simplify the static pull test model:

- The rockbolt has no threads

- No head nut and plate for the rockbolt
- Rock-resin interface is assumed to be tied
- Friction interface is assumed for the bolt-resin interface.

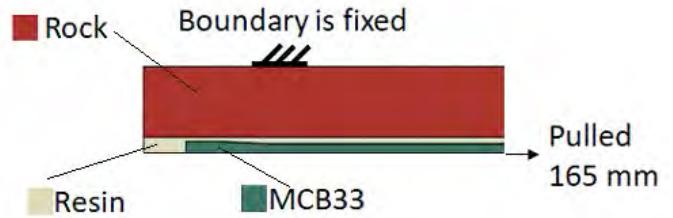

Figure 3. Schematic of the axisymmetric static pull test model (not to scale).

### B. Dynamic drop test

An axisymmetric finite element model of the modified conebolt is developed to simulate the dynamic drop test. A conebolt is fully encapsulated in resin in a steel pipe with 33 mm inner diameter. The pipe wall is 13.5 mm thick. A drop weight around the pipe is dropped from 1.5 m height to impact the plate. The model has five components: (a) a modified conebolt for borehole size 33 mm with a plate, (b) resin bonding the modified conebolt and the pipe, (c) surrounding pipe, (d) drop weight, and (d) interface between the bolt and the resin.

The following assumptions are considered to simplify the dynamic drop test model:

- The rockbolt has no threads
- No head nut for the rockbolt
- Resin-pipe interface is assumed to be tied
- Friction interface is assumed for bolt-resin interface.

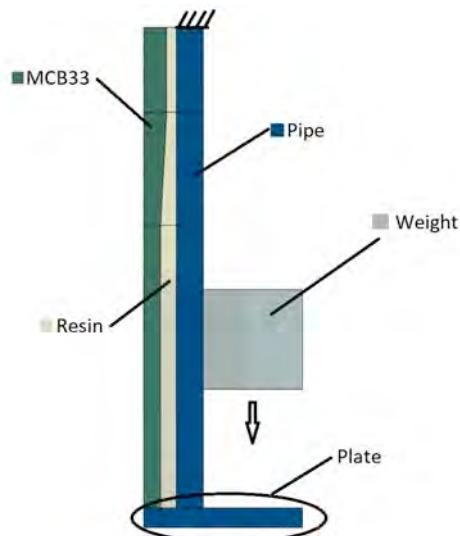

Figure 4. Schematic of the axisymmetric dynamic drop test model (not to scale).

### C. Finite element model properties

All finite element models developed in this study are analyzed using dynamic explicit analysis. Axisymmetric stress quad (CAX4R) element in ABAQUS is utilized to simulate the static pull test and the dynamic drop test. Because computational time is less for this type of analysis, a fine mesh with an aspect ratio between 1 and 1.5 is used.

As mentioned above the MCB has a debonded shank. The coefficient of friction affects the contact behaviors of the shank-to-resin interface and the cone-to-resin interface. We assume frictionless for the shank-to-resin interface due to perfect debonding, but the friction of the cone-to-resin interface is unknown thus a parametric study is needed to investigate the effect of the coefficient of friction of the cone-to-resin interface on the performance of MCB.

### D. Material properties

For initial models the material properties are either measured through lab testing or obtained from available values in literature. The aim is to choose a property that best represents each component. The two main components of concerns are the encapsulate resin and the rockbolt. All other parts (e.g. rock, pipe, plate and weight) are simplified to isotropic elastic homogenous materials.

To represent the rockbolt, the model must be able to represent pre- and post-failure. The steel's (C1055) tensile and compressive behaviors are the same; thus the selection of an appropriate material model is based on elasticity, plasticity and ductile damage consideration. Experiments were conducted to determine the deformation behavior of the steel. The force-displacement curve obtained from the experiments was converted into true stress–true strain curve for input into ABAQUS.

The encapsulated resin is difficult to represent in the model because of the plastic softening behavior. Laboratory experiments were conducted to determine the Faslok resin behavior. It is found that the behavior of the resin can be captured using Concrete Damage Plasticity [5] model.

The simulation results are compared with the experimental results [2] to calibrate the parameters of the static pull test model. Once the final model of fully calibrated data best represents the static pull test from the field experiments, the parameters (i.e. resin material properties and coefficient of friction) are used in the dynamic drop test.

Parameters obtained from the static pull test are utilized for the initial dynamic drop test model with an impact energy of 16 kJ. The results from the dynamic drop test model are compared with the experiment ones [2]. The finite element model is further calibrated to replicate the experimental results for all drop tests with an impact energy of 16 kJ. Then those parameters are used to simulate the drop test with 26 kJ impact energy.

### IV. INPUT DATA USED IN ANALYSIS

Table 1 presents the material properties used for each part of the simulation model. Table 2 presents the coefficients of friction between different interfaces for the static and dynamic tests. Fig. 5 shows the converted nominal stress–nominal strain curve from laboratory testing of tensile samples of the rockbolt material (C1055). Faslok resin is used for the encapsulating a bolt in a borehole or a steel pipe (for dynamic drop test). The pipe, plate, and weight are simulated using a general steel property. The density of the drop weight is varied to obtain the desired weight for each drop test. The rock material is for the surround rock and the Young's modulus can be varied to consider soft and hard rocks.

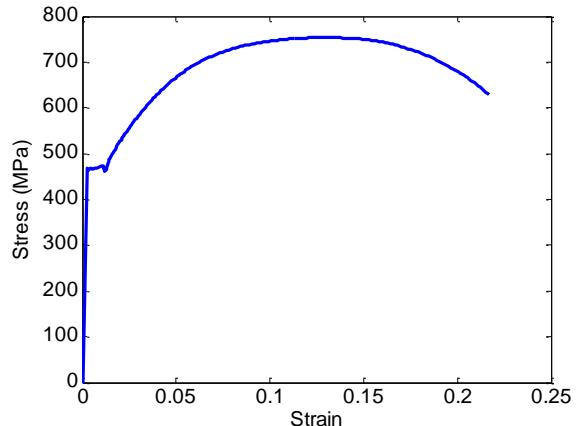

Figure 5. Stress–strain curve of C1055 steel obtained from lab test.

TABLE I. MATERIAL PROPERTIES FROM EXPERIMENTS AND LITERATURE [4]. \* DEPENDING ON THE TEST AND THE GEOMETRY OF THE WEIGHT THE DENSITY IS CALCULATED TO GET 16 KJ AND 26 KJ IMPACT ENERGY

Material	Properties			
	Young's modulus (GPa)	Poisson's ratio	Density (Kg/m <sup>3</sup> )	Uniaxial compressive strength (MPa)
C1055	200	0.3	7500	-
Faslok resin	10-30	0.15-0.38	2050	30
Steel	210	0.3	*	-
Rock	5-50	0.25	2440-2700	-

TABLE II. COEFFICIENTS OF FRICTION BETWEEN DIFFERENT INTERFACES

Test	Interface	
	Cone-resin	Shank-resin
Static pull	0.1-0.3	0
Dynamic drop	0.5-0.1	0

## V. SIMULATION RESULTS

### A. MCB33 static pull test simulation results

With the axisymmetric models, preliminary design parameters are used to get a general idea of the trends and behavior of the MCB33 rockbolt under static loading. The model is further calibrated to give satisfactory results. Fig. 6 shows the stress in the y-direction (parallel to the bolt's long axis) when the cone bolt is pulled 165 mm. Fig. 7 presents the modeled load-displacement relation superimposed with the experiment results [2], showing a good agreement between the two.

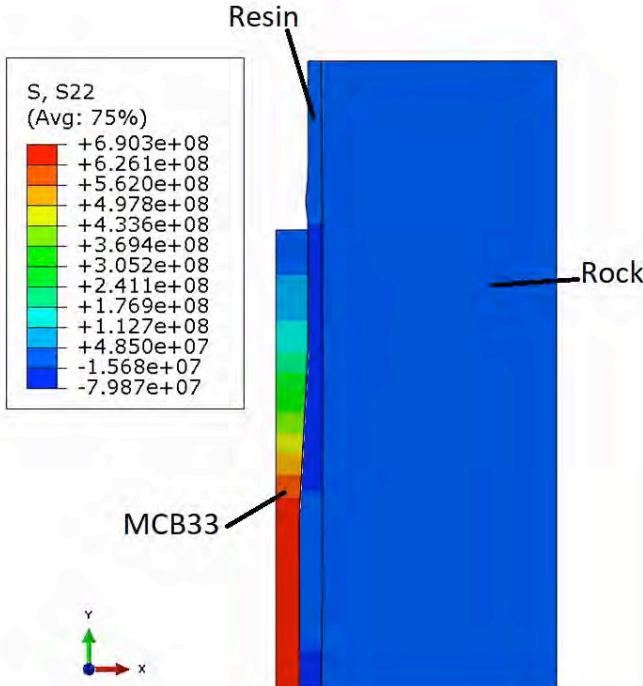

Figure 6. Top section of the MCB33 finite element model for the static pull test showing the stress (Pa) distribution along the y-direction (S22).

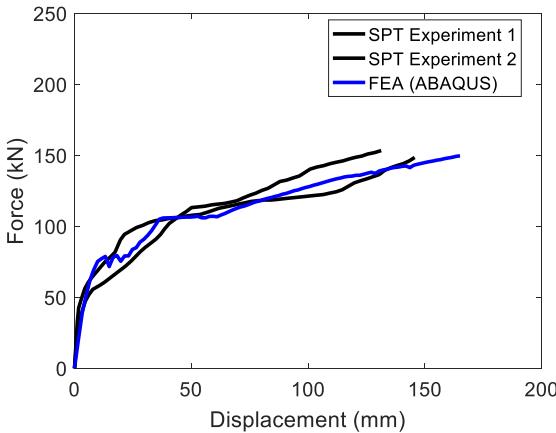

Figure 7. Static pull test (SPT) results [2] superimposed with the results from numerical modeling (FEA).

### B. MCB33 dynamic drop test simulation results

With the calibrated parameters using the static pull test results, dynamic drop test simulations were conducted. Fig. 8 shows the y-stress distribution at time 0.57 s from a 16 kJ drop test simulation. Figs. 9 and 10 show the plate displacements from the numerical simulations for 16 kJ and 26 kJ impact energy, respectively, superimposed with the experiment results [2]. It is seen that the numerical modeling captures the test results very well.

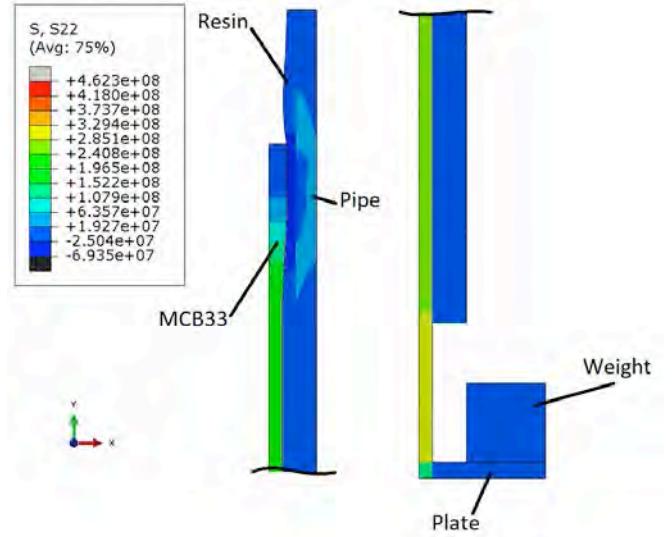

Figure 8. Top section (left side) and bottom section (right side) of the MCB33 dynamic drop test model showing stress (Pa) distribution in the y-direction (S22).

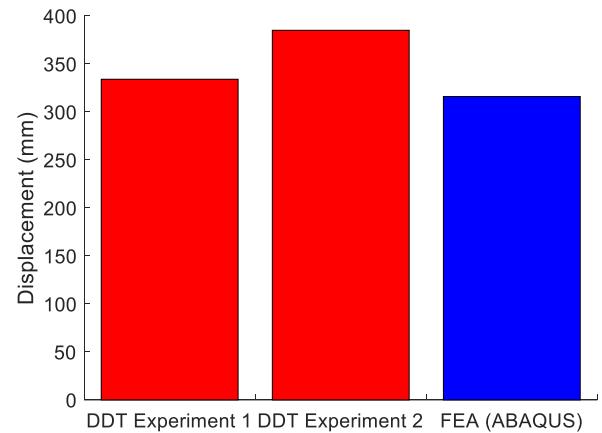

Figure 9. Dynamic drop test results for plate displacement at 16 kJ impact energy [2] superimposed with the numerical modeling results.

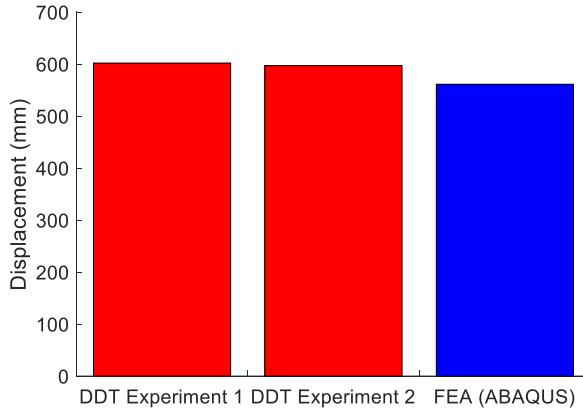

Figure 10. Dynamic drop test results for plate displacement at 26 kJ impact energy [2] superimposed with the numerical modeling results.

A further parametric study was conducted for both static and dynamic tests. The rockbolt material's strength and geometry, the resin material's strength and geometry, and the coefficient of friction between the bolt-resin interfaces are varied to study the performance of the bolt. It is seen from the static pull test and drop test simulation results that increasing the rockbolt material strength will increase performance of the MCB33. The resin material properties have a large influence on the performance of the MCB33. Higher Young's modulus of the resin grout can lead to less cone plough. Smaller coefficients between the bolt and the resin lead to more cone plough and increasing the cone angle reduces cone plough. Hence, it is possible to use numerical tools such as ABAQUS to calibrate available test results and refine design to optimize the performance of the MCB33 rockbolts.

## VI. CONCLUSION

Static and dynamic test results of MCB33 rockbolts have been simulated using an explicit FEM tool. The modeling results agree well with field and lab test results. Dynamic rock support is needed for mining in highly stressed ground to reduce rockburst damage risk and increase workplace safety. Further development of yielding rockbolts such as refinement of MCB33 and proofing other new support technologies can be assisted with the use of advanced numerical modeling to reduce product development cycle and cost.

# **Effect of the Error Propagation Rates in Developing a Skin Model of Measured Surfaces in Coordinate Metrology**

Cody Berry, Lillian Goodwin, and Ahmad Barari

Faculty of Engineering and Applied Science  
UOIT

Oshawa, Canada  
ahmad.barari@uoit.ca

**Abstract**— Coordinate metrology is the most commonly used inspection method to analyze surfaces for manufacturing errors and imperfections. The computational in today's coordinate metrology are composed of a series of extensive computational tasks. Developing a triangulated skin model using a finite element method is an approach to construct a surface based on the discrete measured points, which can be used for integrated computational algorithms reducing the uncertainty of the inspection process. Reducing the errors in developing the skin model by calibrating the two main parameters of the algorithm, which specify the propagation of the geometric deviations in two orthogonal directions, is the objective in this work. By varying these propagation parameters and tracking the overall error of the constructed skin model, their effects are evaluated. Various cases are studied and the resulting patterns of the errors for different surfaces are used to make suggestions on selection of the two parameters resulting accurate construction of the skin model of the measured work pieces based on the coordinate metrology data. This will provide a reliable technique to develop the skin model of the manufactured products for quality control, manufacturing process control, or repair and finishing of the products.

**Keywords:** coordinate metrology; skin model; error propagation rates; Deviation Zone Evaluation (DZE); Point Measurement Planning (PMP)

## I. INTRODUCTION

Coordinate metrology incorporates the use of three different processes, namely, Point Measurement Planning (PMP), Substitute Geometry Estimation (SGE), and Deviation Zone Evaluation (DZE). In such systems, the inspection accuracy is subject to the issue of uncertainties due to estimating some aspects of a probability distribution on the basis of sampling which adversely affects the accuracy and reliability of the inspection.

Selection of location, distribution, and number of sample points using the available information is the objective of PMP

process. Finding the best ideal substitute geometry that represent the selected sample points using a desired fitting criteria is performed by SGE process. Developing a comprehensive representation of geometric deviation for any point of the measured surface including the points that are not physically measured, is the goal of DZE process. These three computational tasks were traditionally conducted in a sequential manner. All three tasks have access to three sets of external data including: the desired geometric features which are typically represented by Computer Aided Design (CAD) models, data and information from the corresponding manufacturing operations used to fabricate the work piece, and the objective of the inspection process corresponding to the downstream processes that are planned for the measured work piece [1].

Output of each task is used as the input for the next task in the PMP-SGE-DZE sequential order. The typical output of the measurement instruction developed by PMP is used for capturing a limited number of discrete 3D points from the work piece. This data set is used as an input to SGE to fit the best representative substitute geometry. The external data regarding the objective of the inspection process is used to define the fitting criteria in SGE process. The geometric deviations of the measured sample points are calculated using the results of SGE and are input to the finishing computational task, i.e., DZE. DZE is responsible to analyze the distribution of geometric deviations and represent a detailed deviation zone for the entire measured surface. This result is the ultimate output of the coordinate metrology process which can be represented by statistical characteristics of the distribution and/or a full skin model of the measured surface. It is worth mentioning that, in order to develop the full skin model, DZE should be capable to estimate the geometric deviation function for the entire measured surface including infinite points that are not physically measured [1].

The concept of skin model is introduced in the field of tolerance analysis [2]. Tolerances are specified during the design process to meet the desired form, fit, and functionality of the products. Today's design and manufacturing paradigms do not allow the design tolerance analysis being performed without considering the manufacturing uncertainties. A

detailed representation of the geometric deviations from the best fitted desired geometry, which are mainly caused by the inherent errors in the employed manufacturing processes is needed to complete an integrated tolerance analyses. This detailed model of geometric deviations is a non-ideal Surface, which is also referred as a Skin Model of the part in Geometrical Product Specification (GPS) standards [2]. The need for developing a Skin Models is addressed by the standards and is the new focus of research [3]. However, methodologies to develop these models need further research.

A skin model is a discretized surface generated from a point cloud. The advantage of this method is its ability to reflect the deviation of the surface at any location, even those that were not sampled from. This data can be used to allow for virtual sampling of the piece. In a previous work, Lalehpour and Barari developed a finite element method to develop the skin model using the coordinate metrology discrete 3D points [1]. However, the developed method was not fine-tuned to provide the most accurate results. This paper will seek to fine-tune that method. The accuracy of the developed skin model

is of paramount importance in design and manufacturing

systems. The skin model is used directly for any possible downstream design and manufacturing processes that need the results of coordinate metrology process, this includes planning for precise finishing operations, manufacturing error compensation, closed-loop of manufacturing and inspection, dynamic process control, or for any tolerance evaluation required for the assembly and interaction of the work piece with the other mechanical components. Therefore, the added value in developing an accurate skin model of the work piece to the design and manufacturing processes is highly significant.

It is shown in several recent research [4-8] that integration of PMP, SGE, and DZE tasks will result in reducing the computational uncertainties in coordinate metrology. Another interesting application of a full skin model is to reduce the uncertainties of coordinate metrology process by conducting mutual closed loops between the computational tasks. The developed skin model by DZE is dynamically feed-backed to SGE and PMP to improve the processes in integrated inspection system using DZE-SGE and DZE-PMP closed-loops.

## II. THEORETICAL BACKGROUND

Lalehpour and Barari [1] developed the finite element method utilized in this paper. In this method, the data set that is obtained from the surface is first randomly pruned down. This is done as the entire sample set should not be required to accurately create a skin model. These points that are removed from the skin model data set will be used to validate the skin model once it is generated.

The new sample set is then transformed from real space, where x, y and z coordinates are used, to a parametric space. In this space, u, v, and d become the axes. The two largest principal axes of the data set become the u and v axes, while the smallest principal axis becomes d, or the geometric deviations. The data set is then divided into windows. Each of

on the size of the data set is selected from each window. These will become non-moving vertices of the skin model. This skin model relies on triangular elements, so a Delaunay triangulation is used on these non-moving vertices to create the triangular model.

This triangular surface becomes the basis for the rest of the skin model. The areas of each triangle are checked for size, with large areas being subdivided into smaller ones with the addition of another point at the centroid. This process repeats until all triangles are under the size threshold defined by the overall size of the data set. This increase in density causes an increase in accuracy for the finished skin model. These additional points do not initially have the correct geometric deviation to accurately represent the measured surface. In order to determine the correct placement of these vertices, a finite element method was used using Poisson Equation as follows:

$$\frac{\partial}{\partial u} \left( K_{uu} \frac{\partial S}{\partial u} \right) + \frac{\partial}{\partial v} \left( K_{vv} \frac{\partial S}{\partial v} \right) + E = 0 \quad (1)$$

where, u and v are two orthogonal directions on the measured surface,  $K_{uu}$  and  $K_{vv}$  are the error propagation rates in u and v directions, E is the determined geometric deviation, and S is the skin model. The K in [1], these K values were both assumed to be equal to unity for simplification and validation purpose. This paper will focus on determining the optimal K values. The effect of these two parameters on the accuracy of the skin model is studied in this paper. This resulting information can be used to produce more accurate skin model or to be used as the initial condition for an optimization process. Particle swarm optimization algorithm [9] is suggested for this case which is one of many algorithms that optimize based on different patterns found in nature.

## III. METHODOLOGY

A large amount of data is measured from the work-pieces using a coordinate measuring machine (CMM). The PMP process is then deployed to virtually sample from the given datasets. Once the smaller datasets were chosen, SGE is performed to find the closest representative plane to fit the given dataset. The method utilized for this purpose is total least squares (TLS) fitting to find the best fit plane for the given surfaces. This can be utilized for the SGE process because of the use of solely planar geometry.

The propagation rates of geometric deviations (PRGD), both in the u and v directions, used to construct the skin model are examined using the following process. A 40 x 40 matrix of PRGD values in the u and v directions ranging from -20 to 20 discrete values. This constructs a total of 1600 different skin models for each given dataset. After the skin model is constructed and the deviation of each point is known, the total error for each skin model is calculated by taking the difference from the generated original chosen data points to the generated skin model. The total error is the cumulative sum of square of the errors for each skin model.

The effect of the fitting parameters (PRGDs) is analyzed by graphing the total error for each skin model to show the total error for the given matrix of values. The results are then optimized using an algorithm to find the lowest values and removing them recursively to find a trend line of values. This trend line is then analyzed for patterns involving different topologies.

#### IV. RESULTS AND DISCUSSION

In order to determine the area for optimization, the results of the error value for the 1600 skin models was graphed for each case study. Since the observed pattern were consistent, the graphs corresponding a typical case study is used for the rest of this paper.

Fig. 1 presents the error values corresponding to 1600 skin models developed for the case study, with a random sample piece for illustrative purposes. With this data, it was easy to determine problem values for the error propagation rate values. The worst results were consistently those where the error propagation rates had signs that differed from one another. With this in mind, a filter was applied to remove a large number of the error samples. For the first pass, any value larger than 0.000001% of the minimum value was removed. This resulted in Fig. 2.

In Fig. 2, the sections with the smallest error can be seen. Those areas where the error propagation rates had differing signs have been completely removed. Another interesting characteristic is the symmetry developed between the two remaining segments. This means the optimization algorithm can be configured to only search one small segment of the overall data set, and it will be likely to achieve an acceptable result in a short amount of time.

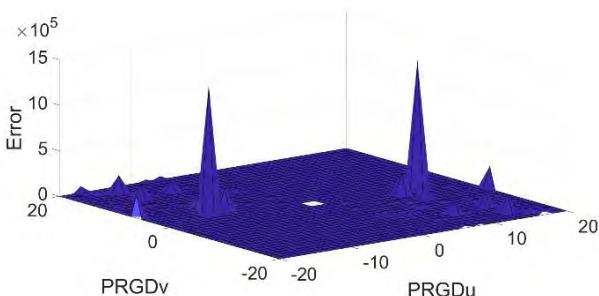

Figure 1. Error Results for 1600 Skin Models

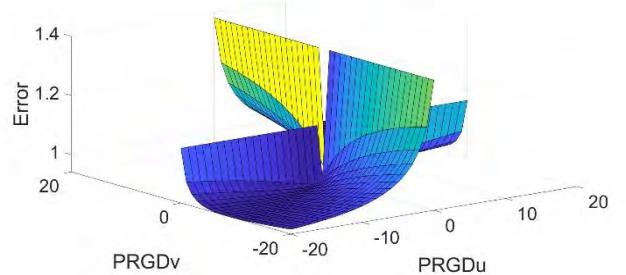

Figure 2. 99.999999% of the Range Removed

Another factor looked at was the density of points in different locations. This was examined to see if there was a correlation between high density zones of points and the lowest error results. With this information, the optimization area could be further refined. To test this, a data set was generated with equally spaced points. Then, a section of the data set was populated with a much higher density data set. Finally, the error graph generated was examined to determine where the lowest points were found. These points had a line fit to them, and the slope of the line was examined. Fig. 3 shows the first of these data sets.

Data Set 1 is heavily weighted to the positive x direction, and is shown in Fig. 3. Fig. 4 shows the results of the error analysis. The final graph has the errors of the opposing signed error propagation rates removed like in Fig. 2. There is also a large decrease in error between these two figures as data set 1 is very planar. None of the minimum error values were found in either of those regions, which was to be expected.

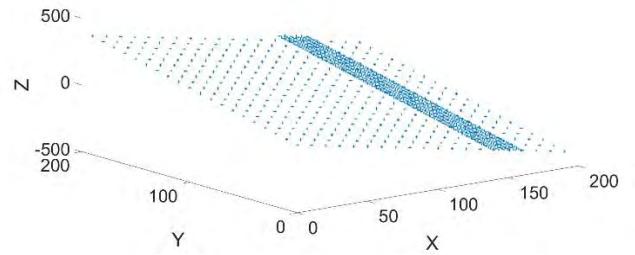

Figure 3. Data Set 1

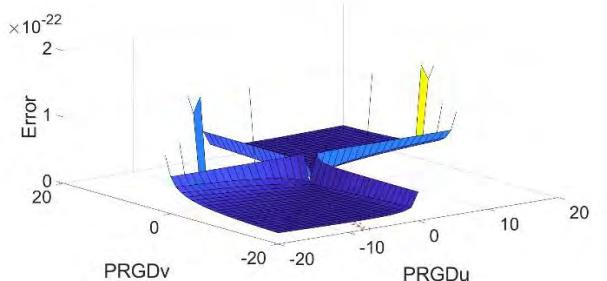

Figure 4. Data Set 1 - Error Modeling Results

The red line on the bottom of the graph is the best fit line for the lowest error values. It has a very large slope, which shows that the error propagation rate in the v axis on the refit data set dominates, corresponding with the increase in point density. This result is reflected in Fig. 5 and Fig. 6.

As the high density area is moved along the x-axis in the negative x direction, there is a corresponding shift in the slope of the line in the results. This test was repeated with the high density section moving along the entire u-axis. In each case, the slope of the line continued to shift in the same direction. This meant that the location of the points had an effect on the location of the minimum values, and therefore the start conditions for the optimization algorithm could be selected more intelligently, increasing the accuracy of the skin model as it would be more likely to find a better solution.

## V. CONCLUSION

The goal of this paper was to determine the area of optimization for the two main parameters involved in the skin model process, i.e. the geometric error propagation rates in the two orthogonal directions. A series of tests are conducted to model the effect of the error propagation rates on the accuracy of the resulting skin model. It was found that when the PRGD values had different signs from each other, the error was greatly increased. This allowed for the removal of those regions from analysis. Further examination showed that the remaining regions were symmetric, and therefore only one of them needed to be used to find the best PRGD values. Next, the effect of the density of sample points on the error values was examined.

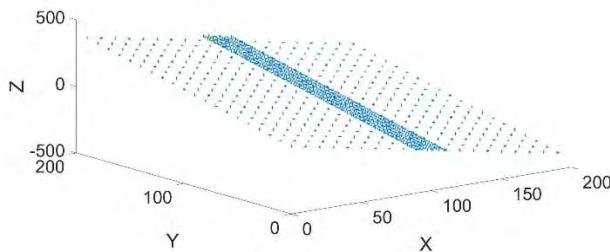

Figure 5. Data Set 2

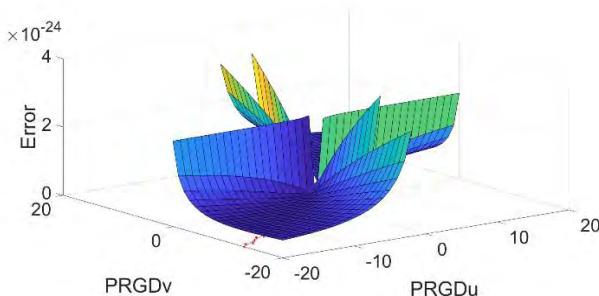

Figure 6. Data Set 2 - Error Modeling Results

The results showed that this density did have a large effect on the error. This effect was also fairly systematic, and therefore could be predicted. With this information, the area of optimization can be further refined. Both of these results can be used to better customize the skin model algorithms and achieve more accurate results using the skin model method.

**Abstract**—Topology Optimization is currently the main technique to optimize an objects structural design. This method commonly produces parts that have exceedingly complex geometry. Additive manufacturing (AM) is the main manufacturing process to produce these optimized designs due to the flexibility and speed it offers. However, results of topology optimization without considering manufacturing process limits, even AM ones, may result in designs that are expensive and difficult to build. This paper presents a topology optimization filter that minimizes the effect of overhang structures. These structures are very difficult to manufacture using conventional AM techniques. In order to constrain the gradient compliances with respect to densities and converge the results towards a structure with the least amount of overhang structures, sensitivities are modified using the proposed filter. To implement the proposed filter and the base topology optimization methods ESO and SIMP, ANSYS Parametric Design Language (APDL) is employed within the ANSYS® Workbench™ environment. The results of a case study using the different topology optimization methods are investigated. Finally, an implementation of the proposed AM filter is used to solve an MBB-beam problem. The result is a structure that needs the least amount of support structure.

## I. INTRODUCTION

Topology optimization is a subset of structural optimization with the goal of finding an optimal design for a certain set of constraints. It can be described as an iterative process where the results of a finite element analysis (FEA) are used to determine the optimal geometry and locations of voids in a solid object [1].

In the context of engineering, finite element analysis is a mathematical method of solving a system which cannot easily be described using closed form equations. Instead it breaks the system into smaller, easier to solve or approximate, parts using what are known as elements [2]. One popular FEA software for engineering is ANSYS®. Released in 1971 and still being

actively developed, ANSYS® can be used to solve a diverse field of engineering problems including static structural, dynamic, heat transfer, fluid flow, and electromagnetism. Currently, the user facing software of ANSYS® is Workbench™, from which a coding language called ANSYS Parametric Design Language (APDL) is called when simulations are run. This language executes the FEA, calculating all necessary parameters to solve the analysis. For advanced users, APDL is user accessible through custom command scripts that can be injected at any point during the analysis.

Creating a topology optimizer from scratch would include the development of a topology optimization algorithm and the development of a complete FEA solver. Additionally, if the creation and editing of geometry was also required, a computer aided design software would also be required. Instead, the accessible interface of ANSYS® and its mature FEA solver can be utilized to create a more extensive and easy to use topology optimizer through custom injected APDL scripts. Since ANSYS® includes Multiphysics simulations, the ability to add additional constraints and objectives, including manufacturing constraints and coupled analyses may become possible.

Additive manufacturing (AM) is a fairly young and quickly developing technology that overcomes many traditional manufacturing limits for complex geometries. However, all additive manufacturing methods still have some constraints that need to be considered during the design process. The use of disposable support material is one method to work around these constraints, but it is not a perfect solution as it often leads to a poor surface quality finish [3]. This support material is used to prevent failure during the manufacturing procedure by preventing overhang structures in the part geometry from collapsing, or otherwise ruining the final parts finish [4]. Since most AM processes use a manufacturing method where material is added layer by layer, each being fused to the previous, it can be said that there exists an angle where supports will be required.

Other approaches to minimize the prevalence of overhangs in topology optimized parts have been developed [5]. In this paper, a 3D implementation of the evolutionary structural optimization (ESO) and solid isotropic material with penalisation (SIMP) methods are presented along with a new

filtering method to reduce the amount of material needed for supports, all in ANSYS®.

## II. BACKGROUND

### A. Evolutionary Structural Optimization (ESO) Method

A topology optimization problem seeks to minimize compliance while satisfying various constraints such as a given amount of material, weight, manufacturing requirement, and cost [1]. The measure of stiffness of a structure can be calculated using a finite element analysis. In literature, instead of stiffness, mean compliance  $C$ , is considered as the objective for topology optimization. The evolutionary procedure based on stiffness as the objective function can be described as follows:

- 1) Discretize the body for FEA.
- 2) FEA determines sensitivity number for each element.
- 3) Remove elements with lowest sensitivity number based on element removal ratio.
- 4) Repeat the procedure to reach termination term (maximum displacement, stress, etc).

### B. Solid Isotropic Material with Penalization (SIMP)

Minimizing compliance is the most used objective in topology optimization, shown in (1).

$$\min_x: c(\rho) = U^T K U = \sum_{e=1}^N (\rho^e)^p u_e^T k^e u_e \quad (1)$$

$$\begin{aligned} \text{Subject to: } & \frac{V(\rho)}{V_0} = f \\ & ; KU = F \\ & ; 0 < \rho_{\min} \leq \rho^e \leq 1 \end{aligned}$$

Where the stiffness matrix for each element can be found from (2).

$$\begin{aligned} k^e &= \int_{\Omega} H^T D H \, d\Omega \\ &= \sum_{i=1}^2 \sum_{j=1}^2 w_i w_j |J(\xi, \eta)| H(\xi, \eta)^T D H(\xi, \eta) \quad (2) \end{aligned}$$

Here, the starting Young's modulus of an object does not influence the optimal results of topology optimization, since any changes will be relative. The general solution of the topology optimization is constructed to minimize compliance using a Lagrange multiplier method as shown in (3).

$$L(\rho, \lambda) = f^T d(\rho) + \lambda^T (f - K(\rho)d(\rho)) \quad (3)$$

By setting  $\lambda = d$  and  $k^e = \int_{\Omega} H^T (E_0 + (\rho^e)^p E_1 D^* H) \, d\Omega$ , the derivative of the lagrangian equation with respect to the design variables can be determined as (4) [6].

$$\frac{\partial L(\rho, \lambda)}{\partial \rho^e} = -P(\rho^e)^{p-1} d^{eT} K_f^e d^e \quad (4)$$

Updating of element densities heuristically can be achieved using the bi-section algorithm. A heuristic algorithm is used here based on the Optimality Criteria (OC) method shown in (5) [7]. A numerical constraint has been considered to limit the update for densities,  $m$ .

$$\rho^e_{new} = \begin{cases} if \quad \rho^e B_e^\eta \leq max(\rho_{min}, \rho^e - m) \\ \quad \quad \quad \max(\rho_{min}, \rho^e - m) \\ if \quad max(\rho_{min}, \rho^e - m) < \rho^e B_e^\eta < min(1, \rho^e + m) \\ \quad \quad \quad \rho^e B_e^\eta \\ if \quad min(1, \rho^e + m) \leq \rho^e B_e^\eta \\ \quad \quad \quad \min(1, \rho^e + m) \end{cases} \quad (5)$$

Where  $B_e^\eta = -\frac{1}{\lambda} \frac{\partial c}{\partial \rho^e}$  and  $\eta (=1/2)$  is a numerical damping coefficient.

### C. Implementation of Overhang Constraint

Applications of developed topology optimization methods have been very restricted due to the limitations in manufacturing and inspection of the resulting complex geometries. A successful design process needs to be conducted by considering all of the manufacturing and inspection requirements [8]. Although additive manufacturing processes are still not able to produce high surface qualities [9], [10], they are highly flexible in producing the complex geometries produced by topology optimization [11], [12]. Also, the advances in coordinate metrology algorithms allow relatively fast inspection of the complex topologies resulting by the topologically optimized designs [13].

These normal topology optimization methods converge to a computationally stiff structure, but without regard for the difficulty of manufacturing. Here is where another constraint is added that limits the surface area of elements to be less than a specified value for the optimal solution. This approach can be used to implement an overhang constraint. In the methodology section a new scheme is developed to estimate the sensitivities of overhanging elements in 3D space. These elements can then be penalized with respect to their overall sensitivity.

### D. Using APDL in ANSYS®

All the simulation and FEA functionality of ANSYS® comes from APDL commands [2]. Any FEA parameter that is calculated in ANSYS® can be read, and as logic applies, can be modified.

The syntax for an APDL commands starts with the name of the commands, followed by a comma, and then the operators of the commands, all separated by commas. There are also logical operators such as *do*, *if*, *ifelse*, and *while*.

The actual FEA solver in ANSYS® operates much like other FEA solvers [14]. There are three overall levels within the solver, the first being the preprocessor. This is where the mesh of the geometry is defined, as well as the loads on the body and boundary conditions. Next, the solver processes the generated simultaneous equations, which results in the values for degrees of freedom for the nodes on each element. This data is then taken into the final level, the postprocessor, where all other results are

calculated, such as stress and strain. It is important to note that only certain APDL commands can be executed in certain levels of the FEA, limiting how one can interact with the program. However, with a large selection of pre-defined commands combined with logical operators, essentially anything related to the FEA process can be modified and manipulated.

### III. METHODOLOGY

#### A. Implementing the Topology Optimization Overhang Constraint

Using a similar method to that Sigmund used to solve the optimality criteria, the area of an element can be considered as a new constraint. A method has been developed to calculate the derivative of the surface area of each element with respect to its density [15]. Using the same approach shown in (6), the approximate surface area sensitives are calculated for the bottom elements, which are multiplied by a constant coefficient  $\gamma$ , as shown in Fig. 1.

$$\frac{\partial A}{\partial \rho_i} \Big|_{face} = \begin{cases} \frac{A(\rho_i - \rho_j)}{|\rho_i - \rho_j|} & \text{if } \rho_i \neq \rho_j \\ -A & \text{if } \rho_i = \rho_j = \rho_{max} \\ A & \text{if } \rho_i = \rho_j = \rho_{min} \end{cases} \quad (6)$$

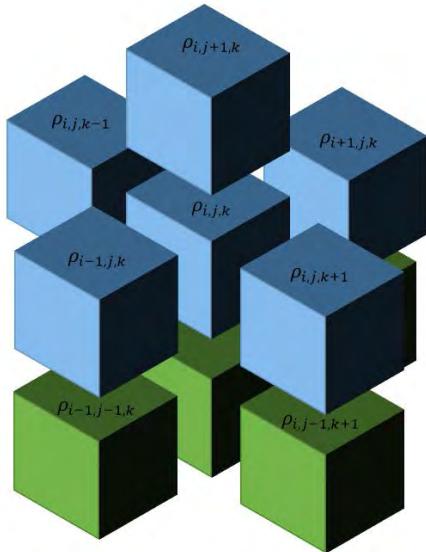

Figure 1. Elements that are considered in the modification of perimeter sensitivities based on each element connectivity

For the estimation of the overhang sensitivities, a scheme used to penalize overhang structures shown in (7) is developed. Individual element connectivity's are found using a predefined function inside ANSYS® that finds the six elements connected to the element.

$$\begin{aligned} \frac{\partial A}{\partial \rho^e} = & \left\{ \frac{\partial A}{\partial \rho_i} \Big|_{face(i,j+1,k)} + \frac{\partial A}{\partial \rho_i} \Big|_{face(i-1,j,k)} + \right. \\ & \frac{\partial A}{\partial \rho_i} \Big|_{face(i+1,j,k)} + \frac{\partial A}{\partial \rho_i} \Big|_{face(i-1,j,k+1)} + \\ & \frac{\partial A}{\partial \rho_i} \Big|_{face(i-1,j,k-1)} + \gamma \left[ \frac{\partial A}{\partial \rho_i} \Big|_{face(i-1,j-1,k)} + \right. \\ & \frac{\partial A}{\partial \rho_i} \Big|_{face(i,j-1,k)} + \frac{\partial A}{\partial \rho_i} \Big|_{face(i+1,j-1,k)} + \\ & \left. \left. \frac{\partial A}{\partial \rho_i} \Big|_{face(i,j-1,k+1)} + \frac{\partial A}{\partial \rho_i} \Big|_{face(i,j-1,k-1)} \right] \right\} \end{aligned} \quad (7)$$

From this, the modified sensitivities are shown in (8).

$$C_e^\eta = -\frac{1}{\lambda} \left[ \frac{\partial c}{\partial \rho^e} + \delta \frac{\partial A}{\partial \rho^e} \right] \quad (8)$$

Now, the update scheme shown in (5) is used for the topology optimization procedure, except the modified sensitivities are used instead of the compliance sensitivities to converge the densities away from overhang structures, (9).

$$\rho^{e\_new} = \begin{cases} & \text{if } \rho^e C_e^\eta \leq \max(\rho_{min}, \rho^e - m) \\ & \max(\rho_{min}, \rho^e - m) \\ & \text{if } \max(\rho_{min}, \rho^e - m) < \rho^e C_e^\eta < \min(1, \rho^e + m) \\ & \rho^e C_e^\eta \\ & \text{if } \min(1, \rho^e + m) \leq \rho^e C_e^\eta \\ & \min(1, \rho^e + m) \end{cases} \quad (9)$$

#### B. Topology Optimization using APDL

Building the topology optimizer on top of ANSYS® allows for a more flexible design platform. Using the methodologies just established, three APDL topology optimizers were coded. One based on the ESO method, one based on SIMP, and the last one adding the overhang constraint in the SIMP program. In each of the programs, the material property APDL command was used to modify the elements young's modulus, therefore directly affecting its stiffness. Overall each script solves the initial FEA problem and gets the initial element values. Then it retrieves each elements sensitivity value, and uses the corresponding methodology to choose which ones to modify. Once all elements are looped through, the script re-solves the FEA and repeats until the convergence criteria are met.

## IV. RESULTS AND DISCUSSION

#### A. Topology Optimization – Case Study 1

As an example, a bell crank was considered. There are two forces and a fixed hole which define the boundary conditions for this analysis. The setup in ANSYS® is shown in Fig. 2. The element size is 2 mm. The topology optimization results using ESO and SIMP without any additional constraints are shown in Fig. 3 and Fig. 4 at iterations 60 and 30 respectively. It can be seen that this structure may be difficult to produce using AM processes.

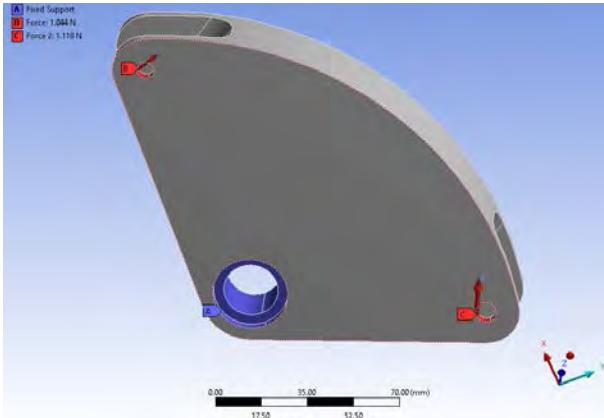

Figure 2. Case Study 1 Setup

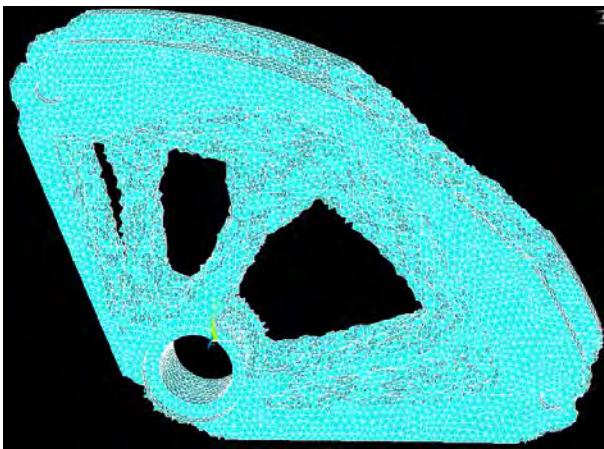

Figure 3. Case Study 1 Results after 60 Iterations using ESO

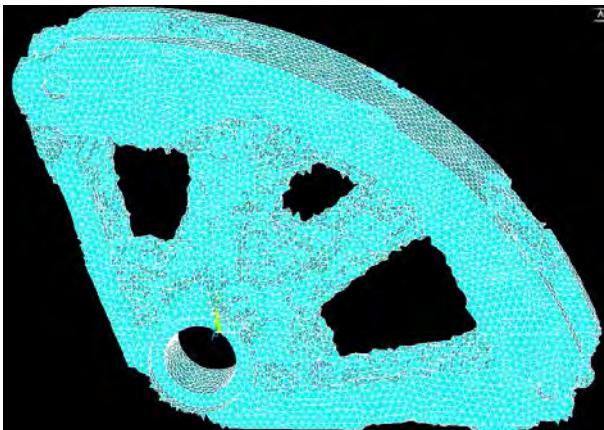

Figure 4. Case Study 1 Results after 30 Iterations using SIMP

#### B. Topology Optimization – Case Study 2: Overhang Constraint

Next, an MBB-beam as shown in Fig. 5 was considered. It has a fixed constraint at the bottom corner of one end and a rolling constraint at the other end, with a 1000 N force applied at the middle point of the top surface. It has a mesh size of 40x180. The setup in ANSYS® is shown in Fig. 6. The SIMP method topology optimization results using half design domain

with symmetry are shown in Fig. 7. The results in Fig. 8 and Fig. 9 are with the overhang constraint with varying  $\delta$  values from (8). The blue line at the bottom represents the build platform, with the blue arrow specifying the build direction. By inspection it appears that this structure does indeed have less overhanging structures than the normal SIMP method.

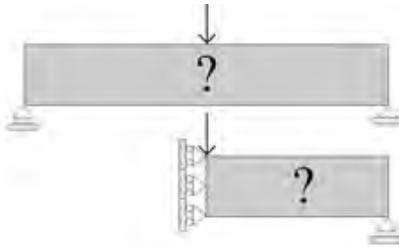

Figure 5. MBB-beam. Top: full design domain, bottom: half design domain with symmetry [7].

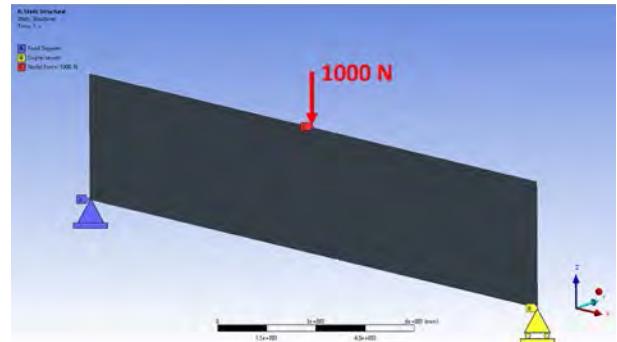

Figure 6. Case Study 2 Setup

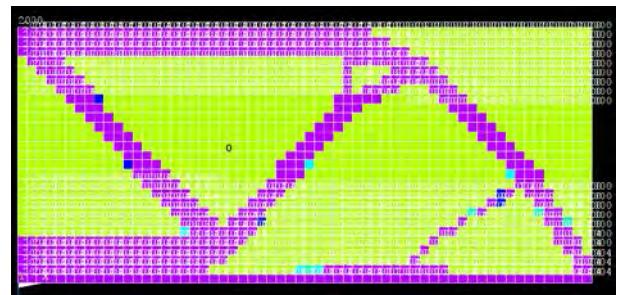

Figure 7. Case Study 2 Half Design Domain Results after 50 Iterations using SIMP (Purple elements are solid, green elements are a void)

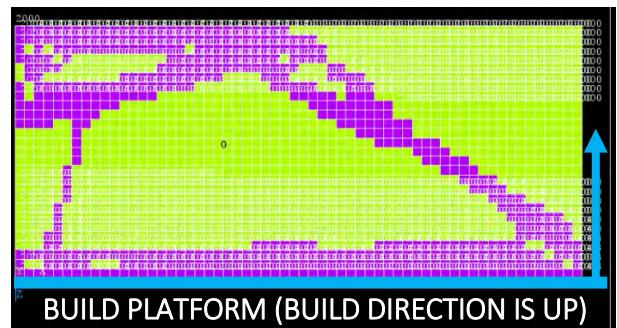

Figure 8. Case Study 2 Half Design Domain Results using Overhang Constraints,  $\delta = 0.00005$  (Purple elements are solid, green elements are a void)

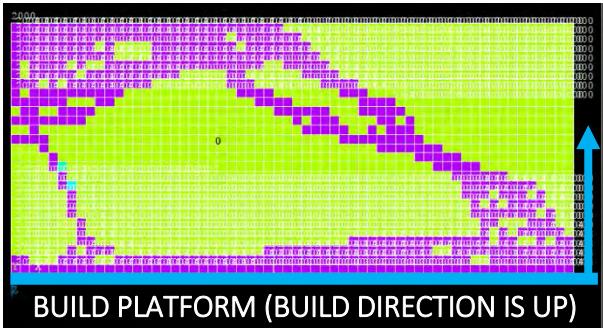

Figure 9. Case Study 2 Half Design Domain Results using Overhang Constraints,  $\delta = 0.0001$  (Purple elements are solid, green elements are a void)

## V. CONCLUSION

In this paper, three topology optimization codes were developed. Two based on previous methodologies, the ESO method and the SIMP method, and the final attempted to optimize the topology for AM processes by reducing the need for support material. All were implemented in ANSYS® directly, using APDL scripts, in order to achieve a flexible and reliable development platform. The first case study looked at the implementation of the ESO and SIMP methods, and the last one looked at the implementation of the overhang constraint. The proposed topology optimization filter modifies the element sensitivities to converge the optimization towards the optimal structure that needs the least amount of material for support structures. This will reduce the manufacturing cost and time for preprocessing and post-processing operations, and reduce material waste. The established methodology can be easily developed for various additive manufacturing technologies in various industrial applications.

**Abstract**—This paper develops an algorithm to estimate the relative pose, motion, and inertia ratio of an unknown target using stereoscopic vision. First, the positions and velocities of detected feature points on the spacecraft are estimated. Second, the angular velocity and attitude of the target are estimated by the least square method and q-method, respectively. Third, the position and velocity of the center of mass of the spacecraft are recovered. Finally, the inertia ratio is estimated based on the angular momentum conversation using the estimated angular velocity and attitude of the target. Numerical simulations are conducted to demonstrate the proposed algorithm.

**Keywords**—relative state; inertia ratio; un-cooperative spacecraft; stereoscopic vision; 3-D reconstruction; constrains.

## I. INTRODUCTION (HEADING 1)

Estimating the dynamical parameters (pose and motion) and inertia property of an unknown target is one of the critical technologies during on-orbit autonomous close proximity operation missions [1], such as spacecraft rescuing, repairing, and capturing. These unknown targets are usually non-cooperative without prior information about their structural and inertia parameters, nor artificial markers located known positions on the target. Therefore, the relative state and inertia properties are complete unknown. For a safe close proximity operation mission, such like approach to and capture the target, the relative state can provide important navigation information for the control strategy. Besides, the knowledge of inertia properties of the target is necessary to propagate its state and can be used in the motion prediction before capture and de-spun control design after capture.

Numerous vision-based estimation methods were proposed in the past [2-6] for non-cooperative targets. Terui et al. [7] proposed a 3D model matching method to estimate the relative state with the prior known structure of the target. Dehann et al. [8] adopted the stereo vision to measure the geometric center of the target as an approximation to its center of mass (CM). Du et al. [9] determined the pose of a large non-cooperative target based on two collaborative cameras by recognizing a rectangular feature on the target. Dong and Zhu [10, 11] estimated the pose and motion of a non-cooperative target with

a monocular camera using some known feature point. Licher and Dubowsky [12] presented a method to estimate the state using thousands of 3D points acquired from several cooperative 3D sensors, which leads to heavy computational efforts. Tweddle [13] proposed a Simultaneous Localization and Mapping (SLAM) solution to estimate the full state of a spinning non-cooperative target, with high computation complexity. Shay Segal [14] calculated the pose and motion with image position and velocity measurements of feature points on the target. By applying torque on the target produced from reaction wheels or a robotic arm, the inertia parameters are in-flight estimated [15, 16].

The purpose of this paper is to develop an innovative stereo vision-based algorithm to estimate the relative pose, motion, and inertia ratio of a non-cooperative target without prior knowledge about the positions of the feature points. The inertia ratio is estimated based on the conservation of angular momentum, assuming that the target is freely tumbling without any external torque on it.

The remainder of this paper is organized as follows. Section II provides the observation model. Section III gives the details of the proposed estimation algorithm. In Section IV, the newly proposed algorithm is validated by numerical simulation. Finally, Section V concludes the paper.

## II. OBSERVATION MODEL

As depicted in Fig. 1, assume that two cameras mounted on the chaser are identical with parallel image planes and separated by a baseline  $b$ , the distance between the right camera's center of projection  $\text{COP}_r$  and the left camera's center of projection  $\text{COP}_l$ . The target is in the field of view (FOV) of the both cameras. Two coordinate frames are used to describe the relative pose and motion of the unknown target: a) the target body frame  $T$  is a Cartesian frame with its origin at the CM of the target; b) the camera frame  $C$  is a Cartesian frame with its origin attached to  $\text{COP}_r$ ,  $\hat{x}_c$  and  $\hat{z}_c$  axes parallel to the image plane and  $\hat{y}_c$  axis pointing towards to the target. Here the frame  $C$  is assumed to be aligned with the inertial frame. The position and attitude of the target are defined by the vector  $\rho_0$  in the frame  $C$  and the direction cosine matrix  $R'_c$

converting vectors from the frame  $\mathcal{C}$  to the frame  $\mathcal{T}$ . The corresponding translational and rotational velocities are denoted as  $\dot{\mathbf{p}}_0$  and  $\omega_{tc}^c$ , respectively.

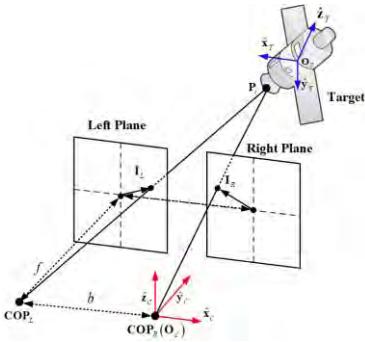

Fig. 1. Stereo vision measurement system.

Assuming that an arbitrary point  $P_i$  on the target has the 3D coordinates  $\mathbf{p}_i = [\rho_{ix} \ \rho_{iy} \ \rho_{iz}]^T$  in the frame  $\mathcal{C}$  and the 2D images coordinates  $\mathbf{I}_R = [u_{iR} \ v_{iR}]^T$  and  $\mathbf{I}_L = [u_{iL} \ v_{iL}]^T$  in the right and left image frames, respectively. According to the ideal pinhole camera model, the perspective projection transforms the feature point  $P_i$  from the 3-D space onto the 2-D image plan, such that

$$\mathbf{\eta}_i = \begin{bmatrix} u_{iR} \\ v_{iR} \\ u_{iL} \\ v_{iL} \end{bmatrix} = \begin{bmatrix} f \frac{\rho_{ix}}{\rho_{iy}} \\ f \frac{\rho_{iz}}{\rho_{iy}} \\ f \frac{\rho_{ix} + b}{\rho_{iy}} \\ f \frac{\rho_{iz}}{\rho_{iy}} \end{bmatrix} \quad (1)$$

where  $f$  is the focal length.

Define the disparity as

$$d_i \triangleq u_{iL} - u_{iR} \quad (2)$$

The image velocity of the feature point is defined as the time derivative of its image coordinates,

$$\begin{bmatrix} \dot{u}_{iR} \\ \dot{v}_{iR} \\ \dot{u}_{iL} \\ \dot{v}_{iL} \end{bmatrix} = \frac{1}{\rho_{iy}} \begin{bmatrix} f & -u_{iR} & 0 \\ 0 & -v_{iR} & f \\ f & -u_{iL} & 0 \\ 0 & -v_{iL} & f \end{bmatrix} \dot{\mathbf{p}}_i \quad (3)$$

Considering the image noise, denoted by  $\boldsymbol{\epsilon}$ , the images coordinates with noise could be modeled as

$$\bar{\mathbf{\eta}} = \mathbf{\eta} + \boldsymbol{\epsilon} \quad (4)$$

where  $\bar{\mathbf{\eta}} = [\bar{u}_{iR}, \bar{v}_{iR}, \bar{u}_{iL}, \bar{v}_{iL}]^T$  is the image measurement and  $\boldsymbol{\epsilon}_i$  is a zero-mean white noise with covariance matrix  $\mathbf{R}_i$ , i.e.,  $\boldsymbol{\epsilon}_i \sim \mathcal{N}(0, \mathbf{R}_i)$ .

### III. DESIGN AND IMPLEMENTATION OF STATE AND STRUCTURE ESTIMATION OF TARGET

#### A. Positions and velocities of feature points

The positions of feature points are estimated by

$$\bar{\mathbf{p}}_i = \begin{bmatrix} \bar{\rho}_{ix} \\ \bar{\rho}_{iy} \\ \bar{\rho}_{iz} \end{bmatrix} = \begin{bmatrix} \frac{b(\bar{u}_{iL} + \bar{u}_{iR})}{2\bar{d}_i} - \frac{b}{2} \\ \frac{bf}{\bar{d}_i} \\ \frac{b(\bar{v}_{iL} + \bar{v}_{iR})}{2\bar{d}_i} \end{bmatrix} \quad (5)$$

The velocities of feature points are determined by

$$\bar{\dot{\mathbf{p}}}_i = C_i^+ \boldsymbol{\xi}_i \quad (6)$$

where the superscript “+” denotes the Moore-Penrose inversion of a matrix, and

$$C_i = \frac{1}{\bar{\rho}_{iy}} \begin{bmatrix} f & -\bar{u}_{iR} & 0 \\ 0 & -\bar{v}_{iR} & f \\ f & -\bar{u}_{iL} & 0 \\ 0 & -\bar{v}_{iL} & f \end{bmatrix}, \quad \boldsymbol{\xi}_i = \begin{bmatrix} \bar{u}_{iR} \\ \bar{v}_{iR} \\ \bar{u}_{iL} \\ \bar{v}_{iL} \end{bmatrix}.$$

#### B. Pose and motion estimation of the target

At time instant  $t$ , the relationship between  $\mathbf{p}_i$  and  $\mathbf{r}_i$  is expressed as:

$$\mathbf{p}_i(t) = \mathbf{p}_0(t) + \mathbf{R}_i^c(t) \mathbf{r}_i \quad (7)$$

where  $\mathbf{R}_i^c = (\mathbf{R}_i^c)^T$  is the rotation matrix that transforms vectors from the frame  $\mathcal{T}$  to the frame  $\mathcal{C}$ . Taking the time derivative of (7) yields

$$\dot{\mathbf{p}}_i(t) = \dot{\mathbf{p}}_0(t) + \omega_{tc}^c(t) \times [\mathbf{R}_i^c(t) \mathbf{r}_i] \quad (8)$$

Defining  $\delta\mathbf{p}_i(t) = \mathbf{p}_i(t) - \mathbf{p}_1(t)$  and  $\delta\mathbf{r}_i = \mathbf{r}_i - \mathbf{r}_1$  yield

$$\begin{cases} \delta\mathbf{p}_i(t) = \mathbf{R}_i^c(t) \delta\mathbf{r}_i \\ \delta\dot{\mathbf{p}}_i(t) = \omega_{tc}^c(t) \times [\mathbf{R}_i^c(t) \delta\mathbf{r}_i] \end{cases}, \quad 1 \leq i \leq N-1 \quad (9)$$

Eliminating  $\mathbf{R}_i^c(t) \delta\mathbf{r}_i$  in (9) leads to

$$[\delta\mathbf{p}_i(t) \times] \omega_{tc}^c(t) = -\delta\dot{\mathbf{p}}_i(t) \quad (10)$$

where  $[\mathbf{a} \times]$  is the cross-product matrix expressed as

$$[\mathbf{a} \times] = \begin{bmatrix} 0 & -a_3 & a_2 \\ a_3 & 0 & -a_1 \\ -a_2 & a_1 & 0 \end{bmatrix} \quad (11)$$

The angular velocity of the target is estimated using LS method by

$$\bar{\omega}_{tc}^c(t) = [\mathbf{J}(t) \mathbf{J}(t)^T]^{-1} \mathbf{J}(t)^T \mathbf{b}(t) \quad (12)$$

where  $N$  is the number of feature points, and

$$\mathbf{J}(t) = \begin{bmatrix} [\delta\mathbf{p}_1(t) \times] \\ \vdots \\ [\delta\mathbf{p}_{N-1}(t) \times] \end{bmatrix}, \quad \mathbf{b}(t) = \begin{bmatrix} -\delta\dot{\mathbf{p}}_1(t) \\ \vdots \\ -\delta\dot{\mathbf{p}}_{N-1}(t) \end{bmatrix}.$$

According to (9), the following relationship holds,

$$\begin{cases} \delta\mathbf{p}_i(t_k) = \mathbf{R}_t^c(t_k)\delta\mathbf{r}_i, & 1 \leq i \leq N-1 \\ \delta\mathbf{p}_i(t_0) = \mathbf{R}_t^c(t_0)\delta\mathbf{r}_i \end{cases} \quad (13)$$

where  $t_k = t_0 + k\Delta t$ ,  $\Delta t$  is the sample interval time, and  $k$  is a positive integer.

Eliminating  $\delta\mathbf{r}_i'$  in (13) gives

$$\delta\mathbf{p}_i(t_k) = \mathbf{R}_t^c(t_k)[\mathbf{R}_t^c(t_0)]^T \delta\mathbf{p}_i(t_0), \quad 1 \leq i \leq N-1 \quad (14)$$

Define  $\delta\mathbf{R}_t^c(t_{k,0}) = \mathbf{R}_t^c(t_k)[\mathbf{R}_t^c(t_0)]^T$  as the attitude change from  $t_0$  to  $t_k$ , then (14) is rewritten as

$$\delta\mathbf{p}_i(t_k) = \delta\mathbf{R}_t^c(t_{k,0})\delta\mathbf{p}_i(t_0), \quad 1 \leq i \leq N-1 \quad (15)$$

Equation (15) is solved by the q-method. Choose a set of non-negative weights  $\{a_i\}, i=1, 2, \dots, N-1$  and define

$$\mathbf{B} = \sum_{i=1}^{N-1} a_i \delta\mathbf{p}_i(t_k) [\delta\mathbf{p}_i(t_0)]^T, \quad \mathbf{L}(\mathbf{B}) = \begin{bmatrix} \mathbf{B} + \mathbf{B}^T - (tr\mathbf{B})\mathbf{I}_3 & \mathbf{z} \\ \mathbf{z}^T & tr\mathbf{B} \end{bmatrix}.$$

where  $\mathbf{z} = \sum_{i=1}^{N-1} a_i [\delta\mathbf{p}_i(t_k) \times \delta\mathbf{p}_i(t_0)]$ .

The optimal estimation  $\hat{\mathbf{q}}_{ct}(t_{k,0})$  is the eigenvector corresponding to the largest eigenvalue of  $\mathbf{L}(\mathbf{B})$ . Given the initial relative attitude, the relative attitude quaternion of the frame  $\mathcal{C}$  relative to the frame  $T$ ,  $\hat{\mathbf{q}}_{ct}(t_k)$ , can be calculated at any time. Accordingly, the estimated quaternion of the frame  $T$  relative to the frame  $\mathcal{C}$  is

$$\hat{\mathbf{q}}_{ct}(t_k) = [-\hat{\varrho}_{ct}^T(t_k) \quad \hat{q}_{ct4}(t_k)]^T \quad (16)$$

### C. Position and velocity of the CM estimation of the target

Assume the CM of the target moves approximately at a constant velocity in a short sampling interval  $\Delta t$ , such that

$$\begin{cases} \mathbf{p}_0(t_k) = \mathbf{p}_0(t_k - \Delta t) + \dot{\mathbf{p}}_0(t_k - \Delta t) \cdot \Delta t \\ \dot{\mathbf{p}}_0(t_k) = \dot{\mathbf{p}}_0(t_k - \Delta t) \end{cases} \quad (17)$$

Define state as  $\mathbf{X} = [\mathbf{r}_i^T \quad \mathbf{p}_0^T \quad \dot{\mathbf{p}}_0^T]^T$ , which satisfies

$$\mathbf{X}(t_k - j \cdot \Delta t) = \mathbf{A}^{-j}\mathbf{X}(t_k), \quad k - c \leq j < k \quad (18)$$

where  $j$  is a positive integer,  $c$  is a time period, and

$$\mathbf{A} = \begin{bmatrix} \mathbf{I}_{3 \times 3} & & & \\ & \mathbf{I}_{3 \times 3} & & \\ & & \mathbf{I}_{3 \times 3} & \\ & & & \ddots \\ & & & & \mathbf{I}_{3 \times 3} & \Delta t \cdot \mathbf{I}_{3 \times 3} \\ & & & & 0_{3 \times 3} & \mathbf{I}_{3 \times 3} \end{bmatrix}_{(3N+6) \times (3N+6)}$$

The measurement model can be written as

$$\mathbf{Y}(t_k - j \cdot \Delta t) = \mathbf{C}(t_k - j \cdot \Delta t) \mathbf{A}^{-j} \mathbf{X}(t_k), \quad k - c \leq j < k \quad (19)$$

with

$$\mathbf{Y}(t_k) = \begin{bmatrix} \mathbf{Y}_1(t_k)^T & \dots & \mathbf{Y}_i(t_k)^T \end{bmatrix}^T, \quad 1 \leq i \leq N$$

$$\mathbf{C}(t_k) = \begin{bmatrix} \hat{\mathbf{R}}_t^c(t_k) & I_{3 \times 3} \\ \vdots & I_{3 \times 3} \\ \hat{\mathbf{R}}_t^c(t_k) & I_{3 \times 3} \\ \left[ \hat{\omega}_{ic}^c(t_k) \times \right] \hat{\mathbf{R}}_t^c(t_k) & I_{3 \times 3} \\ \vdots & I_{3 \times 3} \\ \left[ \hat{\omega}_{ic}^c(t_k) \times \right] \hat{\mathbf{R}}_t^c(t_k) & I_{3 \times 3} \end{bmatrix}$$

The state  $\mathbf{X}$  can be estimated by LS given as

$$\hat{\mathbf{X}}(t_k) = (\mathbf{H}\mathbf{H}^T)^{-1} \mathbf{H}^T \mathbf{Y} \quad (20)$$

where

$$\mathbf{H} = \begin{bmatrix} \mathbf{C}(t_k) \\ \mathbf{C}(t_k - \Delta t) \mathbf{A}^{-1} \\ \vdots \\ \mathbf{C}(t_k - j \cdot \Delta t) \mathbf{A}^{-1} \\ \vdots \\ \mathbf{C}(t_k - c \cdot \Delta t) \mathbf{A}^{-1} \end{bmatrix}, \quad \mathbf{Y} = \begin{bmatrix} \mathbf{Y}(t_k) \\ \mathbf{Y}(t_k - \Delta t) \\ \vdots \\ \mathbf{Y}(t_k - j \cdot \Delta t) \\ \vdots \\ \mathbf{Y}(t_k - c \cdot \Delta t) \end{bmatrix}$$

### D. Inertia ratio estimation

In the absence of external torques, the angular momentum of the target is constant in the inertial frame. Since the frame  $\mathcal{C}$  is assumed to be aligned with the inertial frame in this paper, the angular momentum of the target is constant in the frame  $\mathcal{C}$ , which is denoted as  $\mathbf{h}^c$ . At time instant  $t$ ,

$$\mathbf{R}_c^t(t)\mathbf{h}^c(t) = \mathbf{I}\boldsymbol{\omega}_{ic}^c(t) \quad (21)$$

where  $\boldsymbol{\omega}_{ic}^c(t) = \mathbf{R}_c^t(t)\boldsymbol{\omega}_{ic}^c(t)$

Define the inertia vector as

$$\mathbf{x} = [\mathbf{I}^* \quad h_x^c \quad h_y^c \quad h_z^c]^T \quad (22)$$

with  $\mathbf{I}^* = [I_{xx} \quad I_{xy} \quad I_{xz} \quad I_{yy} \quad I_{yz} \quad I_{zz}]^T$ , (21) can be rewritten as

$$\mathbf{Ax} = \mathbf{0} \quad (23)$$

where

$$\mathbf{A} = \begin{pmatrix} \Omega^t(t_1) & \mathbf{R}_c^t(t_1) \\ \vdots & \vdots \\ \Omega^t(t_M) & \mathbf{R}_c^t(t_M) \end{pmatrix} \quad (24)$$

with

$$\Omega^b(t) = \begin{pmatrix} \omega_{tx}^t(t) & \omega_{ty}^t(t) & \omega_{tz}^t(t) & 0 & 0 & 0 \\ 0 & \omega_{tx}^t(t) & 0 & \omega_{ty}^t(t) & \omega_{tz}^t(t) & 0 \\ 0 & 0 & \omega_{tx}^t(t) & 0 & \omega_{ty}^t(t) & \omega_{tz}^t(t) \end{pmatrix}$$

Equation (23) can be solved in the least square, which means that the solution should minimize

$$f(\mathbf{x}) = \|\mathbf{Ax}\|_2^2 = (\mathbf{Ax})^T \mathbf{Ax} = \mathbf{x}^T \mathbf{A}^T \mathbf{Ax} \quad (25)$$

Obviously  $f(\mathbf{x})$  has the minimum when

$$\mathbf{Bx} = \mathbf{0} \quad (26)$$

with  $\mathbf{B} = \mathbf{A}^T \mathbf{A} \in \mathbb{R}^{9 \times 9}$ .

Reordering such that

$$\mathbf{B} = \begin{bmatrix} b_{11} & \mathbf{b}_1^T \\ \mathbf{b}_1 & \mathbf{B}_r \end{bmatrix} \quad (27)$$

where  $b_{11} \in \mathbb{R}^+$ ,  $\mathbf{b}_1 \in \mathbb{R}^{8 \times 1}$ , and  $\mathbf{B}_r \in \mathbb{R}^{8 \times 8}$ . Setting the first variable in  $\mathbf{x}$  to 1, i.e.  $\mathbf{x} = [1 \ \mathbf{x}_r]^T$ , (26) is reduced to

$$\mathbf{B}_r \mathbf{x}_r = -\mathbf{b}_1 \quad (28)$$

However, there are physical constraints between the elements of the inertia tensor  $\mathbf{I}$ . Assuming that  $I_{xx}$  is the largest diagonal element of  $\mathbf{I}$ , the following constraints hold,

$$\begin{cases} 0 < I_{yy} < I_{xx} \\ 0 < I_{zz} < I_{xx} \\ I_{yy} + I_{zz} > I_{xx} \\ 2|I_{xy} + I_{xz} + I_{yz}| < I_{xx} + I_{yy} + I_{zz} \end{cases} \quad (29)$$

Since  $\mathbf{B}_r$  is also a positive-definite matrix. Therefore, the problem is a convex quadratic programming problem with convex quadratic function  $q(\mathbf{x}_r) = \frac{1}{2} \mathbf{x}_r^T \mathbf{B}_r \mathbf{x}_r + \mathbf{b}_1^T \mathbf{x}_r$  and inequality constraints (29) by setting the first variable in  $\mathbf{x}$  to 1. The interior-point-convex method is adopted here to solve this convex quadratic programming problem.

#### IV. NUMERICAL SIMULATIONS

In this section, numerical simulations are performed to verify the proposed estimation algorithm. The estimation errors are defined as:

$$e_{\rho_0} = \frac{\|\hat{\rho}_0 - \rho_0\|_2}{\|\rho_0\|_2}, e_{\dot{\rho}_0} = \frac{\|\hat{\dot{\rho}}_0 - \dot{\rho}_0\|_2}{\|\dot{\rho}_0\|_2}, e_{\omega_{ic}^c} = \frac{\|\hat{\omega}_{ic}^c - \omega_{ic}^c\|_2}{\|\omega_{ic}^c\|_2} \quad (30)$$

$$e_{\mathbf{r}_i} = \frac{\|\hat{\mathbf{r}}_i - \mathbf{r}_i\|_2}{D}, e_{\mathbf{I}_i} = \frac{\|\hat{\mathbf{I}}_i^* - \mathbf{I}_i^*\|}{\|\mathbf{I}_i^*\|} \quad (31)$$

where the superscripts “ $\hat{\cdot}$ ” and “ $\cdot$ ” denote the estimated value and true value, respectively,  $\|\cdot\|_2$  is the norm of a vector,  $\mathbf{I}_i^*$  is the component of the normalization of  $\mathbf{I}^*$ , and  $D$  is a reference dimension. The relative attitude estimation error is defined as

$$e_\theta = 2 \cos^{-1}(q_{e4}) \quad (32)$$

where  $q_{e4}$  is the scalar part of the error quaternion defined by  $\mathbf{q}_e = \mathbf{q}_{tc} \otimes \hat{\mathbf{q}}_{tc}$ .

In the simulation, the sample time step is assumed to be 1 s, the total simulation period is 3,000 s, and the time period is 10, the number of feature points is 4 and the reference dimension is 3 m, the other conditions are listed in Table I.

**Table I Simulation parameters.**

Simulation parameter		Values
Camera parameters	Baseline length	1 m
	Focal length	0.1 m
	Image noise	0.2 pixel
	Pixel Size	2.55 $\mu$ m
Initial state	Initial relative angular velocity	[1.5 2.3 -1.9] rad/s
	Initial relative attitude	[1 0 0 1]^T
	Initial position	[20 60 30] m
	Initial velocity	[-0.01 -0.01 -0.02] m/s

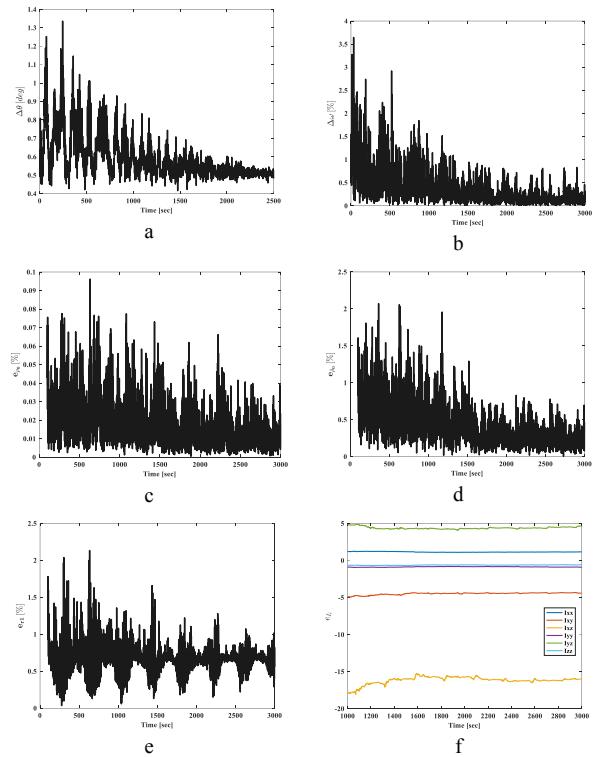

Fig. 2. Error of estimation. a) error of relative attitude, b) error of relative angular velocity, c) error of position for CM of the target, d) error of velocity for CM of the target, e) error of position estimation of one feature point, f) error of inertia ratio estimation.

As shown in Fig. 2, the relative state and inertia ratio estimation can get high accuracy by the designed algorithm. The relative attitude error is less than 2.5%, the relative angular velocity error is no more than 4%, and the position and velocity errors of the CM are less than 0.1% and 2.5%, respectively, and the position error of one feature relative the reference dimension is less than 2.5%, the error of the normalized moments of inertia is of magnitude 18%. In fact, the number of the attitudes and angular velocities influence the accuracy of inertia ratio which is based on a least square optimization.

## V. CONCLUSIONS

This paper develops an effective algorithm to estimate the relative pose, motion, CM and inertia ratio of an unknown target based on the consecutive images obtained from stereoscopic vision. The positions and velocities of the detected feature points on the target are estimated first, and then the estimation of the pose, motion, CM and inertia ratio. The advantage of this algorithm is its ability to estimate the CM, inertia ratio and the constellation of feature points of the target simultaneously without prior knowledge of the target. The simulation results show that the proposed algorithm can get a good estimation accuracy in acceptable measurement noise level.

**Abstract** — This work examines identifying reuses for wind-turbine blades that are retired when they reach the end of their technical life. Wind-turbine blades are made from fiber-composite materials, for which effective material-based recycling technologies are extremely limited. An approach to avoid or postpone recycling is to repurpose wind-turbine blades in other applications, as they should not be reused as wind-turbine blades for safety reasons.

However, identifying promising reuses for wind-turbine blades is challenging due to their specific shape properties. In addition to issues of functional fixedness, wind-turbine blades are physically much larger than everyday objects with which people typically reason. Following a series of studies where engineering students were asked to identify wind-turbine-blade reuses, a method involving perspective-taking was developed and applied. The effects of this method on concept generation are reported and compared to SCAMPER, an existing design method. To better understand and motivate human designers, this work also incorporates psychological concepts, including Need for Closure and Regulatory Focus Theory.

**Keywords:** Sustainability, Component reuse, Wind-turbine blades, Concept generation, Functional fixedness

## I. INTRODUCTION

Global installation of wind-turbine technology is expected to continue to increase, decreasing reliance on energy sources that contribute to climate change. However, wind-turbine blades of up to 100 meters in length are typically manufactured using glass-fiber reinforced polymer (GFRP). While GFRP provides structural integrity, it is also comprised of thermoset resins, which is difficult to reform or recycle. Although wind turbines are maintained over their use life for effective operation, they are eventually retired based on durability and prediction models. Ramirez-Tejeda et al. (2017) estimates that by 2028, retired wind-turbine blades will comprise 330,000 tons/year of composite waste. Recycling of retired wind-turbine blades for their scrap material is challenging since GFRP can only be reformed through machining, which destroys reinforcing fibers and compromises the material's integrity.

For the above reasons, the current work explores the process of identifying possible repurposes or reuses for retired wind-turbine blades. In contrast to other cases of reuse, wind-turbine blades should not be reused in the same application, i.e., as wind-turbine blades nor aircraft components for safety reasons. While retired wind turbines have been repurposed as children's play structures and benches for public seating, such reuses alone will not likely fully absorb the supply of retired wind-turbine blades.

## II. BACKGROUND

This work combines design-related and social-psychology concepts to better understand and motivate designers. Thus, we begin with background on the seemingly disparate concepts before describing how they are incorporated in the current work.

### A. Functional Fixedness

Adamson (1952) described functional fixedness as a tendency to focus on an object's previously known function, which inhibits discovering appropriate new uses for this object. Related to design fixation, functional fixedness often leads designers to repeat the same set of solutions they identified, unable to see more creative solutions. Specific to the reuse of wind-turbine blades, individuals who are strongly affected by functional fixedness may have trouble identifying reuses other than as wind-turbine blades.

### B. SCAMPER

SCAMPER is an acronym that corresponds to: Substitute, Combine, Adapt, Modify, Put to other use, Eliminate, and Reverse. SCAMPER is often applied to make modifications in configuration design, but it also has potential to help identify reuses for products. That is, each word or phrase of the acronym can be applied to a product or part to trigger potential reuses. Moreno et al. (2016) observed SCAMPER's effectiveness in generating novel concepts, since reflecting on each corresponding word or phrase could provide novel insights.

### C. Regulatory Focus Theory (RFT)

A motivational framework developed by social psychologist Higgins (2000), Regulatory Focus Theory (RFT) has two independent self-regulatory orientations: prevention and promotion. This framework adds a dimension to the hedonistic model of approaching pleasure and avoiding pain. In RFT, a prevention-focused individual would approach safety and security (non-losses) and avoid losses. In contrast, a promotion-

focused individual would approach hopes and accomplishments (gains) and avoid stagnation (non-gains).

In a variety of applications over the past two decades, Higgins et al. have demonstrated that increased task engagement results when individuals' regulatory focus and task orientation align. Thus, appropriate framing of a design task may improve the engagement of designers with different regulatory foci.

#### D. Need for Closure (NFC)

Individuals in general have different needs when it comes to obtaining firm answers to questions. Webster and Kruglanski (1994) developed a scale, called Need for Closure (NFC) that aims to measure these needs for cognitive closure and aversion to ambiguity. This scale has the following five subscales and corresponding sample statements: (1) order and structure: I enjoy having a clear and structured mode of life; (2) ambiguity: I'd rather know bad news than stay in a state of uncertainty; (3) decisiveness: I usually make important decisions quickly and confidently; (4) predictability: I don't like to go into a situation without knowing what I can expect from it; (5) closed mindedness: I do not usually consult many different options before forming my own view. To such statements, respondents select from choices that range from strongly disagree to strongly agree, with each choice contributing to their NFC score.

#### E. Authors' Related Past Work

Lai and Shu (2016) found that individuals with high NFC scores are more likely to fixate on a provided example when asked to develop a new concept. Olteteanu and Shu (2018) also linked subscales of the NFC to functional fixedness.

Olteteanu and Shu (2018) presented objects in various orientations, i.e., turned 0, 90 and 180 degrees from a default orientation, and asked participants to identify alternative uses for the shown objects. Analysis of participant responses revealed that participants who were more receptive to reorientation cues were more likely to identify more, and more varied, uses for the objects. Thus, reorientation was shown to be an effective strategy to overcome functional fixedness in identifying alternative uses for everyday objects. These findings are consistent with those of Kudrowitz and Dippo (2013), whose Alternative-Uses-Test participants with more responses had more original responses.

Relating to the current study, wind-turbine blades are much larger than the everyday objects used in past AUT studies. In addition, people do not tend to interact with wind-turbine blades as they would with common everyday objects. Wind-turbine blades also rotate, i.e., change orientation during use, which may further reduce the effectiveness of using reorientation in the same way to decrease functional fixedness.

### III. METHODS

A series of studies were conducted to gain insight into the process of generating reuse concepts for wind-turbine blades. This paper focuses on the fourth and fifth iterations, but major changes between iterations are summarized below to clarify previously encountered obstacles and how they were addressed. These studies serve to demonstrate the challenge in developing reuse concepts for a sustainable-energy object, which currently has few sustainable end-of-life options.

#### A. Overview of Studies

In each iteration of the study, engineering students were asked to identify reuses for parts of wind-turbine blades. They were shown drawings of four wind-turbine blade sections in at least one isometric and three orthogonal views. For parts with hollow sections, an additional isometric view was provided to show the section cut in half. The wind-turbine blades were presented as sections, since they are often cut into smaller pieces after being decommissioned for easier transportation. To convey part size, the first three iterations of the study used male and female CAD models as human scales. Since no difference in concepts were observed as a result of the different gendered models, the scale was replaced with a neutral stick figure to facilitate the introduction of other interventions. Fig. 1 shows the isometric views of all four sections, using this neutral figure to convey scale. Fig. 2 shows how the first part was presented to participants.

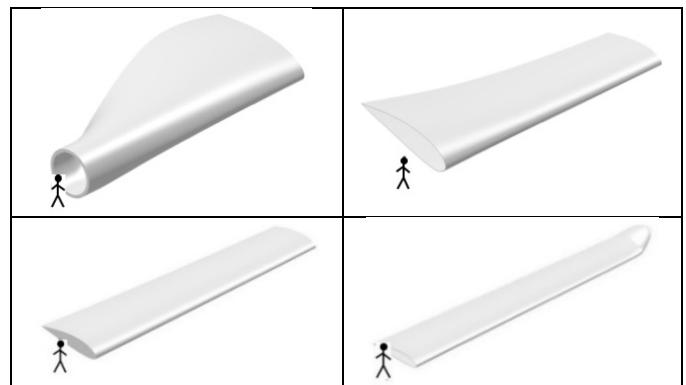

Figure 1. Isometric views of four wind-turbine blade sections.

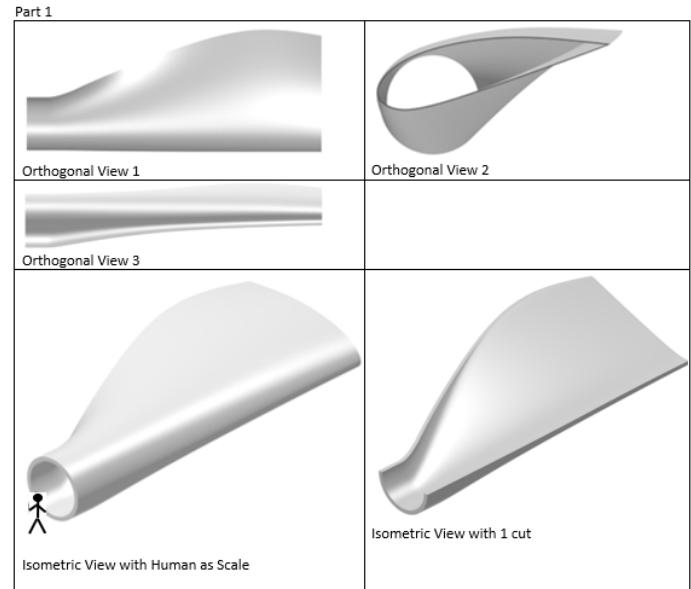

Figure 2. Different views of wind-turbine-blade Part 1.

#### B. Previous Iterations of Study

The first iteration of the study was conducted at Oldenburg University in Germany, in a graduate-level engineering course. To reduce functional fixedness, participants were not told that the parts were wind-turbine blades. For the same reason, they

were not specifically prohibited from identifying reuses as wind-turbine blades. However, many engineering-student participants recognized the air-foil cross-section (in parts 2 and 3), and thus identified reuses as wind-turbine or airplane parts. Since the parts could not be reused in wind turbines, much less airplanes for safety reasons, these reuses were not feasible.

Thus, the second iteration, conducted in an engineering course at Bremen University in Germany, revealed that the parts were wind-turbine blades, and prohibited their reuse as the same or as airplane components. Although this restriction succeeded in reducing these specific reuse applications, the resulting reuse concepts either already exist, e.g., as children's play structures, or were impractical, e.g., as giant industrial mixing paddles.

Personal communication with a life-cycle engineering expert (Hauschild, 2017) towards more promising reuses led to the additional constraint that concepts address climate change. As this constraint could be expressed in multiple ways, they were formulated in line with Higgins' promotion versus prevention foci. Thus, third-iteration participants were asked to develop concepts that either "Enable pro-environmental behaviors to decrease the rate of climate change" (promotion focused), or "Help people cope with the inevitable results of climate change" (prevention focused). While this additional constraint provided direction and focus for concept generation, third-iteration participants in a 4th year undergraduate design course at the University of Toronto were observed to struggle when developing concepts. Thus, subsequent iterations explored existing (SCAMPER) and new (perspective-taking) methods to support this concept-generation activity.

#### IV. ITERATION FOUR USING SCAMPER

The fourth iteration of the study was conducted at the Technische Universität Braunschweig in Germany.

##### A. Methods

Sixty-five (65) participants were recruited from a course on the basics of engineering design and product development, in a bachelor degree program. Of the 65, 29 were asked to use SCAMPER, and the remaining 36 comprised the control group. However, the participants were known to be unfamiliar with SCAMPER. Therefore, those who were asked to use SCAMPER were given a four-page instructional aid, demonstrating how it could be applied towards concepts that reuse plastic bottles. Viswanathan et al. (2016) showed that examples with familiar features caused more fixation. Thus, examples in plastic-bottle reuse were chosen as they were dissimilar to wind-turbine blades in both function and scale. Fig. 3 shows examples for SCAMPER's "adapt" (similar features). In the top example, the cylindrical portion of the bottle is adapted for use as cylindrical magazine holders. In the bottom example, threads on the mouth of the bottle are adapted to fit with threads on a garden hose.

As was the case for the third iteration, participants were asked to complete the Need for Closure (NFC) questionnaire, and to identify which of two climate-change related goals their concepts addressed. They were specifically asked to clarify how each of their concepts can be used to either decrease the rate of climate change, or cope with the results of climate change.

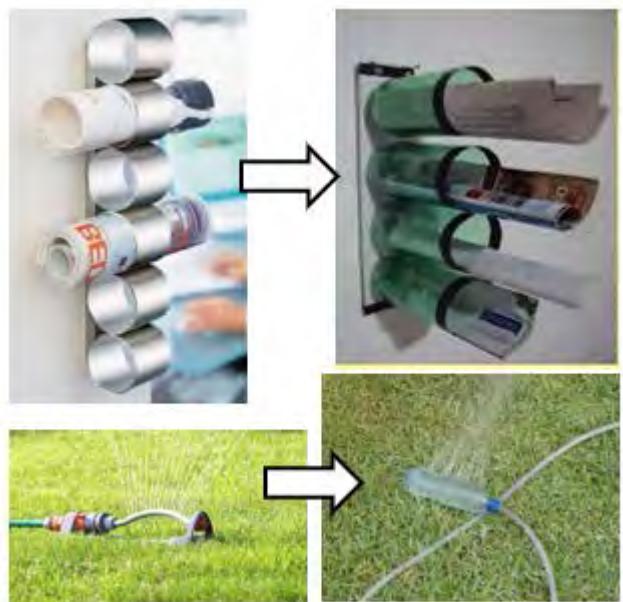

Figure 3. SCAMPER plastic-bottle reuse examples for Adapt (Top left image used with permission of APPlaceForEverything.co.uk; Bottom right image used under <https://creativecommons.org/licenses/by-nc-nd/2.0/>).

To reduce instances of inaccurate claims, participants were reminded that reusing the material alone, e.g., as art, count as neither preventing nor coping with climate change.

##### B. Results

Table 1 compares by condition the average number of concepts generated per participant (including those who did not generate any concepts), as well as per concept-generating participant. The SCAMPER intervention led to fewer concepts compared to the control condition for both groups of participants, but this difference is significant for neither.

TABLE 1. AVERAGE NUMBER OF CONCEPTS PER PARTICIPANT

	SCAMPER	Control	p
Concept-generating participants	2.54	2.95	0.12
All participants	1.14	1.64	0.10

Fig. 4 compares between conditions, the percentage of participants who generated concepts for none, to all four, of the four wind-turbine-blade parts. The first pair of bar graphs correspond to the number of participants who did not generate any concepts: 16/36 (44.4%) control and 16/29 (55.2%) SCAMPER participants. Combining the latter four bar graphs for the SCAMPER condition, 13 of 29 participants (44.8%) were able to generate reuse concepts for one or more of the four wind-turbine parts. In contrast, 20 of 36 (55.6%) control-condition participants generated concepts for one or more of the four parts. The 10.7% difference between conditions in the proportion of participants who were able to generate concepts for at least one part is insignificant ( $p=0.38$ ). Thus, the SCAMPER condition was not successful in increasing the proportion of participants who were able to generate at least one reuse concept, and in fact decreased the proportion.

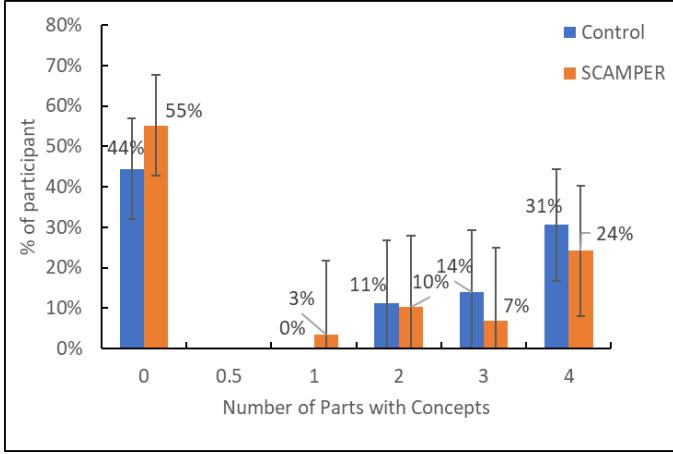

Figure 4. Proportion of participants who generated concepts for 0 to 4 of the four wind-turbine blade parts.

After removing the participants who produced zero concepts, Fig. 5 compares the proportion of participants who produced concepts for just one, up to all four of the parts. On average, each concept-generating participant in the control condition developed concepts for 3.35/4 parts, while SCAMPER-condition participants generated concepts for 3.15/4 parts, which is an insignificant difference.

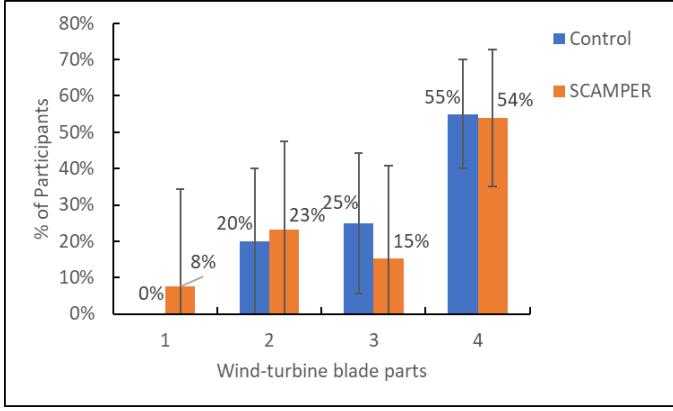

Figure 5. Proportion of concept-producing participants who generated concepts for just 1 up to all 4 of the four wind-turbine blade parts.

Fig. 6 compares the proportion of concepts generated for Parts 1 through 4 of the wind-turbine blade, which were always presented in the same order. As expected, more concepts are generally produced for the first versus last part presented, likely due to participant fatigue.

Table 1 compared by condition the average number of unique concepts generated per participant. However, participants often identified similar reuses for different wind-turbine parts, e.g., used both Parts 2 and 3 as fences. For concepts repeated by a participant, the one count for that same concept was allocated between the parts where the concept appears.

The SCAMPER method increased neither the number of concepts generated to reuse the wind-turbine blade parts, nor the proportion of participants who were able to generate concepts. However, the reuse concepts generated both with and without SCAMPER were categorized towards another possible method to support concept generation, as described in the next section.

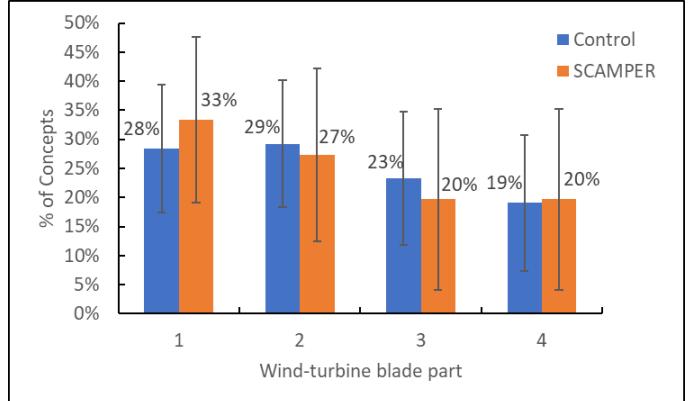

Figure 6. Proportion of concepts generated for wind-turbine-blade Parts 1-4.

## V. ITERATION FIVE USING PERSPECTIVE TAKING

Building on previous iterations, a fifth iteration was conducted at Technische Universität Braunschweig in Germany.

### A. Methods

Several approaches to categorizing the viable concepts from previous iterations were considered. One approach that emerged as promising for not just categorization, but also concept generation, involved perspective taking. This approach was then developed and tested in the current iteration on whether it can support participants to develop reuses for wind-turbine blades.

Participant responses in the fourth iteration also suggested a language barrier as non-English notes were found on the worksheets. To reduce this possible language barrier in the fifth iteration, the worksheets were translated to German.

#### 1) Participants

Two hundred and four (204) participants were recruited from a second-year machine-elements course in mechanical engineering at TU Braunschweig. Demographic information, e.g., gender, native language and program of study, were collected along with their concepts and NFC responses. Of the participants who generated concepts, 85% identified as male, 10% identified as female, and 5% did not select from these choices. With respect to language proficiency, 87% were native speakers of German. Since all participants had attended a German university for at least one year, they were assumed to be able to understand and follow all the instructions in German.

#### 2) Intervention: Perspective-Taking Method

In a way, the reorientation cue developed by Olteteanu and Shu (2018) for everyday objects was modified to support participants in developing reuses for much-larger wind-turbine parts. Rather than ask participants to reorient wind-turbine blade parts, they were asked to imagine the part on six different sides of them (above, below, front, back, left, right). In other words, participants were asked to mentally place the parts around themselves and view the parts from different perspectives. The perspective-taking intervention will also be referred to as the perspective method or condition below.

Fig. 7 shows how the perspective-taking intervention was conveyed graphically to participants, using “Teil”, the German

word for part, in a single-page aid. Compared to the four-page aid for SCAMPER in the fourth iteration, the perspective aid sheet is concise and requires minimal reading. The figures shown in Fig. 7 were revised multiple times to maximize neutrality and reduce suggestion of specific concepts.

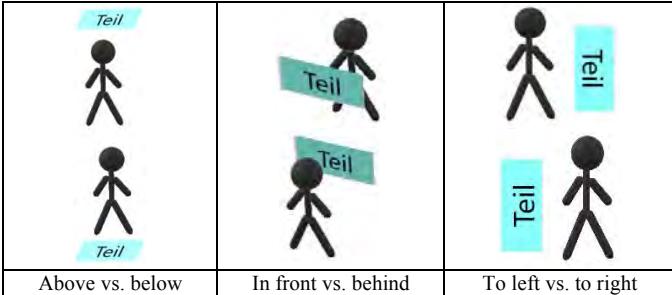

Figure 7. How the perspective-taking intervention was conveyed.

### 3) Instructions to Participants

The importance of wind-turbine-blade reuse was first conveyed through a presentation that highlighted the expected amount of waste generated from retired wind-turbine blades. Participants were then provided with worksheets that showed views of the four wind-turbine parts, with one part on each page. As in the two previous iterations, the worksheets asked participants to choose between and explain how their concepts either allow people to reduce the rate of climate change, or protect people from the effects of climate change.

Participants were asked to represent their concepts by simple sketches and minimize required cutting to the parts. They were also reminded that reusing the material alone counts towards neither preventing nor coping with climate change.

### 4) Distribution of Worksheets

Of the 204 participants, 98 were given the perspective-visualization method shown in Fig. 7 as the intervention, or perspective condition. The remaining 106 were not given the intervention and comprise the control group or condition. Worksheets with the two conditions were alternatively distributed to participants. That is, participants should have received a condition that is different from their immediate neighbors. Finally, worksheets were collected at the end of the 45-minute limit given for generating and explaining concepts.

## B. Results

To evaluate participants' concepts, their responses were first translated to English. The generated reuse concepts were then analyzed and classified. For concepts repeated by the same participant, the count for that same concept is allocated between the parts for which the concept appears, as demonstrated in Table 2. Table 3 compares by condition, the average number of unique concepts generated per participant by all participants (including those who did not generate any concepts), versus only the participants who generated at least one concept.

TABLE 2: EXAMPLE CONCEPT ALLOCATION TO WIND-TURBINE-BLADE PARTS

Part	Concepts	Points
Part 1	Roof for a house	1
Part 2	Wind barrier, ship's hull	1.5
Part 3	Wind barrier	0.5
Part 4	Dike reinforcement	1

TABLE 3: AVERAGE NUMBER OF CONCEPTS GENERATED PER PARTICIPANT

	Perspective	Control	p
Concept generating participants	2.81	3.10	0.29
All participants	1.91	1.55	0.043

Considering only the concept-generating participants, the perspective group produced fewer concepts compared to the control condition, although this difference is insignificant. This non-intuitive trend could be because participants who persisted (instead of abandoned) the control condition were intrinsically stronger designers, and thus able to generate more concepts.

What was significant, is that the perspective group produced more concepts compared to the control condition when averaged over all participants. That is, when including all participants, the perspective group has a 0.36 higher average number of concepts than the control group. This difference is significant with a 1-tailed t-test at  $p=0.043$ , supporting the hypothesis that perspective-taking helps participants to generate concepts.

Furthermore, in the perspective condition, 72 of 106 participants (67.9%) were able to generate reuse concepts for one or more of the four wind-turbine parts. In contrast, 49 of 98 (50.0%) control-condition participants generated concepts for one or more of the four parts. The 17.9% difference between the proportion of the two groups who were able to generate concepts for at least one part is significant ( $p=0.0095$ , 95% Confidence Interval: 4.40% to 30.6%). Thus, the perspective method was successful in increasing the proportion of engineering-student participants who were able to generate at least one reuse concept.

Fig. 8 compares by condition, the proportion of participants who generated concepts for zero up to four of the wind-turbine-blade parts. Consistent with the above results, a higher number of participants in the control condition returned worksheets with no concepts. However, when analyzing participants who did generate at least one concept, the gap between conditions reduces. Fig. 9 compares by condition the number of wind-turbine parts for which concept-generating participants identified reuses. On average, each concept-generating participant in the control condition identified reuses for 2.80/4 parts while perspective-condition participants identified reuses for 2.72/4 parts, an insignificant difference.

The difference between the average number of parts with concepts and the average number of unique concepts (Table 3) is due to a combination of repetition and multiple concepts per part. Participants would generate similar concepts for different wind-turbine parts, or multiple concepts per part.

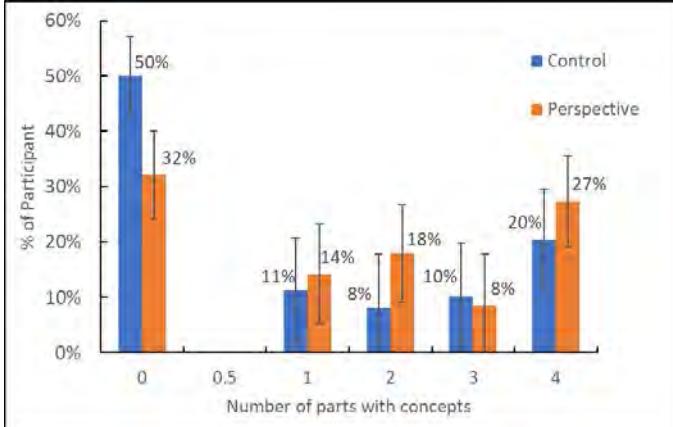

Figure 8. Proportion of participants who generated concepts for 0 to 4 of the four wind-turbine blade parts.

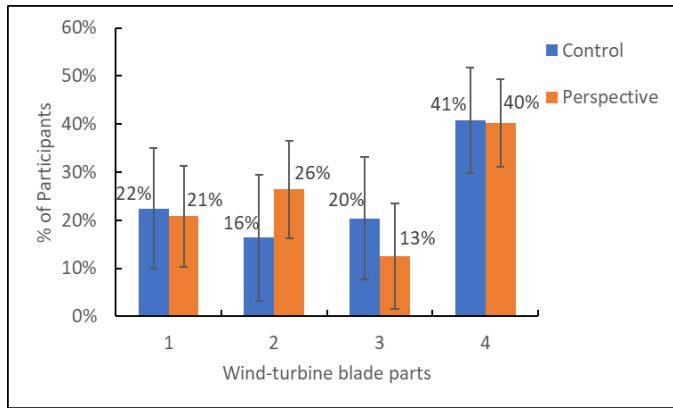

Figure 9. Proportion of concept-producing participants who generated concepts for just 1 to all 4 of the four wind-turbine-blade parts.

Similar to the previous (fourth) iteration, since participants went through worksheet pages ordered corresponding to wind-turbine-blade Parts 1 to 4, the number of concepts generated for each subsequent part decreased as shown in Fig. 10. This result is likely due to participant fatigue. Again, for concepts repeated by the same participant, the count for that same concept is allocated between the parts where the concept appears.

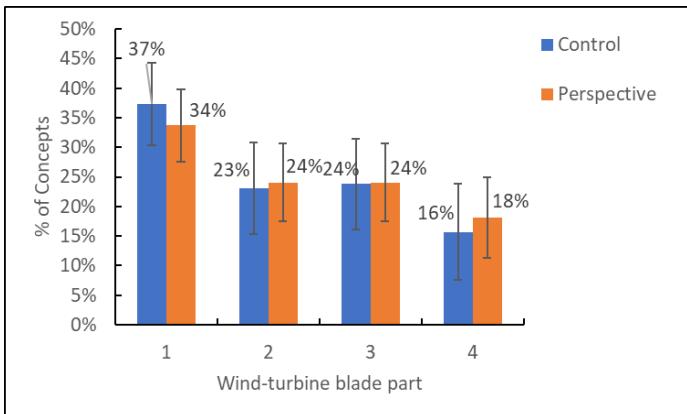

Figure 10. Proportion of concepts generated for wind-turbine-blade Parts 1-4.

## VI. DISCUSSION

### A. SCAMPER vs. Perspective-Taking Conditions

Comparing the SCAMPER group of the fourth iteration and the perspective-taking group of the fifth iteration yields a 23% difference in proportion of participants who produced no concepts ( $p=0.024$ , 95% Confidence Interval: 3.05% to 41.3%). This significant difference suggests the benefit of the perspective-taking method by comparing it against an existing method as an intervention. Furthermore, the corresponding proportions for the control condition in the fourth iteration that used SCAMPER was 44%, versus 50% for the control condition in the fifth iteration that used the perspective-taking method. The difference of only 6% in the control-group participants between iterations of the study that used different interventions is insignificant ( $p=0.54$ ). Fig. 11 shows the proportion of participants who produced no concepts for both conditions of the fourth and fifth iterations of the study.

Limitations of this comparison include the following. While both the SCAMPER and perspective-taking iterations were performed at TU Braunschweig's mechanical engineering department, participants were from different classes and years of study. Moreover, the SCAMPER materials were provided in English vs. German for the perspective-taking materials. Finally, the length of the 4-page SCAMPER aid sheets was considerably longer than the 1-page perspective-taking aid sheet.

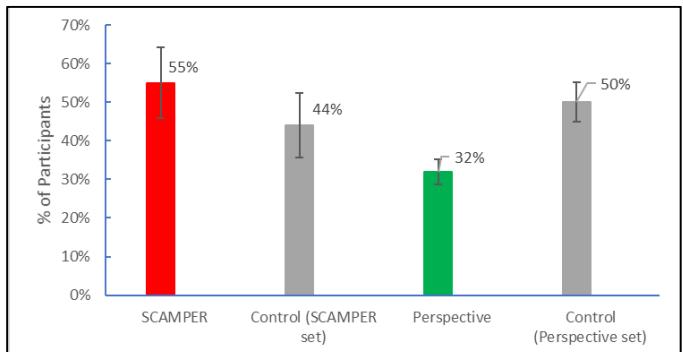

Figure 11. Proportion of participants who produced no concepts in fourth iteration using SCAMPER and fifth iteration using perspective-taking.

### B. Regulatory Focus Theory and Need for Closure

As previously mentioned, participants were asked to develop concepts that either 1) Allow people to reduce the rate of climate change, or 2) Protect people from the effects of climate change.

The first choice corresponds to the promotion focus of Regulatory Focus Theory (RFT) by approaching hopes and gains, e.g., improvement of the environment. The second choice corresponds to the prevention focus of RFT, which is about preventing losses, e.g., protecting people.

Common promotion-focused concepts included: turbines for hydroelectric power stations; artificial coral reefs; and solar panel mounts. Concepts generated under the prevention-focus (protect people) category included: flood and wind barriers; dike reinforcement or erosion protection; sun covering; and emergency shelters.

In the perspective condition of the fifth iteration, 65 (of 106) participants completed the Need for Closure (NFC)

questionnaire. Linear regression yielded a negative relationship between the ambiguity subscale of NFC and the proportion of promotion-focused concepts. That is, the higher a participant's desire to avoid ambiguity, the fewer promotion-focused concepts they produced as a proportion of all the concepts they generated. Shown in Table 4, a medium negative correlation ( $r = -0.31$ ) was found between participants' ambiguity subscale and their tendency to produce promotion-based concepts. This finding is related to the work of Toh and Miller (2014), who found that creativity is affected by varying tolerance levels for ambiguity.

TABLE 4: REGRESSION RESULTS FOR PERSPECTIVE-CONDITION PARTICIPANTS' NFC AMBIGUITY SUBSCALE AND PROPORTION OF PROMOTION-FOCUSED CONCEPTS

Coefficients	Estimate	95% Confidence Interval	p
Intercept	1.38	0.633 to 2.13	0.0005
Ambiguity	-0.0237	-0.0431 to -0.00424	0.018

$F = 5.96$ ,  $R^2 = 0.0961$ ,  $r = -0.31$

This same trend was not seen in the control condition of the fifth iteration. Instead, the proportion of promotion-based concepts correlated with the decisiveness subscale of the NFC. That is, the more decisive the participant, the more promotion-focused concepts they generated. Analysis of the 46 participants with complete NFC scores yielded a medium positive correlation between their decisiveness subscale and the proportion of promotion-based concepts they generated, as shown in Table 5.

TABLE 5: REGRESSION RESULTS FOR CONTROL-CONDITION PARTICIPANTS' NFC DECISIVENESS SUBSCALE AND PROPORTION OF PROMOTION-FOCUSED CONCEPTS

Coefficients	Estimate	95% Confidence Interval	p
Intercept	-0.336	-1.133 to 0.463	0.40
Decisiveness	0.0284	-0.0004 to -0.0572	0.053

$F = 4.84$ ,  $R^2 = 0.131$ ,  $r = 0.36$

Overall, only 75 of 204 (48 perspective- and 27 control-condition) participants explicitly identified whether their concepts aimed to achieve promotion-focused versus prevention-focused goals. Some uncategorized concepts were analyzed and added to the two categories. Overall, the control group generated 42 prevention-based concepts and 25 promotion-based concepts, and the perspective group generated 65 prevention-based concepts and 67 promotion-based concepts. Therefore, the perspective condition appeared to help balance the categories.

### C. Effects of Conditions on Shredding Concepts

While participants were discouraged from making excessive cuts to wind-turbine blade parts, some participants suggested incineration or shredding the parts for use as insulation.

In the fifth iteration, 2% of the perspective-taking participants generated concepts which required shredding compared to 7% in the control condition. This 5% decrease ( $p =$

0.011) suggests that the perspective-taking method encouraged reuses that utilize the overall shape of the part, by asking participants to imagine the parts around them.

In the fourth iteration using the SCAMPER intervention, too few (3) concepts that involve shredding were observed over both conditions combined; therefore, no conclusions can be drawn.

### D. Prevention-Based vs. Promotion-Based Example Reuses

Using wind-turbine-blade parts in shelter construction is a common participant-generated concept. Fig. 12 shows a bus-shelter concept generated by a participant in the perspective-taking group. The participant selected the box indicating that this concept is for protecting people from climate change, i.e., the prevention-focus choice. In the perspective-taking condition, 27 of 76 (35.5%) concept-generating participants produced ideas involving shelter or roofing. In the control condition, 16 of 49 (32.6%) participants produced similar concepts.

Fig. 13 presents a unique (control-condition) participant's concept of a vertical planter for plants to absorb carbon dioxide. The participant selected the box indicating that this concept is for enabling people to reduce the rate of climate change, i.e., the promotion-focus choice.

## VII. SUMMARY AND FUTURE WORK

Five iterations of a study asked engineering-student participants to generate reuse concepts for wind-turbine blades. With focus on the fourth and fifth iterations, this paper examined the effect of different methods to support this challenging concept-generation activity.

To reduce functional fixedness, the first iteration did not reveal that the parts shown were wind-turbine blades, nor were participants specifically prohibited from identifying reuses as wind-turbine blades. However, many participants identified reuses as wind-turbine blades or airplane parts, which are excluded for safety reasons. Thus, the second iteration revealed that the parts were wind-turbine blades, and prohibited their reuse in the same or airplane applications. While this restriction reduced these specific reuse applications, the resulting reuse concepts either already exist or were impractical. Kwon et al. (2018) report in more detail the first two iterations.

To help guide possible concepts, third-iteration participants were asked to develop concepts to address climate change. While this additional constraint provided direction and focus for concept generation, participants were observed to struggle to develop solutions. Thus, subsequent iterations explored methods to support this concept-generation activity.

The fourth iteration used SCAMPER, an existing method, to support engineering-student designers in concept generation. However, SCAMPER did not appear to aid in reuse-concept generation. Thus, the perspective-taking method was developed for the fifth iteration. This method was observed to reduce the number of participants who produced no concepts, but did not affect the number of parts for which concepts were generated, nor the number of concepts generated by participants who persisted in the study. However, participants were not specifically encouraged to maximize the number of concepts they generated.

While participants were asked to generate reuse concepts to address climate change, they were not given guidance to increase the environmental benefits of their concepts. Therefore, future work could also incorporate aspects to guide concepts towards those that maximize environmental benefits. Metrics to evaluate how well reuse concepts contribute to sustainability include manufacturing cost, waste management, and energy consumption (Jawahir & Dillon, 2007).

This work aims to gain insights on the process of finding potential alternative uses of wind-turbine blades, which currently lack sustainable end-of-life solutions. The lack of sustainable post-use opportunities is recognized as a major impact area in sustainable manufacturing (Haapala et al., 2013). While attention to recycling and remanufacturing contributes to environmentally conscious product design, end-of-life options for already-designed and installed wind-turbine blades are required. Typical product end-of-life options include: direct reuse, repair, remanufacturing, recycling, and disposal (Ramani et al., 2010; Ilgin & Gupta, 2010), with Sabbaghi & Behdad (2018) noting that repair decisions are highly price dependent. Missing from these options is the opportunity to design for alternative uses of products at end-of-life. The role of product design in sustainable manufacturing has long focused on designing for the environment (Allen et al., 2002). In the case of closing the loop for wind-turbine blades, product design methods could also be leveraged towards alternative reuses of these parts, in the absence of other viable end-of-life solutions.

## ACKNOWLEDGMENTS

The authors thank: Drs. Alexandra Pehlken (Oldenburg Univ.) and Klaus-Dieter Thoben (Bremen Univ.); Elisa Kwon (Univ. of Toronto); Study participants and colleagues at TU Braunschweig; Prof. Gernot von Collani (Univ. of Leipzig) for his German translation of NFC questionnaires.

**Abstract** - Cellular materials are found extensively in nature such as wood, honeycomb, butterfly wings and foam-like structures like trabecular bone and sponge. This class of materials proves to be structurally-efficient by combining low weight with superior mechanical properties. Recent studies have shown there are coupling relations between the mechanical properties of cellular materials and their relative density. Due to its favorable stretching-dominated behavior, continuum models of the octet-truss were developed to describe its effective mechanical properties. However, previous studies were only performed for the cubic symmetry case where the lattice angle  $\theta = 45^\circ$ . In this work, we study the impact of the lattice angle on the effective strength of the octet-truss. A graphical method is utilized to plot the collapse surfaces for plastic yielding and elastic buckling for different loading combinations at different lattice angles. Generally, the  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  loading space is preferable for lattice angles greater than  $45^\circ$ , while the  $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$  loading space is preferable for lattice angles lower than  $45^\circ$ .

**Keywords** - octet-truss; collapse surfaces; lattice angle; effective strength

## I. INTRODUCTION

In the last few decades there has been a growing interest in lightweight load-bearing structures. Inspiration from nature can be found in natural cellular materials like wood, honeycomb, butterfly wings, and foam-like structures such as trabecular bones and sponge [1]. Architectural cellular materials have been used to create mechanically-efficient engineering structures such as the Eiffel Tower and the Garabit Viaduct [2]. This class of materials combines the benefits of low density as it only occupies a fraction of the monolithic bulk solid, and strength by arranging its elements efficiently to carry the loads. Previous studies have shown that the macroscopic mechanical properties of cellular materials depend on three parameters: the constituent material properties, the deformation mechanism, and the relative density  $\bar{\rho}$  (defined as the solid volume within the unit cell divided by the total volume of the unit cell). Cellular-solids theory predicts scaling relationships between the macroscopic stiffness and strength vs. the relative density, namely  $E_s \propto \bar{\rho}^m$  and  $\sigma_y \propto \bar{\rho}^n$  respectively, where the dimensionless parameters  $m$  and  $n$  depend on the unit cell geometry [3].

For a 3D structure to be rigid (i.e. statically and kinematically determinate), a minimum nodal connectivity of  $Z = 6$  is required. A connectivity of  $Z = 12$  categorizes the structure as stretching-dominated where the lattice members deform by tension/compression. Bending-dominated structures that deform through the bending of their members, has a connectivity of  $6 \leq Z < 12$  [4], [5]. For stretching-dominated structures such as the octet-truss lattice, these scaling relationships are linear. On the other hand, for bending-dominated structures such as honeycombs or the octahedral lattice, they are quadratic or stronger [6], [7].

When the dimensions of the lattice members are scaled down below the micron length scale, they exhibit different mechanical behavior. Examples of these size-dependent changes include strengthening in single crystalline metals and transition from brittle to ductile behavior in metallic glasses and ceramics [8], [9]. Recent advances in additive manufacturing techniques have made it possible to manufacture lattice structures with more geometrical and dimensional freedom. Certain AM techniques like self-propagating photopolymer waveguides [10], projection micro stereolithography [1], and two-photon lithography [11], [12] have been utilized to produce micro and nanolattices within the length scales required to activate material size effects. This is in addition to the structural effects activated by changing the various geometric parameters of the lattice unit cell [13].

Continuum constitutive models have been developed to describe the effective mechanical properties of the octet-truss lattice structure. A common assumption amongst these models is that the lattice members are pin-jointed at all nodes, hence the contribution from the bending resistance of the members and nodes is negligible compared to the axial tensile/compressive stiffness of the members [14]. Deshpande et al. (2001) checked the accuracy of the pin-jointed assumption by comparing FE calculations of rigid-jointed structures against analytical values of pin-jointed models for relative densities  $\bar{\rho}$  ranging 0.01 to 0.5, the results showed excellent agreement between the FE and analytical values proving the validity of this assumption [4]. Generally, symmetry considerations could be employed to deduce the number of independent constants in the macroscopic stiffness tensor. Following the pin-jointed assumption, these elastic constants are determined by averaging the contribution from each element to the macroscopic stiffness, which is achieved through 3D coordinate transformations [15], [16].

Nayfeh and Hefzy (1978) derived a first order approximation of the relative density of the octet-truss lattice by dividing the solid volume within the unit cell by the total volume of the unit cell [15]. They employed 3D coordinate transformation and volume averaging in order to obtain the macroscopic stiffness matrix. Lake (1992) constructed a strength tensor by converting applied stresses to strains for each parallel group of members using the macroscopic compliance matrix [17]. Failure would occur in a member if its axial strain exceeded a critical value based on an elastic buckling limit. The choice of elastic buckling over plastic yielding is somehow justified given that space structures, the typical application of lattice structures at that time, usually compose of slender members. Lake's strength tensor could easily accommodate multiaxial loading as well as different loading directions through coordinate transformation. The author also developed a 3D plot of the uniaxial compression strength in cartesian coordinates, from which he concluded the direction and value of the maximum strength of the octet-truss lattice for the case of cubic symmetry where the lattice angle  $\theta$  equals  $45^\circ$  (the angle between the individual members and the horizontal midplane as shown in Fig. 1). Deshpande et al. (2001) investigated the effective properties of the octet-truss lattice structure both theoretically and experimentally [4]. They validated the analytically-predicted elastic modulus and strength using FEM and experimental uniaxial compression of octet-truss lattice made from a casting aluminum alloy. They also explored the collapse criteria of two competing mechanisms (plastic yielding and elastic Euler buckling) and plotted the collapse surfaces for these two mechanisms under different loading conditions. The macroscopic collapse stress was evaluated by equating the external work for the kinematically admissible modes of collapse to: (i) the plastic dissipation in stretching the struts for the case of plastic yielding, (ii) and the internal work in buckling the struts for the case of elastic buckling. In addition, they proposed a third-order approximate formula for the relative density that includes a parameter dependent on the nodes' detailed geometry.

It is important to note that the previous studies were performed only for the case of cubic symmetry. At this angle, the octet-truss is considered to be at the highest attainable level of symmetry. However, potential applications of metamaterials (e.g. thin-walled pressure vessels) necessitates the use of anisotropic lattice structures in order to achieve the optimal combination of low density and high load-carrying capacity.

## II. EFFECTIVE STRENGTH

The macroscopic strength of the octet-truss lattice is defined as the maximum stress the lattice can sustain without any of its members reaching a critical stress limit. This limit can be defined according to two main modes of failure: (i) yielding for ductile materials or fracture for brittle materials (tensile or compressive), (ii) and Euler beam buckling (compressive). An additional mode of failure for hollow-tube lattices is the shell buckling (compressive). Dominance of either one of these types depends on the loading conditions and the geometry of the lattice members, namely their aspect ratio and cross-section [18].

In order to relate the effective strength of the octet-truss lattice to the local strength of its individual members, the effective macroscopic strains are transformed from the global

coordinates to the local member coordinates as follows:

$$\varepsilon^{(k)} = N_{ij}^{(k)} \bar{\varepsilon}_{ij} = n_i^{(k)} n_j^{(k)} \bar{\varepsilon}_{ij} \quad (1)$$

where  $\varepsilon^{(k)}$  is the axial strain in the  $k^{th}$  member,  $N_{ij}^{(k)}$  is a linear transformation operator that can be reduced to the product of the  $k^{th}$  member's direction cosines  $n_i^{(k)}$  and  $n_j^{(k)}$ , and  $\bar{\varepsilon}_{ij}$  is the macroscopic strain, which can be related to a general stress tensor  $[\bar{\sigma}''']$  applied through a general direction defined by the angles  $\varphi$  and  $\alpha$  as shown in Fig. 1 through the following relation:

$$\{\bar{\varepsilon}_{ij}\} = [S] [T_1] [T_3] \{\bar{\sigma}'''\} \quad (2)$$

where  $[S]$  is the macroscopic compliance matrix,  $[T_1]$  and  $[T_3]$  are the first and second strain transformation matrices respectively. The reader is referred to [19], [20] for details on the coordinate transformations. By considering the tetrahedron substructure selected as the structural basis in the continuum-based modelling of the octet-truss, the stress in its six members can be expressed as follows:

$$\sigma^{(k)} = E_s n_i^{(k)} n_j^{(k)} [S] [T_1] [T_3] \{\bar{\sigma}'''\} \quad (3)$$

where  $i = 1, 2, 3$ ,  $j = 1, 2, 3$ , and  $k = 1, 2, \dots, 6$ .

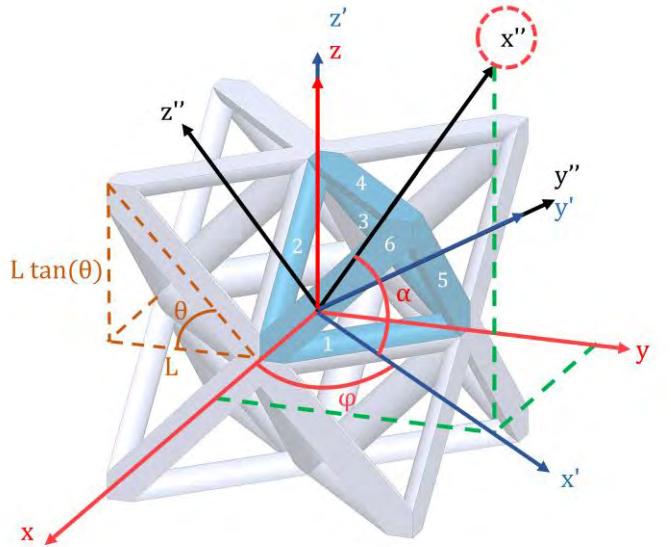

Figure 1. The octet-truss unit cell with the tetrahedron substructure geometry (shown in blue) and the transformation coordinate systems (numbers shown in white identify the six tetrahedron truss members).

## III. COLLAPSE SURFACES

The collapse surfaces of the octet-truss lattice due to plastic yielding and elastic buckling are calculated for two combinations of loading, namely  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  and  $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$  for different lattice angles. The tetrahedron substructure is used in the analysis in both cases, along with the pin-jointed assumption employed in the continuum-based modelling of the octet-truss. The collapse surface for each combination of loading can be

categorized into a number of modes depending on the governing collapse equation and which members would reach the stress limit (i.e. buckling or yielding) with reference to Fig. 1. Unlike the analytical methods used by Deshpande et. al (2001) [4], we utilized a graphical method to plot the collapse surfaces. Collapse lines are plotted according to the collapse criteria of each of the six tetrahedron members, the inner-most area is then isolated, and the surrounding collapse lines are used to plot the collapse surface. Hence, fundamentally each of the following governing equation is the collapse criteria of one (or more) of the six tetrahedron members.

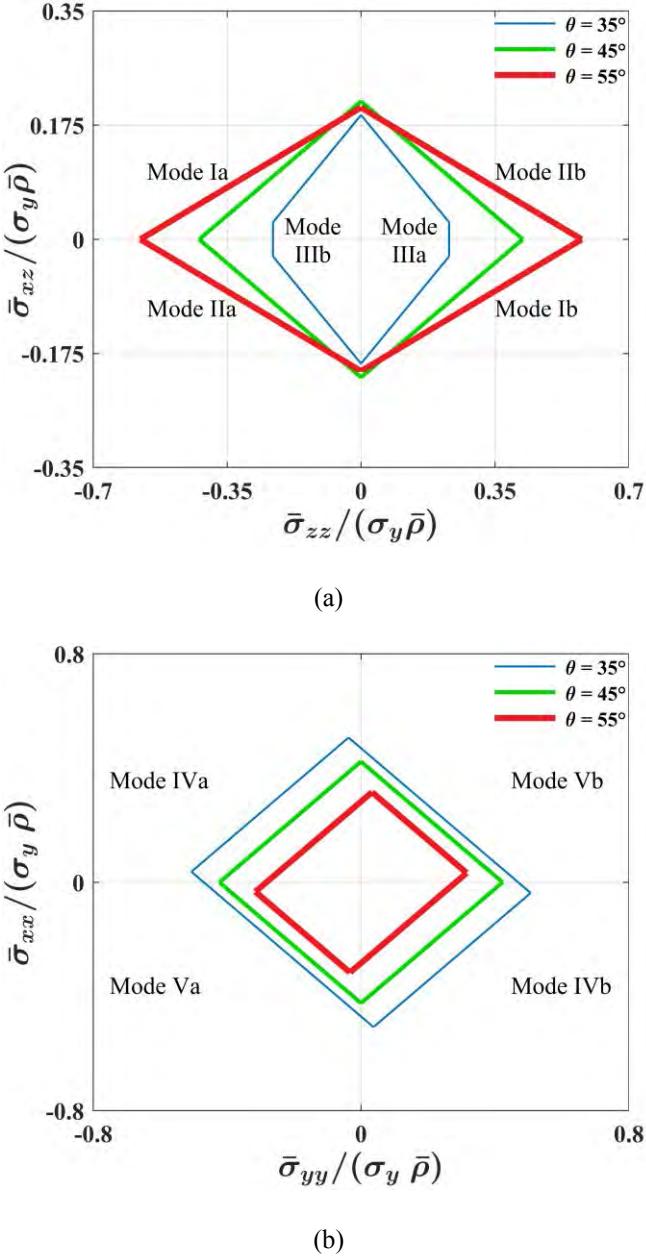

Figure 2. Collapse surface of the octet-truss due to plastic yielding in  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  space (top) and  $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$  space (bottom) in specific strength formulation at an aspect ratio of  $r/L = 0.14$ .

#### A. $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$ space due to plastic yielding

The collapse surface under the applied loads  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  for three different lattice angles is shown in Fig. 2a using the specific formulation  $\bar{\sigma}/(\sigma_y \bar{\rho})$ .

In Modes *Ia* and *Ib*, member no. 2 has reached the yield stress  $\sigma_y$  (under compression in Mode *Ia* and tension in Mode *Ib*). The governing equations are as follows:

$$\text{Mode } Ia: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{\bar{\sigma}_{zz}}{2 \tan(\theta) \sigma_y} + \cos(\theta) \frac{A_c}{L^2} \quad (4)$$

$$\text{Mode } Ib: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{\bar{\sigma}_{zz}}{2 \tan(\theta) \sigma_y} - \cos(\theta) \frac{A_c}{L^2} \quad (5)$$

As for Modes *IIa* and *IIb*, member no. 5 has reached the yield stress  $\sigma_y$  (under compression in Mode *IIa* and tension in Mode *IIb*). The governing equations are as follows:

$$\text{Mode } IIa: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{-\bar{\sigma}_{zz}}{2 \tan(\theta) \sigma_y} - \cos(\theta) \frac{A_c}{L^2} \quad (6)$$

$$\text{Mode } IIb: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{-\bar{\sigma}_{zz}}{2 \tan(\theta) \sigma_y} + \cos(\theta) \frac{A_c}{L^2} \quad (7)$$

For lattice angles  $\theta < 45^\circ$ , there exists two additional Modes, *IIIa* and *IIIb*, where members no. 1 & 4 have reached the yield stress  $\sigma_y$  (under compression in Mode *IIIa* and tension in Mode *IIIb*). The governing equations are as follows:

$$\text{Mode } IIIa: \frac{\bar{\sigma}_{zz}}{\sigma_y} = +\sqrt{2} \tan(\theta) \frac{A_c}{L^2} \quad (8)$$

$$\text{Mode } IIIb: \frac{\bar{\sigma}_{zz}}{\sigma_y} = -\sqrt{2} \tan(\theta) \frac{A_c}{L^2} \quad (9)$$

#### B. $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$ space due to plastic yielding

The collapse surface under the applied loads  $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$  for three different lattice angles is shown in Fig. 2b using the specific formulation  $\bar{\sigma}/(\sigma_y \bar{\rho})$ .

In Modes *IVa* and *IVb*, members no. 2, 3, 5 & 6 have reached the yield stress  $\sigma_y$  (albeit 2 & 5 are under tension and 3 & 6 are under compression in Mode *IVa* and the opposite in Mode *IVb*). The governing equations are as follows:

$$\text{Mode } IVa: \frac{\bar{\sigma}_{xx}}{\sigma_y} = \frac{\bar{\sigma}_{yy}}{\sigma_y} - \frac{2 \cos(\theta) A_c}{\tan(\theta) L^2} \quad (10)$$

$$\text{Mode } IVb: \frac{\bar{\sigma}_{xx}}{\sigma_y} = \frac{\bar{\sigma}_{yy}}{\sigma_y} + \frac{2 \cos(\theta) A_c}{\tan(\theta) L^2} \quad (11)$$

As for Modes *Va* and *Vb*, members no. 1 & 4 have reached the yield stress  $\sigma_y$  (under compression in Mode *Va* and under tension in Mode *Vb*). The governing equations are as follows:

$$\text{Mode } Va: \frac{\bar{\sigma}_{xx}}{\sigma_y} = \frac{-\bar{\sigma}_{yy}}{\sigma_y} - \frac{\sqrt{2} A_c}{\tan(\theta) L^2} \quad (12)$$

$$\text{Mode } Vb: \frac{\bar{\sigma}_{xx}}{\sigma_y} = \frac{-\bar{\sigma}_{yy}}{\sigma_y} + \frac{\sqrt{2} A_c}{\tan(\theta) L^2} \quad (13)$$

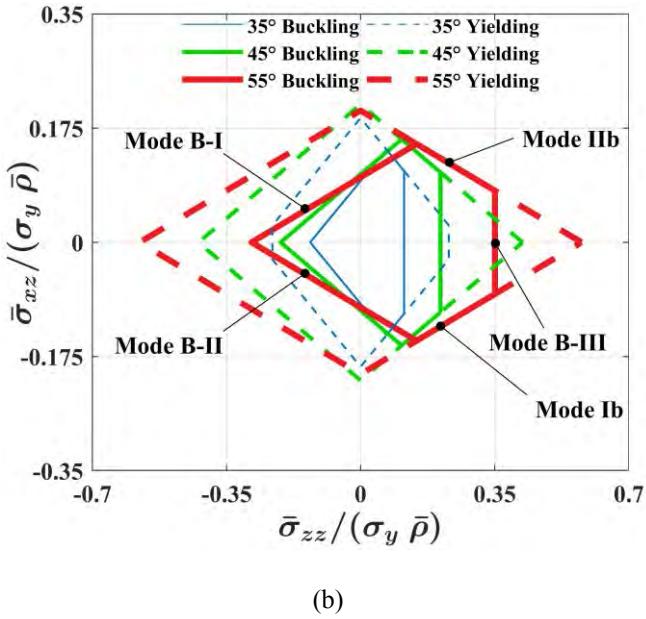

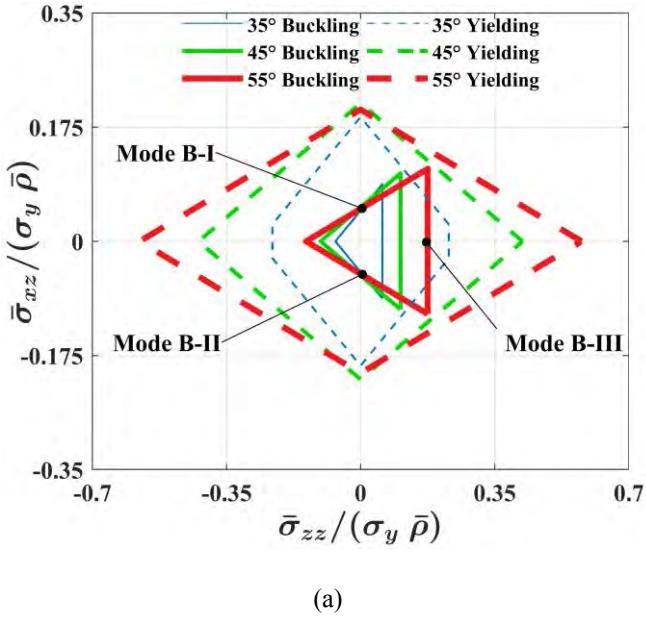

Figure 3. Collapse surface of the octet-truss due to elastic buckling in  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  space at an aspect ratio of  $r/L = 0.14$  and a yield strain of  $\epsilon_y = 0.1$  (top) and  $\epsilon_y = 0.05$  (bottom).

### C. $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$ space due to elastic buckling

The collapse surface under the applied loads  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  for three different lattice angles is shown in Fig. 3 using the specific

formulation  $\bar{\sigma}/(\sigma_y \bar{\rho})$ . A yield strain has to be used in order to show both elastic buckling and plastic yielding collapse lines in the same plot. Yield strains of  $\epsilon_y = 0.1$  and  $0.05$  are utilized in Fig. 3a and 3b respectively. It can be seen that the yield strain value has no effect on the yielding collapse lines.

In Mode  $B - I$ , member no. 2 has reached its elastic buckling limit. As for Mode  $B - II$ , member no. 5 has reached its elastic buckling limit. In Mode  $B - III$ , members no. 1 & 4 have reached their elastic buckling limit. The governing equations are as follows:

$$\text{Mode } B - I: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{+\bar{\sigma}_{zz}}{2\sigma_y \tan(\theta)} + \frac{\pi A_c^2 \cos(\theta)}{8\epsilon_y L^4} \quad (14)$$

$$\text{Mode } B - II: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{-\bar{\sigma}_{zz}}{2\sigma_y \tan(\theta)} - \frac{\pi A_c^2 \cos(\theta)}{8\epsilon_y L^4} \quad (15)$$

$$\text{Mode } B - III: \frac{\bar{\sigma}_{zz}}{\sigma_y} = \frac{\pi A_c^2 \tan(\theta)}{4\sqrt{2}\epsilon_y L^4} \quad (16)$$

### D. $(\bar{\sigma}_{xz}, \bar{\sigma}_{yy})$ space due to elastic buckling

The collapse surface under the applied loads  $(\bar{\sigma}_{xz}, \bar{\sigma}_{yy})$  for three different lattice angles is shown in Fig. 4 using the specific formulation  $\bar{\sigma}/(\sigma_y \bar{\rho})$ . Similar to Fig. 3, a yield strain of  $\epsilon_y = 0.1$  and  $0.05$  are utilized in Fig. 4a and 4b respectively.

In Mode  $B - IV$ , members no. 2 & 5 have reached their elastic buckling limit. As for Mode  $B - V$ , member no. 3 & 6 have reached their elastic buckling limit. In Mode  $B - VI$ , members no. 1 & 4 have reached their elastic buckling limit. The governing equations are as follows:

$$\text{Mode } B - IV: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{+\bar{\sigma}_{yy}}{\sigma_y} - \frac{\pi A_c^2 \cos(\theta)}{4L^4 \epsilon_y \tan(\theta)} \quad (17)$$

$$\text{Mode } B - V: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{+\bar{\sigma}_{yy}}{\sigma_y} + \frac{\pi A_c^2 \cos(\theta)}{4L^4 \epsilon_y \tan(\theta)} \quad (18)$$

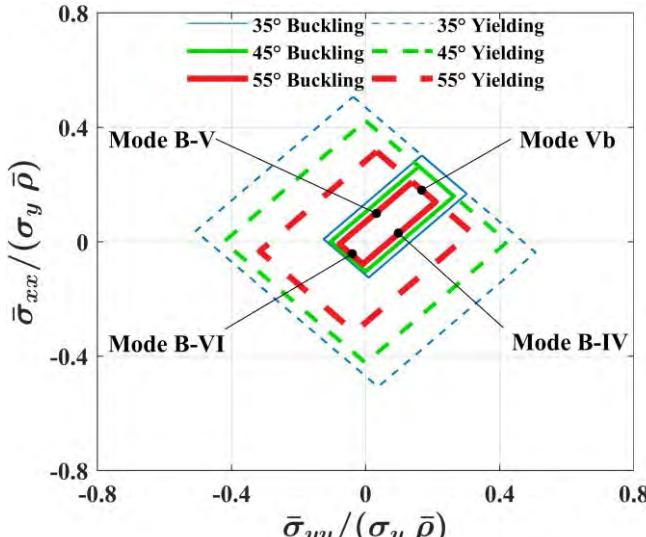

$$\text{Mode } B - VI: \frac{\bar{\sigma}_{xz}}{\sigma_y} = \frac{-\bar{\sigma}_{yy}}{\sigma_y} - \frac{\pi A_c^2}{4\sqrt{2}L^4 \epsilon_y \tan(\theta)} \quad (19)$$

Upon comparison, the collapse surfaces at the lattice angle of  $\theta = 45^\circ$  under the two loading combinations of  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  and  $(\bar{\sigma}_{xz}, \bar{\sigma}_{yy})$  for both plastic yielding and elastic buckling clearly agree with those developed by Deshpande et al. (2001) [4].

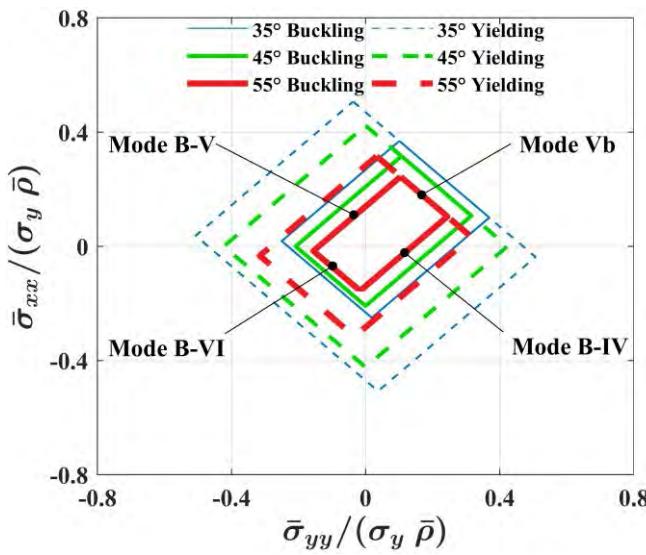

## IV. CONCLUSIONS

The purpose of the present research is to investigate the effect of the lattice angle on the effective strength of the octet-truss lattice structure. A graphical method is utilized to plot the collapse surfaces for plastic yielding and plastic buckling for different loading conditions and different lattice angles. Generally, the  $(\bar{\sigma}_{xz}, \bar{\sigma}_{zz})$  loading space is preferable for lattice

angles greater than  $45^\circ$ , while the  $(\bar{\sigma}_{xx}, \bar{\sigma}_{yy})$  loading space is preferable for lattice angles lower than  $45^\circ$ .

**Abstract**—This paper presents a manufacturing process for extrusion assisted foam production with a physical blowing agent (PBA) for Rapid Rotational Foam Molding. A completely new experimental setup was designed to identify, conceive, establish, and develop, the necessary processing concepts and conditions for fabricating a new class of rotationally molded integral-skin cellular composite having low-density foamed core. The new design incorporates a helical static mixer that can operate at 31 MPa in 200°C environment. Supercritical CO<sub>2</sub> will be injected into the pressurized static mixer to thoroughly disassociate into the polymer melt to create a single-phase solution. The process temperature is maintained by PID controlled band heaters and an integral liquid cooling jacket. The system can facilitate rapid pressure drop as high as 30 MPa to produce polyolefin foam.

**Keywords:** *helical; static mixer; RRFM; PBA; Polyolefin; supercritical fluid; QFD; carbon dioxide*

## I. INTRODUCTION

Rotational molding technology has been in use for the last few decades to produce light weight structural foam composites with a distinct foamed core encapsulated by an unfoamed outer skin. This type of roto-molded articles are in high demand in the automotive, construction and marine industries for their enhanced strength-to-weight ratio [1, 2]. However, the manufacturing process associated with rotational molding is lengthy and highly energy intensive. In recent years a newly patented rotational foam molding process, referred to as Rapid Rotational Foam Molding (RRFM) was developed to reduce the lengthy production time and to improve the overall quality of the foamed composites [3, 4].

The RRFM technology by design produces the outer skin independent from the foaming process. This novel processing concept takes advantage of an extruder to produce the polymer foam, which is directly injected inside the hot mold cavity containing the soft outer skin. The foamed core encapsulated by the outer skin is gradually cooled to room temperature before extracting the final part from the mold. Through greater control over the manufacturing process, RRFM technology has reduced the cycle time and energy consumption compared with traditional rotational foam molding process [3].

In the current art, RRFM process is open to further improvement. The technology can be modified in two areas, rotational molding process, or the foam extrusion process.

However, the foam extrusion process shows greater potential for improvement. Currently the polymer foam is created using chemical blowing agents (CBA). The foamable resin is mixed in with the CBA before introducing the mixture into the extruder. In the extruder the CBA activates to produce the polymer foam. An alternative approach to this process is to produce the foam using a physical blowing agent (PBA). Polymer foaming with a PBA for rotational foam molding has never been attempted. Plastic foam produced with PBA have higher cell density which can further improve the strength-to-weight ratio [5]. Therefore, it is the next logical step in development to replace CBA with PBA for processing polyolefin integral-skin composites with RRFM.

The principal objective of the presently presented research is to design and develop an experimental setup that would enable testing and verification of novel processing concepts that would improve further melt extrusion-assisted rotational foam molding operations. In this context, the existing lab-scale rapid rotational foam molding experimental setup will have to be modified to introduce a physical blowing agent.

## II. CONCEPT GENERATION

The RRFM experimental setup consists of a rotational arm assembly; mold translation system; convection oven and the extruder assembly (Fig. 1). The new modification will be applied to the extruder assembly to introduce PBA into the polymer melt. In the subsequent experiments, super critical carbon dioxide will be used as the blowing agent. CO<sub>2</sub> is ideal for foaming application for having higher solubility in polymer melt compared to nitrogen gas. In this context, the foam produced from carbon dioxide is of a higher quality [6].

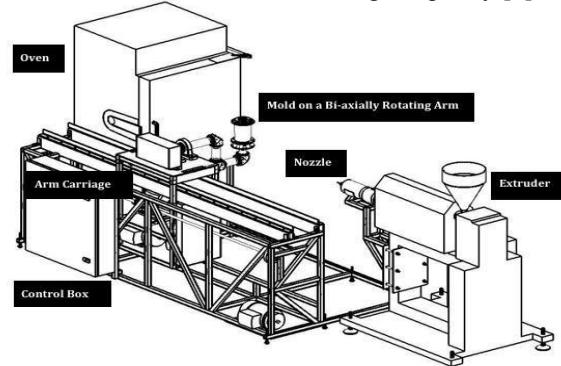

Figure 1. Existing Rapid Rotational Foam Molding experimental setup.

#### A. Design Selection Methodology

It is important to identify the engineering specifications that are necessary for a good design. In the current state, the experimental setup is not equipped for PBA introduction. The goal is to design a system that can work efficiently with the existing extruder and produce foamed articles that are of equal or of a higher quality than RRFM foam composites. To identify the design requirements, a quality function deployment (QFD) tool was used. It translates general qualitative (non-specific) customer needs into engineering specifications for a new system design. Utilizing the house of quality (QFD tool), the most important engineering specifications were identified from the prospective of a customer. In this QFD assessment the primary customer is identified as a researcher in polymer processing industry. The strongest relationship between a customer requirement and the design parameters are identified in table I.

The identified design parameters are implemented in the concept generation phase. A decision matrix is used to select a system design from one of these concepts. The criteria for selection is based on the overall operation of each concept, rather than on each individual component. The importance of each criteria is assigned a value from 1 to 10, where 10 is the most important criteria. One of the concept is selected as the datum to compare against the alternatives. A positive or a negative symbol is given on how well a criterion is satisfied under each concept against the datum (table II). The weighted total is tabulated for each concept by multiplying the symbol to each criteria rating. The concept with the highest weighted total is selected for the new system design.

#### B. Concept Selection

Each concept is represented in a simplified block diagram where all major components are identified in Fig. 2. The functional requirement for every concept is to achieve high degree of mixing between the polymer melt and supercritical CO<sub>2</sub>. It is through the mixing process where CO<sub>2</sub> gas is dissolved into the polymer melt to produce a single-phase solution [7]. This process is controlled through manipulating the chamber pressure, temperature, and the flow rate of both gas and molten polymer. The dissolved CO<sub>2</sub> gas within the molten polymer will produce the foam after experiencing a rapid pressure drop at the die exit. In order to understand the necessary processing condition for PBA application in RRFM technology, each concept presents a different foaming strategy for feasibility analysis.

*a) Concept 1:* In this experimental setup, the molten polymer is fed into a static mixer from the extruder. The melt pressure and the polymer flowrate are controlled by the screw RPM. The CO<sub>2</sub> gas is injected into the static mixer chamber to begin the mixing process. The gas laden polymer melt moves down the static mixer barrel toward stationary mixing blades. These blades provide the mixing action through splitting the polymer flow and then recombining it to disassociate the CO<sub>2</sub> gas into the polymer matrix. The temperature of the mixture is controlled by band heaters and an oil-based cooling jacket placed on the exterior shell. The final polymer solution is extruded out of the die where rapid drop in pressure produces

the foam.

*b) Concept 2:* In this configuration, two extruders are placed in tandem seen in Fig. 2. The first extruder plasticizes the polymer resin and the second extruder is used to mix the CO<sub>2</sub> gas. It is through the rotation of the second screw where vigorous shear mixing can be achieved [7]. The polymer/gas solution pressure and flowrate are controlled from the second extruder. However, the feedrate into the second extruder is controlled by the first one. Temperature of the gas laden polymer melt is maintained by PID controlled band heaters on the extruder barrel.

*c) Concept 3:* The final proposal is a modified version of concept 1. In this setup, a gear pump is used to compensate for pressure loss incurred in the static mixer because of frictional losses at the blade surface. The pressure and flow rate can be controlled by both the gear pump and the extruder screw RPM. In the cooling system, water is used as the cooling fluid rather than oil.

The weighted total from the decision matrix is negative for concepts 2 & 3. Therefore, concept 1 will be used as the experimental setup for PBA application. Although concept 1 has lower degree of process control, it is more attractive for having fewer design and fabrication complexity than the alternatives. In regards to safety, concept 2 is better for having an integrated heating element housed within the extruder and thereby lowering the risk of contact with the operator. However this setup requires more lab space which makes it difficult for

TABLE I. QUALITY FUNCTION DEPLOYMENT ANALYSIS

Customer	Design Parameters from House of Quality Assessment	
	Customer Requirements	Engineering Specifications
Researcher	Homogenize Mixing	Gas solubility in polymer melt; Heat Input; Screw RPM; Blade geometry & length

	Process Control	Heat Input; Gas injection pressure; Screw RPM; Cooling fluid flowrate

TABLE II. CONCEPT FEASIBILITY OF PBA APPLICATION

Criteria	Importance	Alternative		
		Concept 1	Concept 2	Concept 3
Design Complexity	10	Datum	-	-
Process Controllability	9		+	+
Space Required for Components	7		-	-
Safety	8		+	-
Fabrication Complexity	9		-	-
Weighted Total	0		-9	-25

the operator to move around and use other equipment. Concept 2 is the least desirable in term of safety for having a water cooling system, where steam might be produced. Which will pose as a hazard for the operator by leaking out through small clearances in the pipefittings and connecting junctions. Steam has to be safely vented to stop pipe rupture. Also, when water turns to steam a liquid pump cannot pump it. Therefore, a cooling fluid with a high boiling point must be selected to prevent this problem. An oil-based cooling system will be implemented to provide all the cooling needs for the foam extrusion process.

### III. FINAL PBA EXPERIMENTAL SETUP DESIGN

The newly modified lab-scale custom-build experimental setup must accomplish high degree of mixing between the CO<sub>2</sub> gas and the polyolefin melt. A single-phase polymer-gas solution with homogeneity greater than 80% is desired. The pressure drop across the length of the mixing apparatus must not exceed the burst pressure of the extruder. The maximum allowable pressure drop should be limited 7 to 10 MPa.

#### A. Design Guidelines

The physical blowing agent (CO<sub>2</sub>) will be injected directly into the static mixer at pressures between 20-30 MPa to mix with the melted polyolefin resin. For instance, CO<sub>2</sub> is soluble in molten polyethylene at high pressure and it can act as a plasticizer. Static mixers have to be attached after the extruder to completely dissolve the gas solution into the polymer melt. The blade design of the static mixer must generate shear field to enhance gas disassociation. Rapid pressure drop will be initiated at the die exit to cause phase separation between the gas and polymer solution. This will cause the gas to bubble out of the solution creating polymer foam. The foam will be injected into the open mold to fill the mold's cavity on top of the hot skin as the mold is rotated in a single axis.

An optimal cooling rate must be established to ensure the generation of microcells and even cell distribution. A cooling system on the static mixer wall will be used to cool the mixture temperature near the die inlet. This will lower the gas solubility within the polymer matrix and this will initiate phase separation and cell nucleation.

#### B. Static Mixer Chamber Design

Static mixers provide advantages and disadvantages in polymer foam processing. Static mixers have static blades that replicate shear fields necessary for high degree of mixing. The geometry of the mixing elements reorients the flow in radial direction to enhance the mixing. Through this mixing process radial temperature gradient is eliminated, and wall-creep material is incorporated into the bulk polymer flow. A major disadvantage is the pressure loss across the length of the static mixer. The static mixer type and size are crucial to determine if the extruder can provide enough force to push the material through the mixing elements. Static mixers are installed in front of the extruder. Many types of arrangements are possible which depends on the specific application. Some industrial applications include, extrusion blow molding, foam sheet production, co-extrusion and for blow film [8].

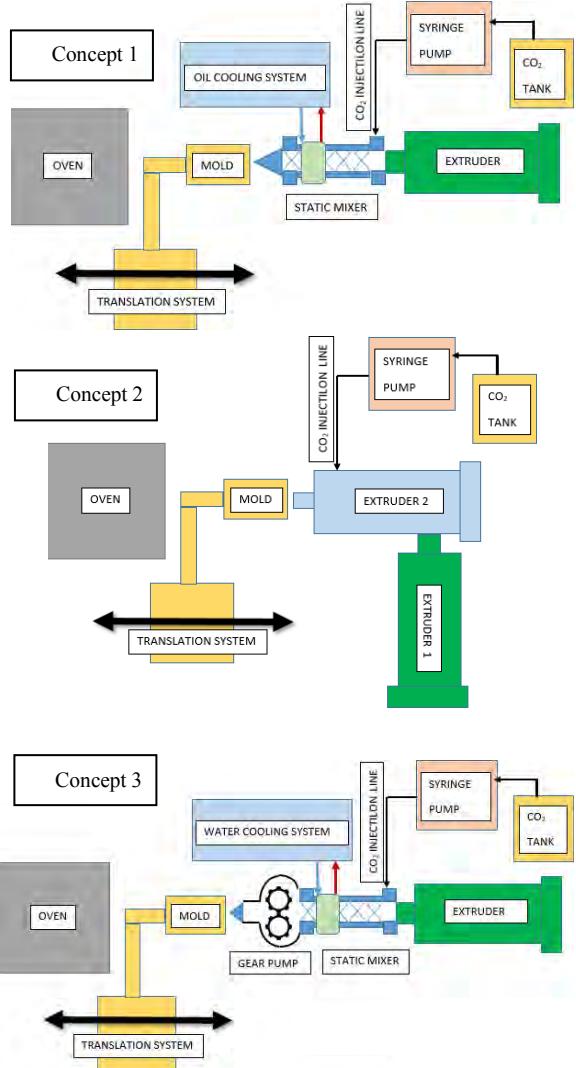

Figure 2. Possible Experimental setup for PBA Application.

The main purpose of the static mixer is to homogenize the melt upstream from the die exit. This is achieved through splitting the flow toward the radial direction and later rearranging the two split streams. The mixing elements are offset by 90° to ensure uniform distribution. The pressure loss across the length of the static mixer is dependent on the polymer-melt viscosity, Reynolds number, mixing element geometry, and process temperature and polymer grade [8].

$$\Delta P = \left( \frac{4}{\pi} \right) NeRe_D \left( \frac{\dot{V}}{D^3} \right) \eta \left( \frac{n_{ME}}{2} \right). \quad (1)$$

$$\eta = f(\dot{\gamma}, T, \text{polymer(type, grade)}, p_{op}). \quad (2)$$

$$\dot{\gamma} = f(\dot{V}, D_{ME}, \text{geometry}). \quad (3)$$

The pressure loss inside a static mixer is obtained from “(1)”, where “NeRe<sub>D</sub>” is the Reynolds number and “ $\dot{V}$ ” is the volumetric flow rate and “ $n_{ME}$ ” is the number of mixing elements and “ $\eta$ ” is the melt viscosity. The melt viscosity is obtained from “(2)”, which is dependent on operating pressure, temperature, polymer type and shear rate “ $\dot{\gamma}$ ”. The shear rate “(3)” is a function of flow rate, and the mixing blade geometry.

In relation to a grid mesh mixer, the Reynolds number can be between 1200 & 2000. However, inside a helical type mixer the Reynolds number is between 200 & 400.

Engineering Equation Solver (EES) software has been used to perform parametric analysis on different types of static mixers. A range of viscosity values was used to calculate the pressure drop across the length of the static mixer. It is important to note here that the gas/polymer solution will have a lower viscosity than a pure polymer in the actual experiment. The pressure loss is highest for GX-type static mixer sold by Stamixco.inc shown in Fig. 3. A higher degree of mixing is possible with the GX-type static mixer compared to a helical static mixer. The minimum length of the static mixer cannot be less than 20 cm. As multiple ports need to be drilled into the wall of the static mixer chamber, shorter tubes are more likely to warp during the drilling process. The extruder's maximum pressure limit is 45 MPa and the maximum pressure loss for a 16.5 cm helical static mixer is 5 MPa at 3000 Pa.s viscosity (Fig. 3). Hence, the maximum possible pressure loss for a helical static mixer is within acceptable range. The acceptable pressure loss range for the GX type mixers is at viscosity levels below 1000 Pa.s. Helical static mixers can be safely operated at higher polymer viscosity composites without rupturing the rupture disc on the extruder. Therefore, the static mixer will be 16.5 cm long with twelve helical mixing elements [8].

Stamixco manufactured the static mixer chamber. It was designed to meet all the engineering requirements for PBA-based extrusion foaming (Fig. 4). The static mixer assembly comprises of three sections: gas injection; homogenization; foam extrusion (Fig. 5). The static mixer pipe thickness was determined according to ASME section 8 division II pressure vessel code. The maximum operating temperature is 200°C, which serves well for polypropylene (PP) foam production. The maximum allowable pressure according to Stamixco's analysis is 31 MPa. The pipe is made of 17-4PH stainless steel with ID = 1.9 cm. The static mixer is 13.5 cm long with 12 helical mixing blades.

a) *Gas Injection Section:* In the aft section of the static mixing chamber, supercritical CO<sub>2</sub> gas will be injected into the polymer melt through an injection port. The port was designed for a 1/8 NPT check valve. The spring activated check valve will be screwed into the injection port to prevent back flow. This will stop molten polymer from getting into the injection tube and "freezing". The check valve cracking pressure will be set higher than the maximum operating pressure of the extruder to eliminate the possibility for back flow into the injection pipe.

b) *Homogenizing Section:* In this section of the static mixer chamber, twelve helical blades are used to dissolve the CO<sub>2</sub> gas into the polymer melt. A single-phase polymer-gas solution is necessary for obtaining fine-celled microcellular foam. Helical blades are a popular design with lower pressure drop compared to more complex shaped mixing blades. The helical blades are manufactured by twisting metal strips or by machining a single piece of solid rod. Advanced machining techniques has allowed for smaller diameter helical blades, which are ideal for high-pressure applications. Each blade is 1.65 cm wide and 2.86 cm long. The blades are welded together

in a series, and each blade is oriented at a 90° offset from the blades on either side. This offset splits the polymer flow toward the radial direction increasing the degree of mixing. The contours of the helical blades generate shear fields to dissolve the gas bubbles into the polymer matrix.

The temperature within the barrel of the static mixer must be maintained above the melting temperature of the polymer. In real test conditions, the temperature within the barrel of the mixer will be kept at the CO<sub>2</sub> saturation point for a given mixing pressure. This will ensure that the maximum possible amount of CO<sub>2</sub> can be dissolved into the polymer. Higher concentration of CO<sub>2</sub> dissolved within the mixture creates higher cell density in the final foamed product. Three Mica band heaters with an output of 200 watts can maintain the surface temperature of the static mixture above 400°C. Band hater output will be controlled using a J type thermocouple in a closed-loop feedback. One inch thick insulation will be placed between the band heaters to maintain the correct temperature profile. The insulating material is made from silica aerogel with thermal conductivity value of 35 (mW/m.K) at 300°C.

c) *Cooling Section:* The cooling shell on the static mixer is an integral part of the overall cooling system design. The inlet and outlet ports are positioned in a manner to make the cooling shell a parallel flow heat exchanger shown in (Fig. 6). Channels on the static mixer wall (ribbed section) increase the overall surface area to promote high rate of heat transfer. The cooling fluid flows from the inlet port and gradually flows through each of the channel before exiting through the outlet port. It is not necessary for the cooling fluid to be pressurized because the flash point of engine oil is over 200°C. The operating temperature of the oil will be well below this point minimizing the presence of any combustible vapor.

The polymer melt cooler consists of an air-cooled radiator, hydraulic oil pump, throttling valve, 1/4" hydraulic tubing, and two 12 V DC power supply (Fig. 6). The two power supply unit provide the same voltage but different current according to the maximum current rating of the radiator fan and the oil pump. The pump can supply cooling oil at a maximum rate of 1.5 l/min to the cooling shell. The flow rate can be reduced with the aid of a throttling valve if needed. The air cooled radiator can cool the return fluid from the static mixer as high as 100°C using a fan capacity of 266 CFM. Two thermocouples will be used to

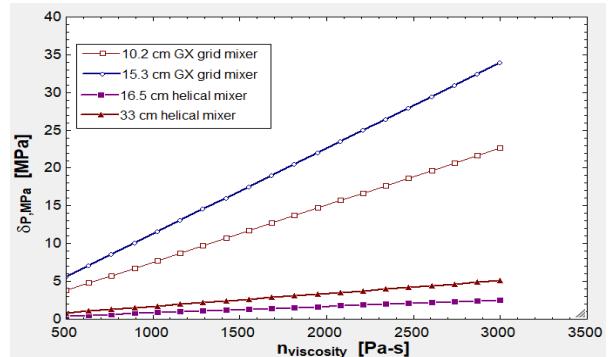

Figure 3. Pressure loss analysis for a GX and helical static mixer blades.

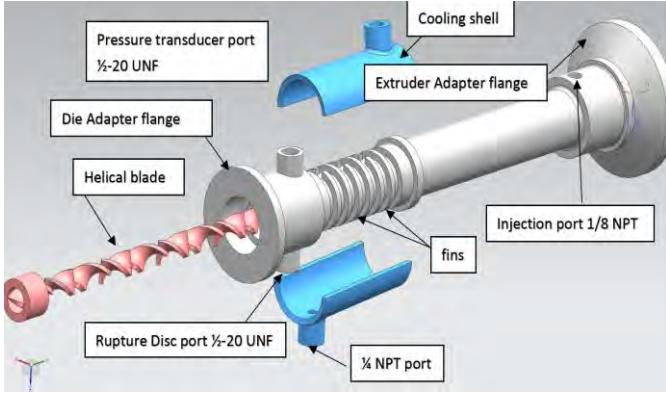

Figure 4. Exploded view of the static mixer chamber assembly.

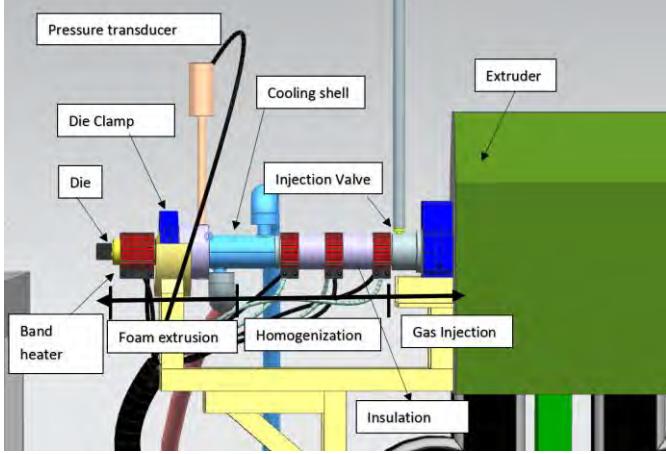

Figure 5. Full assembly arrangement of the static mixer chamber.

monitor the oil temperature at the inlet and the outlet ports. If the return fluid temperature is above 110°C, a safety switch will be triggered to shut down the pump. A manual emergency switch has been integrated into the system to shutdown operation if a leak is present. The whole system can be turned on and off using the green switch during normal operation (Fig. 6).

*a) Extrusion Section:* The single-phase solution will experience rapid pressure drop as it flows out of the die nozzle opening. This will initiate phase separation within the mixture and the polymer melt will start to foam and fill the mold cavity. The interior contours of the die channel the gas laden polymer melt toward the opening seen in Fig. 7. The die opening is 3 mm and the length is 100 mm. It has been designed to deliver the polymer foam inside a cylindrical mold. The overall pressure drop inside the die was determined from ANSYS Polyflow software package for polyethylene melt. It was determined from the analysis that with a maximum melt flow rate of 5 kg/h and 1000 Pa.s die inlet viscosity, the maximum pressure drop from the inlet to the outlet is 30 MPa as seen in Fig. 8.

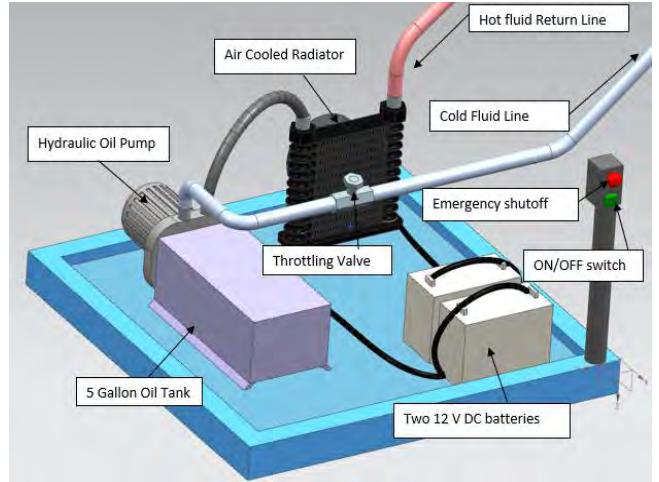

Figure 6. Polymer melt cooler assembly.

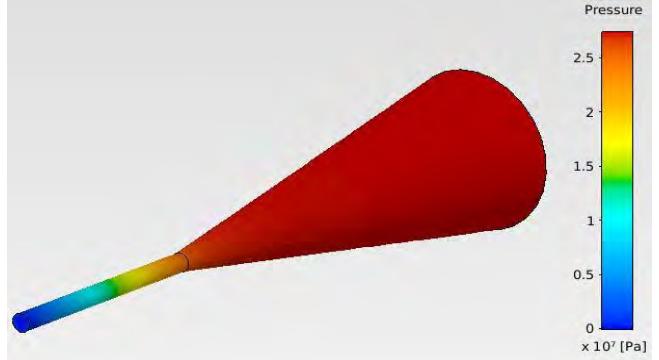

Figure 8. Pressure loss along the die length.

#### IV. CONCLUSION

The presented experimental setup was designed to produce polyolefin foam with PBA for RRFM process. The new setup was selected for having fewer design and fabrication complexities compared against the alternative proposals. In this unique design, the PBA is directly injected into the mixing chamber rather than the extruder barrel. The gas/polymer solution will be produced inside the static mixer. It has been shown, that helical static mixers are suitable for polymer foaming application for having significantly lower pressure loss. The new experimental setup could lead to developing breakthrough processing concepts that would be capable of fabricating new classes of ultra-low-density rotationally molded integral-skin cellular composites.

**Abstract**—The present paper addresses the challenges in design and analysis of 3D printed structures with anisotropic material properties. In recent years the additive manufacturing technologies have been used in most of the industries because of their freedom in fabrication of any complex geometry part. However, the final properties of the 3D printed parts are anisotropic though the material used is isotropic. Further, the properties of printed part are not homogeneous. This change in the properties is due to process parameters and build orientation of the parts. Therefore, this calls special attention of the designer for effective design and analysis of such parts. In this paper, design consideration of the parts for 3D printing and also, their structural analysis for effective design of parts for 3D printing are discussed. Further, different steps involved from design to 3D printing of a product are discussed.

**Keywords**-3D printing; Material properties; Design; Analysis;

## I. INTRODUCTION

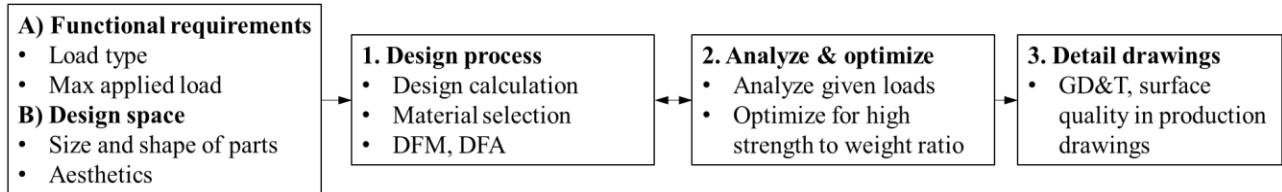

Additive manufacturing, also known 3D printing, fabricates 3D part by deposition of material layer upon layer. This layer by layer fabrication technology can build a part of any kind of geometry. It means that the technology facilitates more freedom for designing of any intricate shape of parts. The ASTM [1] classifications of AM processes based on process methodology are binder jetting, direct energy deposition, material extrusion, material jetting, powder bed fusion and sheet lamination and photo-polymerization. The other main benefits are rapid prototyping, fabrication of product with minimum part count, better structural integrity of product, no special tooling, flexibility for fabrication of wide range of products, no need of skilled operator, eliminates different sizes of stock materials and minimal or no wastage of processing materials. Furthermore, the AM techniques allow tailoring the material properties of the part by printing desired mesostructure during material deposition and also building functional graded parts much easier. The design of part for 3D printing is not same as traditional design for machining methods and the design rule for additive manufacturing is discussed by [2]. The material properties of the printed parts are differing form their initial properties and the effect of anisotropic material properties on structural behavior of the printed parts was addressed in [3]. Effect of process parameters on the material microstructure and design principle for additive manufacturing a part is available in [4]. The design of a part for 3D printing

involves much more than just fabricating a three dimensional part. It involves design of microstructure, selection of printing direction, process parameters and build orientation. This paper addresses the effect of anisotropic material properties on the design of a part. Also, challenges in design and analysis of part for 3D printing are discussed. Then the different stages and the factors that need to be considered during design stage of a part for additive manufacturing process are presented.

## II. CHALLENGES IN DESIGN AND ANALYSIS

The 3D printing of any complex geometry allows the designer for designing of parts of size microstructural (micrometers) to structural level (meter level). At the same time the designer needs to pay attention to the fabrication process and its process parameters while designing the part for 3D printing. The physical phenomena that take place during the layer upon deposition of the material have strong impact on the quality of the printed parts that includes mechanical properties. This is due to printing the microstructure of the part during layer upon layer material deposition and the mesostructure is mainly governed by the process parameters. This introduces the anisotropy in the material properties even though the isotropic material used for printing. Also, the degree of anisotropy depends on the type of AM process employed for printing the part. Furthermore, the material of the printed part is not homogeneous in different sections of the part. This inconsistency in the material properties of the printed part is major challenge to designer to specify the final material properties of the part. To account this change in the material behavior, the parts have to be designed not just based on geometrical analysis but also based on the phenomena that is taking places during printing. Therefore, it is essential to consider type of AM process and its process parameters while designing the parts for 3D printing.

The limitations of AM processes are range of materials for printing, dimensional accuracy, build time, support structures, surface finish, mass production, post processing and consistency in the material properties. These are mainly governed by the type of AM process and its process parameters. Also, the build orientation of the parts influences the build time, quality of the part and material properties. So far, the design of parts for printing is based on geometrical analysis, reduction in build time and cost, minimal support structures and for better surface finish. The anisotropy in the material properties of the printed part via different AM

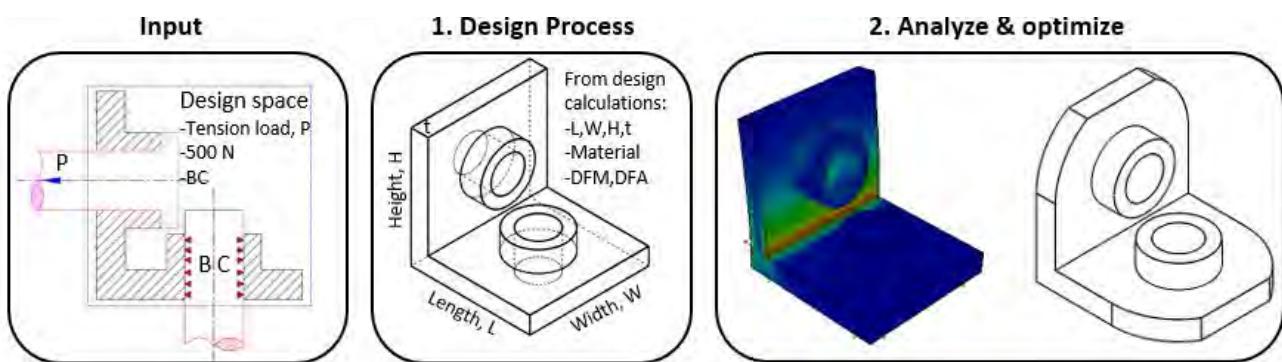

**Figure 1.** Stages in the product design, development and fabrication

processes was addressed [5]. Effect of the build orientation of the part and process parameters on the mechanical properties of the printed part via FDM was discussed in [6]. The anisotropic material behavior of printed parts via SLA [7]. The variation in the material properties of the printed part via SLM are discussed in [8]. Therefore, while designing a part for 3D printing the designer need to consider the influence of AM process and its process parameters on the final printed part. Further, the limitation of the process and influence of build orientation on quality and performance of the part are to be considered while designing. It means that for effective design and analysis of parts for 3D printing the designer need to have idea about the relationship between process-structure-property-performance.

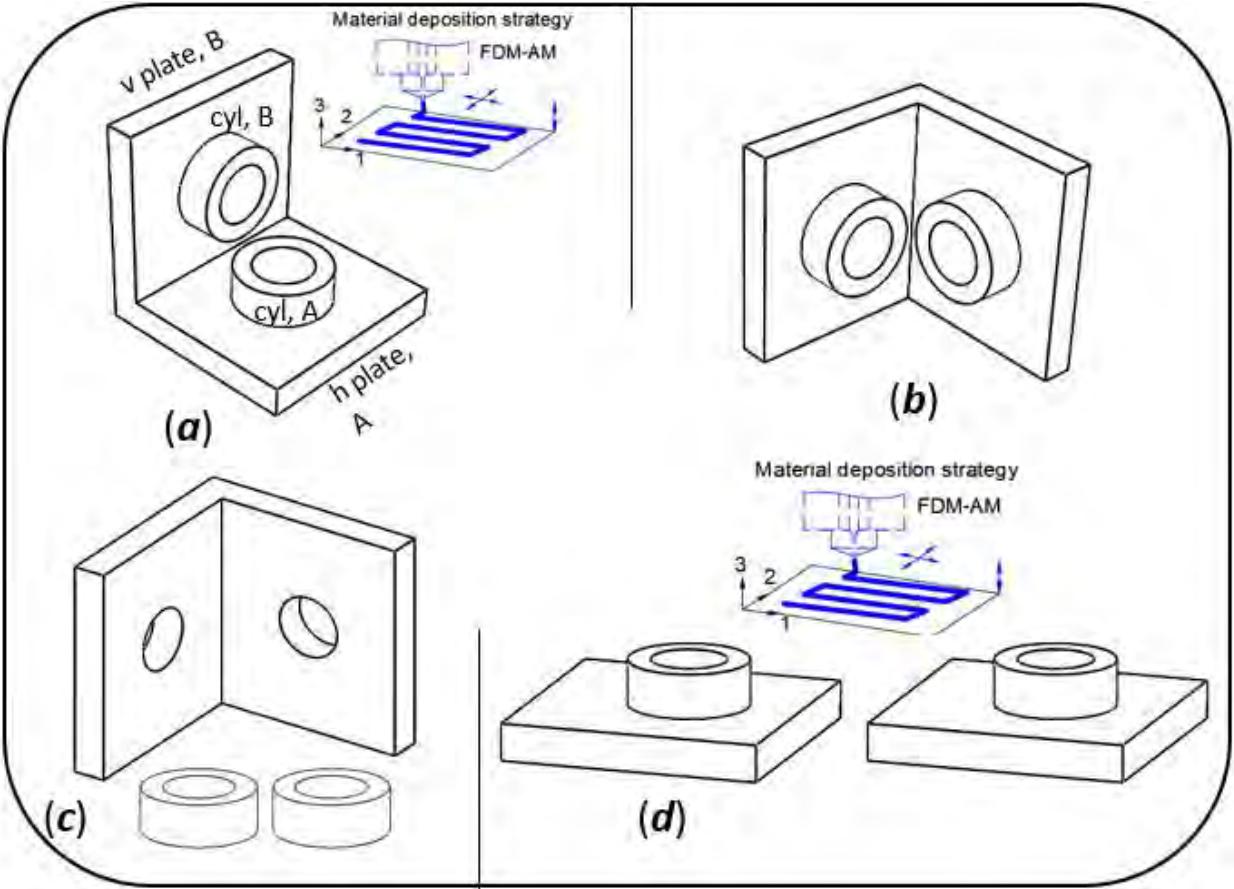

The parts subject to certain loads are designed and analyzed for a selected material to get the its geometrical parameters. It means the geometrical features (size, shape) of the part derived from design and analysis calculations for desired strength to sustain the applied load on it. Different stages involved in the design and development of a product for traditional machining methods are shown in Fig. 1. The main inputs for the product design are its functional requirements and design space. The functional requirements of product include its purpose, load type and maximum applied load. Then the design space defines the maximum allowed size and shape of the product. Then the geometry of the parts of the product are designed for the applied load and selected material. This involves the design calculation that the stresses of the parts produced due to applied load lower than the strength of the selected material. Simultaneously during design stage, the design for manufacturability (DFM) and design for assembly (DFA) are considered for fabrication and assembly and disassembly of the parts of the product. Then in the next stage, the product is analyzed and optimized for higher strength to weight ratio. Finally, the detail drawing of the optimized parts are produced with the tolerances, surface quality requirements and

suggestions of machining methods for fabrication of the parts. For instance, a part is to be designed for holding two shafts and subjects to load ( $P$ ). The Fig. 2 explains different stages involved in design and analysis of the part.

The design of a part for 3D printing could not follow the same stages, because the challenges in designing and their limitations of AM processes as mentioned earlier. Anisotropy and inconsistent material properties of printed part are the main challenges during the design. Let us consider a 3D printed L bracket via FDM process. The bracket has two plates; horizontal and vertical plate and a cylindrical section to each of them. The horizontal plate is oriented on the substrate of the printer and the orientation of the vertical plate is perpendicular to the horizontal. As discussed earlier that the properties of the printed parts depend on process parameters and it build orientation. The material properties and behavior of the two plate would not be same because of their build orientation. The behavior of printed horizontal plate would be orthotropic and vertical is transverse isotropic. The 3D printing of L bracket with different build orientations is shown in Fig. 3 and their influence is presented in Table I. The other process parameters of FDM such as layer thickness, printing direction, percentage of infill, infill pattern, air gap between the fibers, temperature of build area and printing speed influence the mechanical properties of the printed part. Because of change in the material properties, the initial properties used in design calculations of a part for 3D printing do not provide reliable design output. That includes the geometrical feature of the part and expected material behavior of the part for applied loads. Besides that, results of analysis and optimization of the part based on initial properties are not correct. Because of such challenges, the design of a product for additive manufacturing (DFAM) is much more than the traditional design process for machining methods. The DFAM requires the designer to take care of type of AM process, material properties, build orientation, support structures, build time, cost and quality of the parts.

**Figure 2.** Stages in design and analysis of a part.

**Figure 3.** Different build orientations of the L bracket for 3D printing.

**TABLE I. INFLUENCE OF BUILD ORIENTATION OF A PART IN 3D PRINTING.**

	3(a)	3(b)	3(c)	3(d)
Properties of A,B	≠	≠	=	=
Homogeneity in A, B	No	No	Yes	Yes
Support structures	Cyl B	Cyl A, B	None	None
Build time	Higher	Highest	Lower	Lower
Assembly	None	None	Yes	Yes
Structural integrity	Strong	Strong	Weak	Weak
Post processing	Yes	Yes	No	No

A modified design process and the special design tools that consider the flow of information between the process–structure–property–performance could help the designer for effective design and analysis of the parts for 3D printing. The modified design process and steps involved during design of part for 3D printing is presented in Table II. The designer tools for 3D printing guides the designer based on the type of AM process and its process parameters for fabricating the parts. More importantly material data of the final printed parts based on the process parameters and build orientation for effective design and analysis of parts for 3D printing.

### III. CONCLUSIONS

The additive manufacturing technologies facilitated more freedom for fabrication of any shape of the part and with additional benefits such as rapid prototyping, no tooling and minimal or no wastage of material. However, the changes in the material properties of a part due to the physical phenomena that is taking places during layer upon layer deposition of a material need to be addressed. The change in the material behavior greatly influences the design and analysis of the parts for 3D printing. The anisotropy and inhomogeneity in the material properties do not allow the designer for effective design of the parts. Also, designing of a part for 3D printing requires to consider influence of other factors that include type of AM process and its parameters and build orientation on build time, cost, support structure

and surface quality of the parts. Further, the relation between the process-structure-property-performance is need to be considered during the design stage of a part for 3D printing for effective design and analysis.

**Abstract**— Control valves are known as the final control element in hydraulic closed/open loops of modern process industries around the world. Proper selection of control valve leads to enhanced performance curve of the hydraulic systems and therefore increases the efficiency, reliability, profitability and safety of the system. Flow coefficient (CV) of a control valve describes the relation between the pressure drop across the valve and the flow passing through it. Despite many computational efforts for calculating the exact value and curve of CV, the experimental procedure of the CV test has not been documented well. We used a control valve test-set up designed based on the standards ANSI/ISA-75.02-1996 and IEC 60534-2-3 (2013) to evaluate the performance of a 3 in. control valve. Upon extracting the results in terms of inlet, and outlet pressure and flow, the characteristic parameters such as CV and opening percentage were derived and compared with an ideal curve. Error analysis was performed to account for the tolerance of the measured parameters by the measuring devices. The results show acceptable agreement within the criteria of a reference standard approving the validity of the design method.

## 1- INTRODUCTION

Control valves have long been used as the final control elements in various types of process lines. They are typically known to be in charge of one-third of the total pressure drop along the hydraulic line which represents a high impact on the regulation of total line performance curve. The coefficient of valve (CV) is related to the surface area through which the fluid can throttle (pass). Such area is controlled via moving (linear) or rotating (rotary) a closure element relative to a fixed housing (seat). The position of the closure element is controlled by various types of actuators including pneumatic, electric, electrohydraulic and hydraulic actuators; among which pneumatic actuators are simpler and more common.

A Globe valve with linear actuator is composed of body, bonnet, plug, seat, stem, and for the case where more pressure drop is required at the price of less CV, various types of cage are used. Flow coefficient (CV) of a control valve describes the relation between the pressure drop across the valve and the flow passing through it. The definition of Control Valve Coefficient was soon accepted and applied universally after its first introduction to industry by Masoneilan in 1944. [1] In more practical terms, the flow coefficient CV is the volume (in US gallons) of water at 60°F that will flow per minute through a

valve with a pressure drop of 1 psi across the valve. [2, 3] A comprehensive laboratorial set-up is required for fine measurement of variables such as flow and pressure drop, from which the CV can be calculated and plotted. The specifications of such set-up for incompressible flow measurement are mentioned in ANSI/ISA-75.02-1996 and IEC 60534-2-3 (2013) standards [4, 5]. Previous researchers have implemented the testing process such as that of Vikas et al., in which a 4 inch globe control valve is tested experimentally for its equal percentage and linear performance curves. [6] Computational methods have been presented by Guy Borden [7] to calculate and plot the ideal performance characteristics for throttling valves which include linear and equal percentage characteristics of the valve. Also, Aragon et al. have presented a method for experimental determination of valve capacity with compressible flow [8].

Despite the achievements of previous publications, a full procedure for testing and analysis of a control valve performance curve has not been proposed. Since such analysis can serve as a validation method for the control valve design and on-site performance, it is of critical importance to consider the effects of various variables such as hysteresis in sequential opening and closing of the valve, error analysis and considering the existing criteria [9] for acceptance of the curve, on which few documents have been published. The current study aims to analyze the results of a performance test on a 3 inch commercial Globe Control Valve with equal percentage trim to represent a nonlinear characteristic behavior.

## 2- METHODOLOGY

### 2-1- Valve Characteristics

A 3 inch. globe control valve manufactured with modern technology was tested. The specifications of the test valve are shown in Table 1.

The trim of the top guided valve is a contoured plug head with equal percentage characteristics. The contoured plug head of the valve is designed based on the computations of [7] for a 3\*2.5 in valve with 40mm of stroke. A computational code in MATLAB was used to estimate the curve of the contoured plug (Figure 1). The control valve is equipped with a single acting pneumatic actuator and a Yamatake positioner with 0.1% travel accuracy for fine positioning of the stem during opening and closing cycles.

Table 1- Type test characteristics and dimensions

Valve Type & Rating	Globe Top Guided GS1000- ANSI 300
Valve Size	3 in. Manifold * 2.5 in Plug
Valve Rated CV (Fully Open)	72
Valve Characteristic	Equal percentage with 0.05 of Rated CV at Min.
Actuator Type	Pneumatic Single Act.
Positioning	Azbil (Yamatake) AVP302

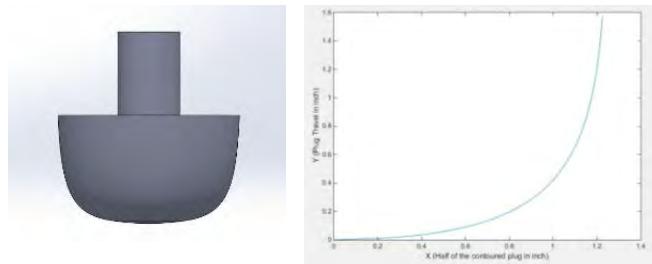

Figure 2- Left: Plug head curve (half of the contoured plug) designed for the 3\*2.5 in valve with 40mm stroke and recovery factor of 0.9 Right: a MATLAB code is written for computation of the curve based on [7] (courtesy of Rasta Group Industrial valve Co.)

### 2-2- Laboratory Test Set-up

A laboratorial test set-up which has been designed for 3 in. valves was prepared for the study. (Figure 4) The set-up was verified for dimensional agreement with ANSI/ISA 75.02-1996. [9] (Figure 3). The standard ANSI/ISA-75.01.01-2002 (2002) was used for sizing calculations which defines equations

for sizing control valves and showing the result as a flow capacity coefficient, CV. [1, 2]

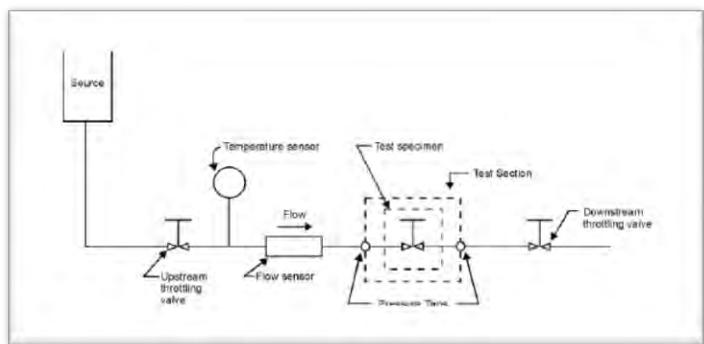

Figure 3- Test Circuit Suggested by ANSI/ASME 75.02 for testing the performance characteristic of control valves [3, 4]

Figure 4- The test bench used for the experiment (Courtesy of Thermo-hydraulic Laboratory of the Iranian Ministry of Power)

The test bench instrumentation was chosen to meet the specifications of standards ANSI/ISA-75.02-1996 (1996) and ANSI/ISA-75.01.01-2002 (2002). [4, 5] Three physical variables were obtained at each run: pressure, temperature and flow rate, with the following characteristics,

**Pressure:** All pressure measurements are made with an error not exceeding  $\pm 2\%$  of the actual value. [4, 5] Rosemount 3051 Pressure Transmitters are used to meet the specified accuracy. (Figure 5)

**Temperature:** The flow temperature should be measured within an error not exceeding  $\pm 1^\circ\text{C}$  ( $\pm 2^\circ\text{F}$ ) of actual value. [4, 5] A standard temperature sensor is used to make sure the temperature of water is within acceptable limits.

**Flow:** The flow rate instrumentation may be any device that meets specified accuracy. This instrument is used to determine the true time average flow rate within an error not exceeding  $\pm 2\%$  of the actual value. [4, 5] The resolution and repeatability of the instrument must be within  $\pm 0.5\%$ . A Magnetic MAXIFLO flow-meter with the accuracy of 2% has been used

to measure the flow. Three readings are made each time and the average is calculated and reported as data.

**Pump:** A centrifugal Pump with maximum flow capacity of 120 m<sup>3</sup>/h and suitable pressure limit for 4 in piping is used.

Figure 5- Valve installed in 3-in pipeline (left), Pressure transducers installed on pressure taps (right)

### 2-3- Test procedure

The set-up was used to test the valve through stepwise closing and opening of the valve and recording the measured parameters including differential pressure across the valve and flow. The test was repeated in three cycles of closing-opening-closing of the valve and during the steps, data was recorded on every 6.25% change in stem travel (This is equivalent to 1 mA change in positioner signal input in the range of 4-20 mA current).

**Scenario A-** Closing the valve from fully-open condition (maximum Cv) to minimum flow at 0.05 of maximum Cv. And recording data including: 1- Inlet and Outlet static pressure using digital pressure gauges. 2- Flow passing through valve measured by a magnetic flow-meter. Results were plotted as calculated Cv vs. travel percentage to characterize the valve. Attempt was made to avoid choking conditions which correspond to maximum allowable pressure drop.

**Scenario B-** The above step was repeated from fully-closed condition to fully open.

**Scenario C-** The above step was repeated once more from fully-open condition to fully-closed.

Calculation of flow coefficient based on the standard ISA 75.01 and IEC 60534 was performed as follows [2, 3]:

$$C_V = \frac{w}{27.3 \times \sqrt{\rho \times \Delta P}} \quad (1)$$

, where w is the mass flow rate in kg/h,  $\rho$  is fluid density in kg/m<sup>3</sup>, and  $\Delta P$  stands for the pressure drop across the valve in

bar. The equal percentage theoretical characteristic of valve is calculated from the formula of equation (2). [7]

$$q = a^{1-h} \quad (2)$$

, where

$$q = \frac{CV \text{ at current opening}}{CV \text{ at fully-open (Rated CV)}} \quad (3)$$

$$a = \frac{CV \text{ at Minimum Opening}}{CV \text{ at fully-open (Rated CV)}} = 0.03 \quad (4)$$

$$h = Travel \text{ Percentage} = \frac{\text{Plug Distance From Seat (Travel)}}{\text{Travel at fully-open (Stroke)}} \quad (5)$$

The resulting curve was compared with the ideal equal percentage curve based on the criteria suggested by ANSI/ISA-75.11.01-1985 (R2002) [9] which provides limits for acceptable deviations of actual inherent characteristic from the characteristic reported by manufacturer. (Figure 6)

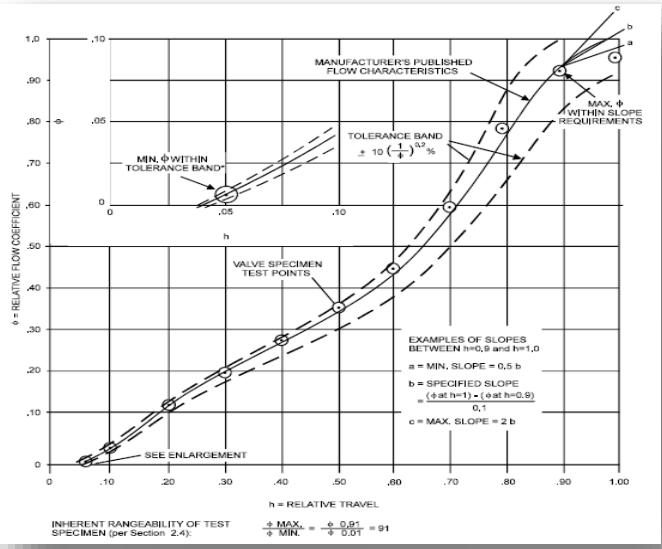

Figure 6- Acceptable range of deviations from catalogue curve by ANSI/ISA-75.11.01-1985 (R2002) [9]

### 3- RESULTS

The obtained results – in terms of valve coefficient (CV) versus travel percentage of valve stem - from the first scenarios (Fully-open to Fully-closed) are shown and compared to the theoretical equal percentage characteristic from equation (3) in Figure 7. As it was expected, the equal percentage characteristic was properly followed by the performance curve of the trim. However, there seemed to be minor deviations around the opening of 80%.

Additionally, the results of the other two scenarios were demonstrated in Fig. 8. It seems that the cyclic hysteresis effect is more considerable in the range 60%-80% opening where it caused fluctuations and minor discrepancy in the results of the three scenarios.  $R^2$  value from statistical analyses of six pairs of results are shown in Table 2. Based on the values, the first scenario is the closest to the ideal characteristic and the closing cycles (scenarios 1 & 3) seem to be more similar in pattern than the other pairs.

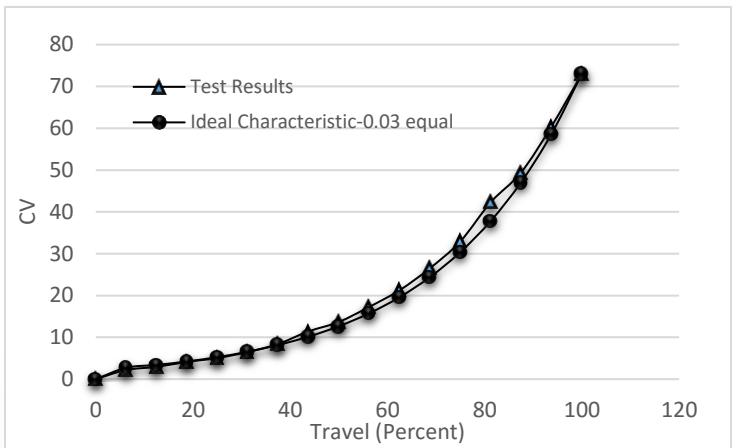

Figure 7– Flow characteristic obtained from the test vs. the ideal equal percentage flow characteristic

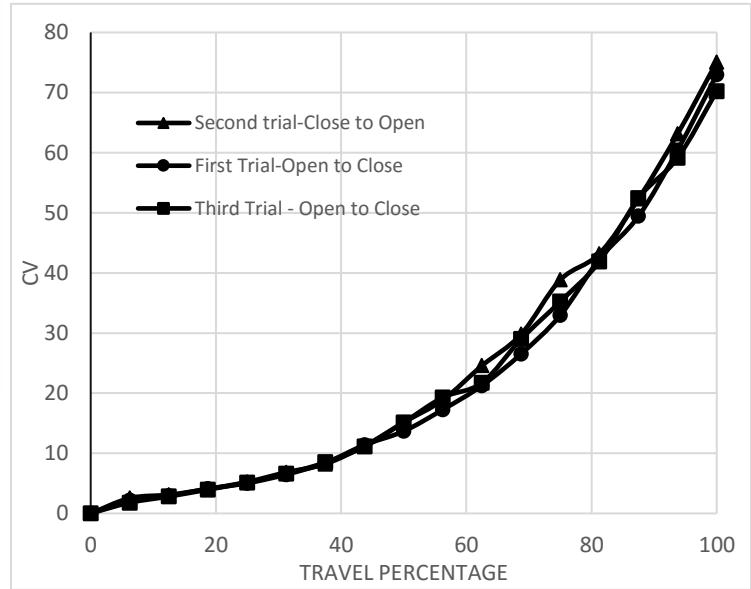

Figure 8– Flow characteristic obtained from the test vs. the ideal equal percentage flow

Table 2- R2 values for trend lines of the three test scenarios with theoretical curve. Ideal characteristic is considered equal percentage with Min CV of 3%

Ideal-Test1	Ideal-Test2	Ideal-Test3	Test1-Test2	Test1-Test3	Test2-Test3
0.991	0.963	0.975	0.985	0.990	0.984

#### 4- DISCUSSION OF RESULTS

The three recorded equal percentage characteristic curves are shown and compared for hysteresis of the hydraulic system denote fluctuations in the measurements at some points along the valve full stroke. The data of the first scenario (fully-open to fully closed condition) are compared to the ideal equal percentage characteristic of reference [7] shown in Equation (2). This is displayed in Figure 7 where the deviations from ideal equal percentage characteristic are almost negligible for the first scenario. However, the deviation becomes more noticeable in the two remaining repetitions of the scenario (scenarios 2 and 3). This can be attributed partly to measurement and reading errors.

The comparison of the trend of test results in terms of R-squared in Table 2 shows that the test results are acceptable valid regression models of the theoretical data. However, the similarity of the trend line is more noticeable in opening curves (higher R-squared value for test1-test3 comparison). For better evaluation of the quantitative validity of test results, a statistical T-test was performed. (Table 3) In this table, the average of the three values for each test point in terms of CV has been considered as test results, which is compared to the ideal characteristic. From equation (6), the result of the T-test show that the averages of the two sets of data do not differ significantly. As it can be seen, the statistical analysis including the qualitative ( $R^2$ ) and quantitative (T-test) results demonstrate acceptable results.

Table 3- T-Test comparison for ideal characteristic and test data

Parameter	Ideal	Test Result
Mean	21.16	22.807055
Variance	461.74	500.219218
Observations	17	17
t Stat	0.21	
P( $T \leq t$ ) one-tail	0.41	
t Critical one-tail	1.69	
P( $T \leq t$ ) two-tail	0.82	
t Critical two-tail	2.03	

,the requirement of the T-test acceptability is as follows:

$$-t_{\text{Critical two-tail}} \leq t_{\text{Stat}} \leq +t_{\text{Critical two-tail}} \quad (6)$$

$$-2.03 \leq 0.2 \leq +2.03$$

More precise analysis can be made through the method of ANSI/ISA-75.11.01-1985 (R2002) which provides limits for acceptable deviations of actual inherent characteristic from the characteristic reported by manufacturer. The Ensemble CV in Equation (7) at fully-open condition is average for the three scenarios at this condition. As it is observed, the maximum relative error is 4.3% at fully-open condition for the third scenario where the calculated CV is 75.09 while the nominal CV equals 72. In addition, the changes of relative error threshold from reference [9] is compared to the actual relative error from ideal equal percentage trim (the average of three scenarios at each control point has been used) in Figure 9. It can be inferred from the Figure that, although the average values of CV do not exceed the threshold level, the values of CV tend to slightly fall beyond the levels at some points of the threefold scenarios. The highest relative errors, which are accompanied by slightly exceeding the threshold, occur when the valve stem is 6.25%, 43.75% and 81.25% open.

$$\text{Average Ensemble CV at full Travel} = \frac{73+70.23+75.09}{3} = 72.77 \quad (7)$$

$$\text{Nominal Rated CV} = 72$$

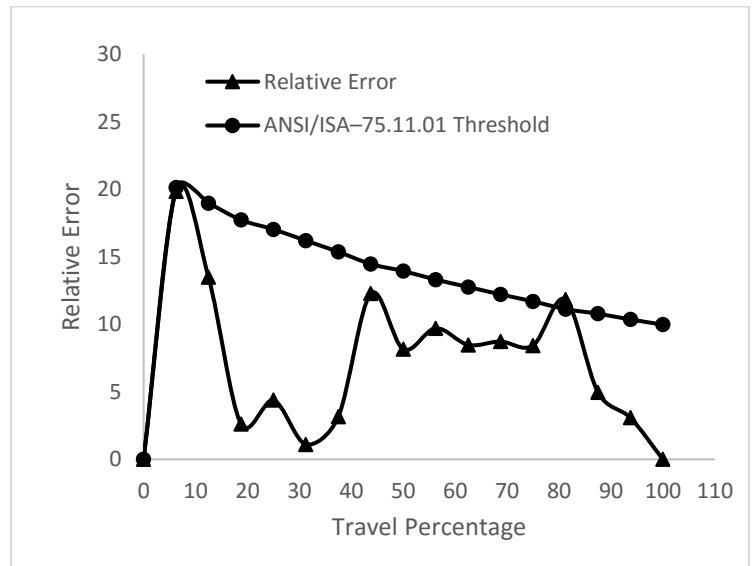

Figure 9- Comparison between experiment relative error (average of three scenarios at each control point has been used) and allowable limit of error from [9]

The compound error of CV calculation from the measured parameters (w and pressure drop) is presented in Equation (8),

$$\delta(CV) = \left[ \frac{1}{27.3 \times \sqrt{\rho \times \Delta P}} \times \delta(w) \right] + \left[ \frac{w}{27.3 \times 2 \times \sqrt{\rho \times \Delta P} \times \Delta P} \times \delta(\Delta P) \right] \quad (8)$$

,where  $\delta(CV)$  is the ensemble error of CV,  $\delta w$  error of flow measurement which is 2% for based on the specifications of the measurement device, and  $\delta(\Delta P)$  represents the error of pressure drop measurements which equals two times the error

of one reading (totally 4% since the pressures are read at input and output and then they are subtracted).

As it can be inferred from Figure 10, the measurement compound error grows as the calculated CV is increased. This occurs due to higher contribution of flow (than pressure drop) to CV measurements in control valve. As a result of the proportionality of flow and CV, and given the somewhat constant pressure drop throughout the test, the width of the error bars grow exponentially similar to the equal percentage characteristic of valve. By adding the values of measurement compound relative error to the relative errors of the experiment results from ideal characteristic (Figure 9), the threshold is surpassed only at 81.5% travel by the amount of 3% relative error which can be considered negligible.

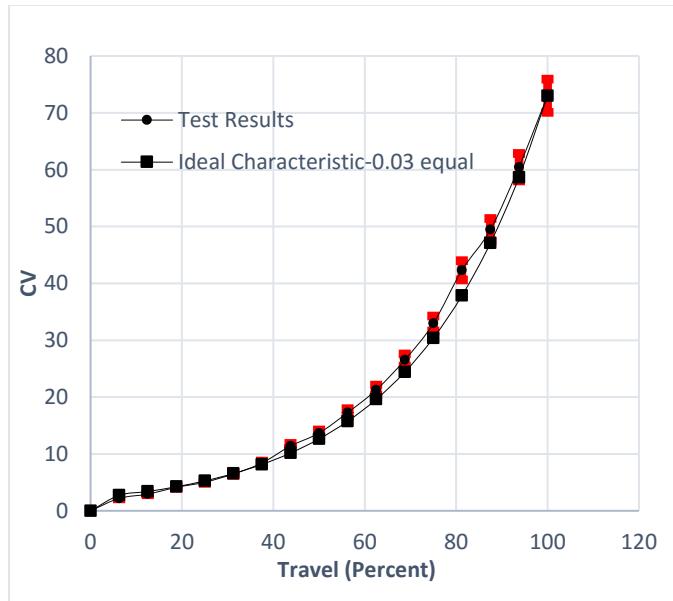

Figure 10- Compound error of CV measurement based on the accuracy of measurement devices shown for the results of the first scenario (fully-open to fully-closed) compared with exact ideal equal percentage characteristic (with minimum relative CV of 0.03)

## 5- CONCLUSIONS

A 3 in. globe control valve with top guided contoured trim was tested experimentally for its performance curve on a standard 3 in. control loop set-up. The performance test was repeated three times starting with a fully-open to fully-closed condition of valve and the data of water flow and pressure drop across the valve were recorded after each 1 mA change in positioner input signal (equivalent to 6.25% change in valve stem travel after calibration of positioner).

The tests were carried out in three various scenarios including successive opening and closing cycles. The results show negligible hysteresis existing between the cycles with opposite moving directions of valve stem. The valve characteristic was compared to the ideal characteristic of reference [7] which

demonstrated acceptable results not exceeding the threshold of relative error addressed by reference [9]. However, it was later shown that the compound measurement error of CV can push the values slightly beyond the acceptable limits of reference [9]. Although, the overall results of the experiment are acceptable, In order to further reduce the compound errors of measurements, there are a number of methods including use of a pressure subtractor measurement device and performing sensitivity analysis.

## 6- ACKNOWLEDGEMENTS

The authors would like to express their appreciations to Rasta Group Industrial Valve Co. for financially supporting the project. Instrumentation specialists Mr. Zargaran and Mr. Arbabi for accompanying the project to the very end. In addition, the cooperation of the Iranian Ministry of Power is appreciated for making the necessary arrangements for valve set-up and installation.

**Abstract**— The majority of epoxy/graphene oxide (GO) composite studies have been conducted on synthetic epoxies. This work presents the results on GO filler loadings of 0.1, 0.2 and 0.3 wt. % to a green bio-epoxy polymer. GO was synthesized from oxidation of graphite flakes. The epoxy/GO composites were prepared using a solution mixing route. Scanning electron microscopy (SEM) was used to examine the graphite and GO powder morphology and composite fractured surfaces. Fourier transform infrared (FTIR) spectroscopy was used to identify functional groups on the produced GO material. Tensile strength of pure and modified bio-epoxy composites was evaluated. SEM showed differences in fractured surfaces which implies the GO material was able to modify the bio-epoxy polymer. The FTIR results confirmed oxidation of the graphite was successful. The tensile strength and modulus improved by 23 % and 35 %, respectively as compared to the pure bio-epoxy with only 0.3 wt. % GO filler. Additions of GO to bio-epoxy revealed a significant enhancement in tensile strength and stiffness could be achieved with considerable lower filler loadings than traditional fillers.

**Keywords**-graphene oxide; bio-epoxy; composite; mechanical properties

## I. INTRODUCTION

Synthetic epoxy polymers are used in a number of industries such as aerospace, automotive and consumer products due to their lightweight, corrosion and chemical resistance. Cured epoxy composites tend to be brittle and have low impact strengths which can have limitations on certain applications. Fillers are added to polymers to reduce component costs. Mineral fillers in thermoset polymers help to improve impact toughness, modulus and hardness of the

composites. However, these fillers tend to decrease the tensile strengths of the polymer composites. It has been reported much less graphene oxide (GO) fillers are required compared to traditional fillers to improve mechanical properties [1].

Graphite, a carbon based three-dimensional crystalline material was discovered by KW Scheele in 1779. Each layer of carbon atoms are covalently bonded, while the bonding between the layers or sheet are weakly bonded with Van der Waals bonds [2]. By exfoliating the sheets of graphite, graphene a two-dimensional material is formed. Graphene was discovered in 2004 and is defined as a single flat sheet of graphite where its carbon atoms are arranged in a hexagon structure [3]. Although studies have shown graphene can improve properties of polymer composites, graphene has a smooth, non-reactive surface which prevents a good bond to form, limiting the load transfer from the polymer matrix to the graphene sheets [4]. Compared to graphene, GO obtained from oxidizing graphite contains a number of GO sheets stacked on top of each other. The GO sheet can be exfoliated into single sheets by sonication in water, solvents and polymers. The advantage of using GO in polymers is the presence of functional groups on the surface and edges of the GO sheets. Significant improvements in mechanical properties can be obtained by adding GO to epoxy resin. For example, when GO was added to a synthetic epoxy in loadings of 0.1 wt. %, 0.2 wt. % and 0.5 wt. %, tensile strength improved by 7 %, 9 % and 11%, respectively and tensile modulus increased by 8 %, 20 % and 24 %, respectively [1].

This study investigates the mechanical tensile strength of a green bio-epoxy composite containing GO fillers in loadings of 0.1-0.3 wt. %. The aim of the work was to evaluate the morphology of the GO filler and fractured surfaces of the

modified and unmodified composites and verify appropriate oxidation of the graphite. The initial results of this work are provided.

## II. EXPERIMENTAL

### A. Materials

Super Sap CPM/CPL a bio-based epoxy was purchased from Entropy Resins Inc., San Antonio, USA. The resin was mixed with a ratio of 10:4 by weight, bio-epoxy to hardener. Natural graphite flakes, -325 mesh ( $44\mu\text{m}$ ), 99.8% (metals basis) were provided by Alfa Aesar Thermo Fisher Scientific.

### B. Graphene Oxide Preparation

GO was prepared according to the modified Hummer's method which oxidizes graphite using sulfuric acid, sodium nitrate and potassium permanganate. The solution was purified with multiple rinsing using millipore water, 30 % hydrochloric acid and ethanol until a pH of  $\sim 7$  was reached. The product was finally vacuum dried at  $40^\circ\text{C}$  for 12 hours to produce a GO film. The film was then made into powder using a mortar and pestle.

### C. GO/Epoxy Resin Composite Preparation

The GO powder was added to acetone in separate batches in weight fractions of 0.1 wt. %, 0.2 wt. % and 0.3 wt. %. The GO powder was homogeneously dispersed and exfoliated in acetone by sonication for 1 h. The GO/acetone mixture was added to the bio-epoxy resin and mechanically stirred for another 1 h. The resin was placed in an oven at  $40^\circ\text{C}$  under vacuum overnight to evaporate the acetone. The hardener was added and mechanically stirred for 10 min. followed by vacuum degassing at room temperature for 30 min. The mixture was then poured into silicone molds and cured for 24 h at room temperature followed by a post-cure at  $82^\circ\text{C}$  for 1h. Tensile specimens are shown in Fig.1.

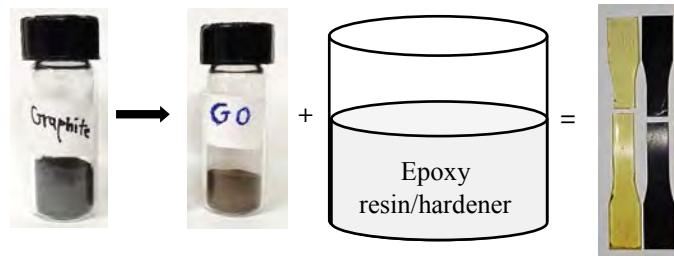

Figure 1. Schematic route for preparation of epoxy and epoxy/GO composites.

### D. Measurements and Characterization

Graphite and GO powder morphology and tensile fractured surfaces were observed by scanning electron microscopy (SEM) using a JEOL JSM-6010 LV (Tokyo, Japan) operated at 10-15 kV. The samples were coated with a thin layer of gold. Fourier transform infrared (FTIR) spectroscopy was performed on as received graphite and as synthesized GO. The FTIR spectra were conducted on a Bio-Rad FTS-40

spectrophotometer. The spectra for each analysis was obtain in reflectance mode with a resolution of  $4\text{ cm}^{-1}$  over the spectral range between 500 and  $4000\text{ cm}^{-1}$ . The samples were made into powdered form and compressed into tablets of KBr in a weight ratio of 1:10 (sample powder: KBr). Tensile strength tests were conducted using an Instron 1137 universal testing machine with a 10 kN load cell. Tensile strength was evaluated at a strain rate of 5 mm/min according to ASTM D638-14 on dog-bone specimens measuring  $165 \times 13.0 \times 3.3\text{ mm}^3$  (l x w x t). Five specimens were tested for each composite and averaged.

## III. RESULTS AND DISCUSSION

### A. Scanning Electron Microscopy Analysis

The different morphologies of the starting graphite and synthesized GO sheets are shown in Fig. 2. The majority of natural graphite has a flake-like structure, with some having smooth, rounded edges stacked together forming solid dispersed materials as shown in Fig. 2 (a). The graphite flakes also show a flat plate-like morphology with sizes less than  $44\mu\text{m}$  and thicknesses of several micrometers. After chemical oxidization, the GO material has an irregular, layered, plate-like structure as shown in Fig. 2 (b). The flakes appear to be thinner with fewer layers than the initial graphite flakes possibly due to exfoliation from the sonication process.

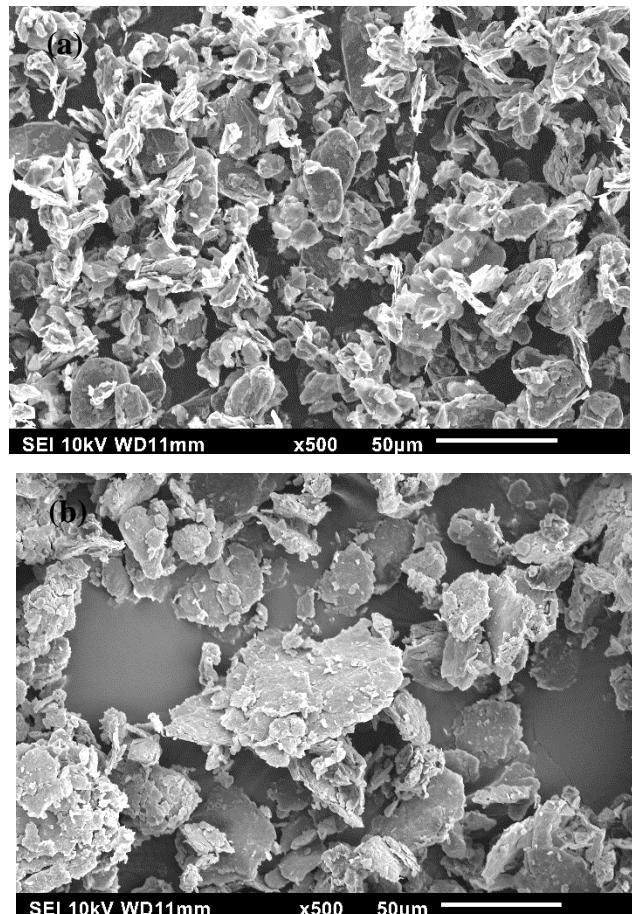

Figure 2. SEM image of (a) graphite powder and (b) GO powder.

The SEM images of the fractured tensile surfaces are shown in Fig. 3. Pure epoxy is shown in Fig. 3 (a) with its typical smooth plate-like featureless surface. Some cracks are present indicating brittle fracture (low ductility). With the addition of 0.3 wt. % GO reinforcement into the bio-epoxy polymer, the fractured surface becomes altered as shown in Fig. 3 (b). The surface appears to be rougher and more irregular with smaller failure surfaces. The image shows additional white regions which exhibits a more ductile fracture. The dispersion and possible agglomeration of GO sheets in the bio-epoxy matrix are difficult to visualize using SEM. One proposed method would be to etch the composite in sulfuric acid to reveal the GO sheets and their locations [6].

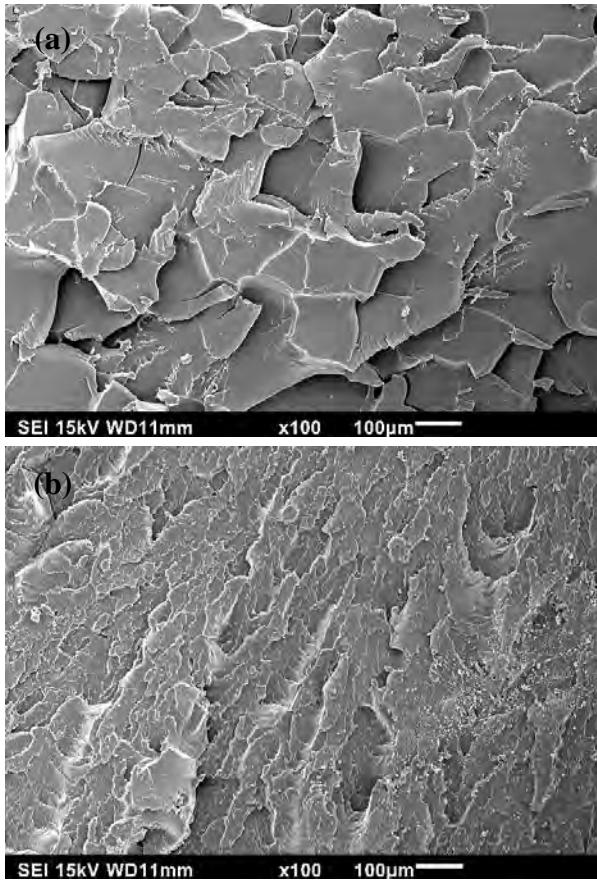

Figure 3. SEM images of fractured tensile surfaces of (a) pure epoxy and (b) epoxy/0.3 wt. % GO composite.

#### B. FTIR Analysis

FTIR tests were carried to confirm successful oxidation of graphite as shown in Fig. 4. Natural graphite powder did not show any significant peaks. In contrast, GO contains different functional groups as observed by characteristic feature peaks in the FTIR spectrum. A broad peak at 3400-3600  $\text{cm}^{-1}$  signifies O-H stretching vibration of the hydroxyl groups [1] and water absorption at 3200  $\text{cm}^{-1}$  [5]. The absorption peak at 1720-1732  $\text{cm}^{-1}$  is attributed to stretching vibration of the carbonyl ( $\text{C}=\text{O}$ )/carboxyl ( $\text{COOH}$ ) groups [1, 5]. The peak at 1620-1622  $\text{cm}^{-1}$  is attributed to the vibration of adsorbed water and vibrations from skeletal un-oxidized graphitic domain

(some regions did not oxidize) which can be assigned to the aromatic  $\text{C}=\text{C}$  bonds [5]. The 1200-1237  $\text{cm}^{-1}$  peak is the C-OH stretching from carboxylic groups [5], while the peak at 1050-1057  $\text{cm}^{-1}$  is attributed to the skeletal C-O or C-C stretching from carbonyl, carboxylic and epoxy groups [5]. FTIR confirmed GO was successfully synthesized based on the presence of the oxygen-containing functional groups (O-H,  $\text{C}=\text{O}$ ,  $\text{COOH}$ , C-OH and C-O).

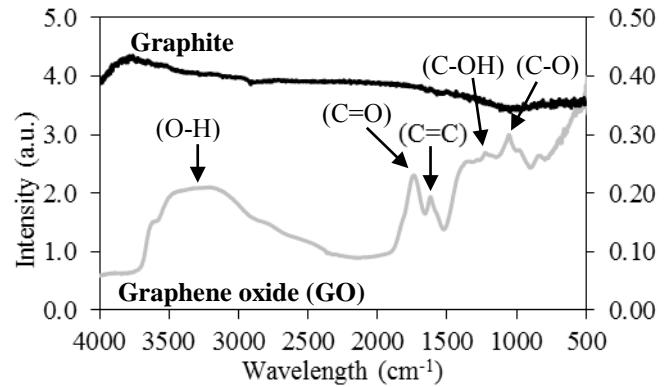

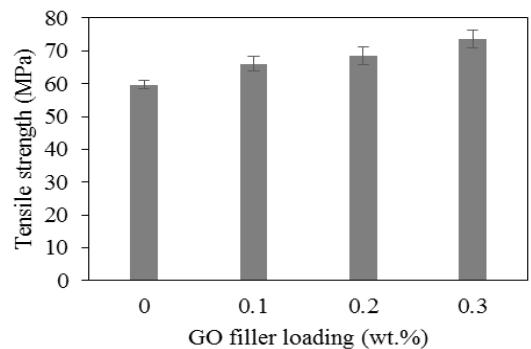

Figure 4. FTIR results for graphite (left scale) and graphene oxide (right scale).

#### C. Mechanical Properties

When GO was mixed into the bio-epoxy, the composites turned black in color as shown in Fig. 1. This occurred for all bio-epoxy/GO composite loadings, even with 0.1 wt. % GO. This change in color was also observed for epoxy composites containing 0.5-2 wt. % GO and was attributed to the addition of the GO material [6].

The tensile strength and modulus results are shown in Fig. 5 with error bars representing the standard deviations. The pure bio-epoxy had a tensile strength and modulus of 59.68 MPa and 2.6 GPa, respectively. The composites showed an improvement compared to the pure bio-epoxy for all GO filler loadings. The most significant improvement was at a loading of 0.3 wt. % GO where the tensile strength and modulus reached 73.55 MPa and 3.5 GPa, respectively which are increases of 23 % and 35 %. The large surface area and functional groups on the surface and edges of the GO sheets have an affinity to the bio-epoxy matrix [7]. This improved interaction translates to a strong interfacial adhesion and load transfer between the matrix and the GO reinforcements.

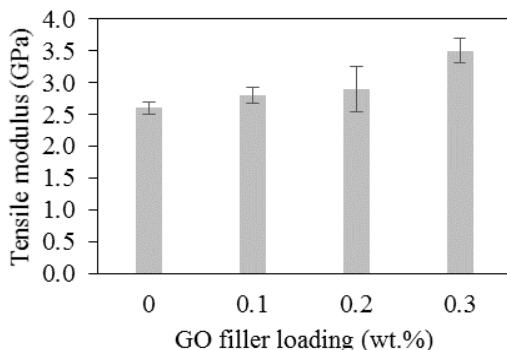

Figure 5. Tensile strengths and tensile modulus results for pure epoxy and epoxy/GO composites.

#### IV. CONCLUSION

Epoxy/GO composites have successfully been produced using a simple solution mixing method. SEM showed the fractured surfaces of the tensile samples were altered from the addition of GO. FTIR verified the presence of oxygen based functional groups on the surface of the GO material and confirmed successful oxidation of graphite using the modified Hummer's method. Both tensile strength and tensile modulus showed a steady increase with the addition of GO. With a 0.3 wt. % loading, the tensile strength improved by 23 % whereas the modulus increased by 35 % over the pure bio-epoxy. Therefore, a reinforcing effect has been observed with the addition of very small amounts of synthesized GO material. Based on the results, adding GO to a green bio-epoxy polymer is seen as a positive approach to enhance its tensile strength properties much more than traditional fillers of the same weight percentages. This composite would be able to compete in industries where synthetic epoxies are currently used.

**Abstract**—Electrically conductive polymer/carbon nanotube nanocomposites have drawn attention for a wide range of applications because of their light weight, good chemical resistance, ease of processing, and tunable multifunctional properties. High density polyethylene (HDPE)/multiwalled carbon nanotube (MWCNT) nanocomposites and their foams were fabricated, and their electrical properties were explored in this research. Parametric studies were conducted to investigate the effects of initial MWCNT loading and processing conditions on the foaming behaviors of HDPE/MWCNT nanocomposites. Experimental results revealed that both the initial MWCNT loading and foam morphology were governing factors to tune the electrical conductivity and the percolation threshold of HDPE/MWCNT nanocomposites.

**Keywords-electrical conductivity; foam morphology; multiwalled carbon nanotubes; percolation threshold; polymer nanocomposites**

## I. INTRODUCTION

Polymer/carbon nanotube (CNT) nanocomposites have drawn extensive interests from researchers and industries because of their low density, superior chemical resistance, good manufacturability, and tunable multifunctional properties. As a result, this versatile material system has found a wide spectrum of applications including electromagnetic interference shielding [1], energy harvesting [2], energy storage [3], sensors [4-6], and thermal management [7]. Recent studies have suggested foaming polymer composites and nanocomposites as a promising fabrication strategy to tailor their micro-and-nanostructures. Through biaxial stress fields induced by foam expansion, it is possible to align both one-dimensional (1D) and two-dimensional (2D) multifunctional fillers and thereby promote the material system's mechanical [8], electrical [9], and thermal [10] properties.

The electrical conductivity of a polymer/CNT nanocomposite can be drastically improved once its CNT loading has increased above a critical level, denoted as percolation threshold ( $p_c$ ). While high CNT loading promotes nanocomposites' electrical conductivity, it is detrimental to the weight, processability, and mechanical properties of

polymer/CNT nanocomposites. In this context, extensive studies were conducted to develop strategies for promoting polymer/CNT nanocomposite's electrical conductivity with lower CNT loading. These includes the utilization of hybrid conductive fillers with different types, sizes, and/or shapes as well as using immiscible polymer blends. Park et al. [11] investigated the effect of hybrid fillers on the electrical conductivity of the polypropylene (PP) composite. In their investigation, the inclusion of both MWCNT and carbon fiber in the PP matrix led to better conductivity than the case filled with only carbon fiber. In another study [12], acrylonitrile butadiene styrene (ABS) was melt-blended in polycarbonate (PC)/MWCNT nanocomposite. Due to the partial solubility of ABS in PC, the selective dispersion of the MWCNTs in the ABS phase significantly promoted the electrical conductivity while reducing  $p_c$ .

This paper reports the application of supercritical carbon dioxide ( $\text{ScCO}_2$ ) foaming to tailor the nanostructure of high density polyethylene (HDPE)/multiwalled carbon nanotube (MWCNT) nanocomposites. Parametric studies were conducted to elucidate the processing-structure-property relationships of HDPE/MWCNT nanocomposites and their foams. The effects of initial MWCNT loading and foaming temperature on the foam morphology and MWCNT networking of HDPE/MWCNT nanocomposites were studied. Furthermore, the interrelations among HDPE/MWCNT nanocomposite's foam morphology, MWCNT localization and networking, as well as the material system's electrical conductivity and percolation threshold were systematically studied. This work provides important guidelines to design and fabricate polymer/carbon nanotube nanocomposites with enhanced electrical conductivity and suppressed percolation threshold.

## II. EXPERIMENTAL

### A. Materials

Commercially available HDPE/MWCNT nanocomposite masterbatch (Nanocyl, Plasticyl HDPE1501), loaded with 15 wt% MWCNT (Nanocyl, NC7000<sup>TM</sup>), and neat HDPE (NOVA Chemicals, SCLAIR<sup>®</sup> 2710) were used to prepare HDPE/MWCNT nanocomposites of different MWCNT

loadings. The constituent MWCNT had an average length of 1.5  $\mu\text{m}$  and an average diameter of 9.5 nm. The physical foaming agent used in this study was carbon dioxide ( $\text{CO}_2$ ) (Linde Gas Inc., 99.8% purity). Tables I through III summarize the physical properties of HDPE/MWCNT masterbatch, HDPE, and MWCNT, respectively. All materials were used as received without any modification.

### B. Sample Preparation

Calculated amounts of HDPE/MWCNT nanocomposite masterbatch were weighed and the MWCNT content were reduced to various levels by adding different amounts of neat HDPE. The dilution was done by melt compounding the mixtures using a micro-compounder (HAAKE<sup>TM</sup> MiniCTW Micro-Conical Twin Screw Compounder) in the circulating mode for 5 minutes at 215°C, with the screw speed set at 75 rpm. The extrudates were pelletized and compression molded into a circular disc sample of 115 mm in diameter and 0.50 mm in thickness using a compression molding machine (Craver Press,

TABLE IV. PARAMETERS STUDIED IN PHYSICAL FOAMING EXPERIMENTS

Parameter	Value	Unit
MWCNT Loading	1, 2, 3, 5, 7, and 10	wt%
$P_{sat}$	1,200 (fixed)	psi
$T_{sat}$	123 - 135	°C
Saturation Time	30 (fixed)	min

4386 CH). The compression molding procedure is summarized below:

- STEP 1. Weighed amount of HDPE/MWCNT nanocomposite pellets were loaded into a circular disc mold of 115 mm in diameter and 0.50 mm in thickness.
- STEP 2. The compression molding machine was equilibrated at 155°C.
- STEP 3. The heat platens of the compression molding machine were brought into contact with the mold, which loaded with the nanocomposite pellets, for 5 minutes to ensure the complete melting of the nanocomposite pellets.
- STEP 4. The molding pressure was ramped up to 4,000 psi and held at this level for 6 minutes.
- STEP 5. The disc samples, which were still inside the mold, were transferred to a cooling module with flowing water channels to solidify the disc samples.
- STEP 6. The samples were cut into rectangular specimens with dimensions of 12 mm  $\times$  10 mm  $\times$  0.50 mm. The specimens would then be characterized using an electrical conductivity analyzer or be foamed by  $\text{ScCO}_2$ .

HDPE/MWCNT nanocomposite foams were fabricated by a batch foaming chamber using  $\text{ScCO}_2$  as the physical foaming agent. In the physical foaming process, nanocomposite specimens were saturated with  $\text{ScCO}_2$  for 30 minutes at preset combinations of saturation pressure ( $P_{sat}$ ) and saturation temperature ( $T_{sat}$ ). Subsequently, an outlet valve of the batch foaming chamber was opened to rapidly depressurize it. This led to thermodynamic instability in the HDPE/MWCNT/ $\text{ScCO}_2$  system, and thereby induced cell nucleation and subsequent cell growth in the HDPE matrices. Table IV summarizes the key parameters being studied in the physical foaming experiments.

### C. Sample Characterization

The apparent density of MWCNT/HDPE nanocomposite foams, were determined in accordance with ASTM D792. After measuring their masses in air and in water, the apparent density of a foam sample ( $\rho_f$ ) and the volume expansion ratio ( $\phi$ ) can be determined by Equations (1) and (2), respectively.

$$\rho_f = \frac{m_{air}\rho_{water}}{m_{air}-m_{water}} \quad (1)$$

where  $m_{air}$  and  $m_{water}$  are the masses of samples measured in air and in water, respectively; and  $\rho_{water}$  is the density of water.

$$\phi = \frac{\rho_s}{\rho_f} \quad (2)$$

where  $\rho_s$  is the density of the solid HDPE/MWCNT nanocomposite sample.

The phase and foam morphologies of the solid and foamed HDPE/MWCNT nanocomposite samples were characterized by scanning electron microscopy (SEM) (FEI Company Quanta 3D FEG). The cross-sections of all samples were exposed by cryo-fracturing the samples under liquid nitrogen. The fractured

surfaces were then sputter-coated with gold (Denton Vacuum, Desk V Sputter Coater). The cell size and cell population density of selected foam samples were obtained by analyzing the SEM micrographs of the foams using Image J (National Institute of Health). The cell population density ( $N_0$ ) with respect to the unfoamed volume was determined by Equation (3).

$$N_0 = \phi \times \left[ \frac{nM^2}{A} \right]^{\frac{3}{2}} \quad (3)$$

where  $n$  is the number of cells in the SEM micrograph;  $M$  is the magnification factor; and  $A$  is the area of the micrograph.

The electrical conductivity of solid HDPE/MWCNT nanocomposite samples were measured by the two-wire technique using a multifunctional source meter (Keithley, 2450 Source Meter). The two-wire technique was performed in accordance with the ASTM D257-07 standard. By printing conductive silver-epoxy paste as electrodes on both ends of a sample, the voltage difference was introduced through the sample and the flowing current was recorded to calculate the electrical conductivity of the nanocomposite sample. Depending on the volume expansion ratios, the thicknesses of foamed nanocomposite samples varied from 0.50 to 2.5 mm. Fig. 1 illustrates the schematic of a nanocomposite sample prepared for the two-wire technique.

### III. RESULTS AND DISCUSSION

Parametric studies were conducted to elucidate the processing-structure-property relationships of HDPE/MWCNT nanocomposite foams. On the one hand, it was expected that the presence of MWCNT would influence the  $\text{ScCO}_2$  foaming of HDPE. On the other hand, the biaxial stress fields induced by foam expansion would affect the alignment and localization of MWCNT in the HDPE matrix.

#### A. Micro-and-Nanostructures of HDPE/MWCNT Nanocomposites and Their Foams

Fig. 2 (a) and (b) illustrate representative SEM micrographs of HDPE/MWCNT nanocomposites loaded with 3 wt% and 10 wt% MWCNT, respectively. While increasing MWCNT loadings would promote the interconnectivity of MWCNT in HDPE matrices, it can be observed that continuous networks of MWCNT were omnipresent in the HDPE matrix even at 3 wt% MWCNT loading.

Fig. 3 (a) through (f) show the SEM micrographs of HDPE/MWCNT loaded with 3 wt% MWCNT before subjected to  $\text{ScCO}_2$  foaming at  $P_{\text{sat}}$  of 1,200 psi and different  $T_{\text{sat}}$ . Experimental observation revealed that foam morphologies of HDPE/MWCNT nanocomposite foams had strong dependence on  $T_{\text{sat}}$ . At 123°C, the HDPE matrix, reinforced by MWCNT, was too stiff to achieve observable foam expansion. As  $T_{\text{sat}}$  gradually increased, the foam morphologies evolved from having a high cell density with fine cells to a reduced cell density with larger cells. The foam structure was finally deteriorated when  $T_{\text{sat}}$  was increased to 135°C. In other words, within the processing window, varying  $T_{\text{sat}}$  would be an effective approach to tune the cell morphologies and thereby the MWCNT network of HDPE/MWCNT nanocomposite foams.

Figure 1. A Schematic of a Nanocomposite Sample Prepared for Electrical Conductivity Measurement by Two-Wire Technique

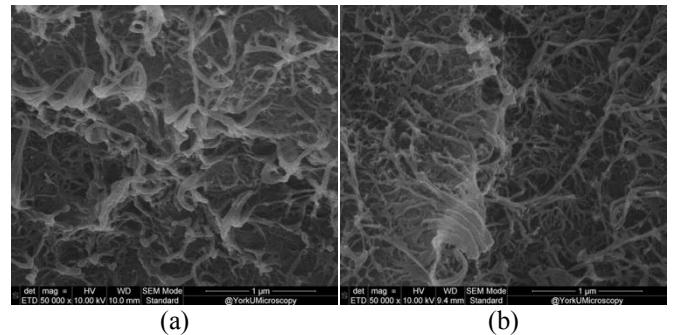

Figure 2. SEM Micrographs of HDPE/MWCNT Nanocomposites Loaded with (a) 3 wt% and (b) 10 wt% MWCNT

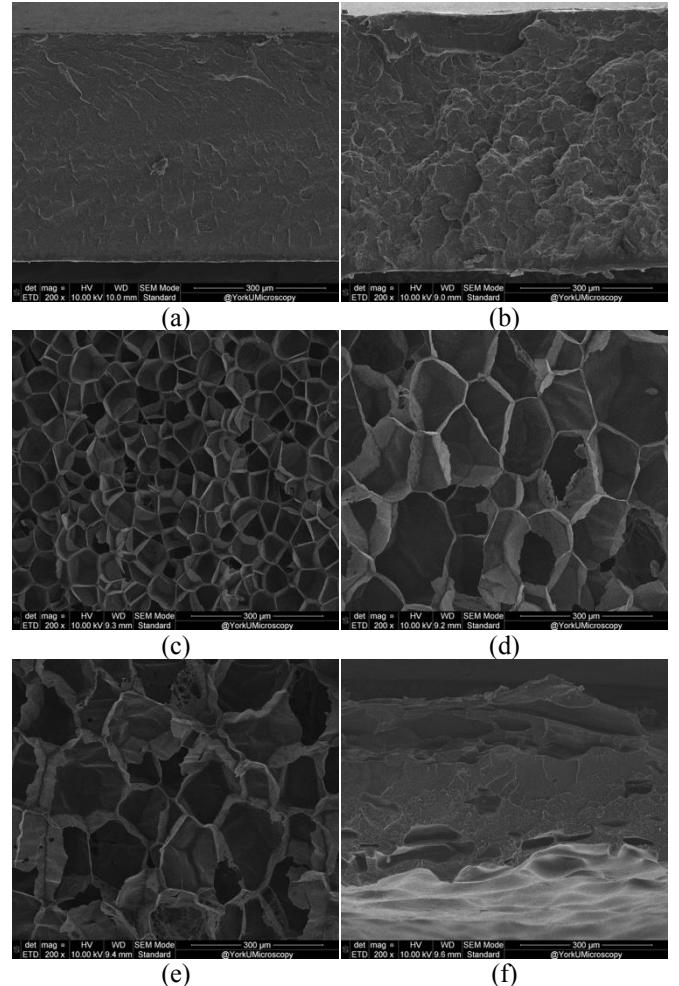

Figure 3. SEM Micrographs of HDPE/MWCNT Nanocomposite and Foams Loaded with 3 wt% Fabricated at  $P_{\text{sat}}$  of 1,200 psi and different  $T_{\text{sat}}$ : (a) Solid Nanocomposite; (b) 123°C; (c) 125°C; (d) 127°C; (e) 130°C; and (f) 135°C

## B. Foaming Behaviours of HDPE/MWCNT Nanocomposites

Experimental observation revealed that the optimal  $T_{sat}$ , to maximize the volume expansion of HDPE/MWCNT nanocomposite foams, depended on the initial loading of MWCNT. According to Fig. 4, by increasing the MWCNT content of the nanocomposites from 1 to 10 wt%, their optimal  $T_{sat}$  value also increases as the nanocomposite's melting temperature rises by increasing the MWCNT loadings. This could be attributed to the increased melt strength of the cell wall and reduced  $\text{CO}_2$  diffusivity as MWCNT loading increased.

## C. Electrical Conductivity and Percolation Thresholds of HDPE/MWCNT Nanocomposites and Their Foams

To compare solid and foamed composites, the loadings of MWCNT were converted from weight fraction to volume fraction by considering the MWCNT density to be  $1.75 \text{ g/cm}^3$  [9]. The volume fraction of MWCNT in foamed samples were calculated with respect to the total volumes of the solid part and the voids. Fig. 5 illustrates the effects of volume fractions of MWCNT on the electrical conductivity of HDPE/MWCNT nanocomposites and their foams at different initial MWCNT loadings (i.e., 3, 5, and 10 wt%). Regarding of the initial MWCNT loading, the electrical conductivity of all nanocomposites increased with the final volume fraction of MWCNT. However, depending on the initial MWCNT content, nanocomposite foams loaded with the same final volume fraction of MWCNT showed significantly different electrical conductivity values. Experimental results also indicated that at low volume fraction of MWCNT, the electrical conductivity of foamed samples was remarkably higher than the solid samples. This increase was more significant for nanocomposites with higher MWCNT loading. As an example, the electrical conductivity of HDPE/MWCNT foam samples initially loaded with 10 wt% MWCNT was two orders of magnitude higher than the solid samples at 0.5 vol% (about 1 wt%) and seven orders of magnitude higher at 0.3 vol% (about 0.5 wt%).

The value of  $p_c$  of the HDPE/MWCNT nanocomposites, which is the minimum MWCNT loading that would transform the nanocomposites from insulating to conductive, was estimated by fitting the percolation model (i.e., Equation (4)) to the experimentally obtained electrical conductivity data.

$$\sigma = \sigma_0 (p - p_c)^t \quad (4)$$

where  $\sigma$  is the electrical conductivity of the nanocomposite;  $p$  is the loading of MWCNT; and  $\sigma_0$ ,  $p_c$  and  $t$  were fitting constants and achieved by curve fitting using the root-mean-square-error method.

Fig.6 presents the effect of foaming process on reducing  $p_c$  of the solid HDPE/MWCNT nanocomposites. Experimental results indicated that  $p_c$  of HDPE/MWCNT nanocomposites effectively decreased after foaming. The initial MWCNT content was a critical factor on suppressing the percolation threshold of the nanocomposite foams. By increasing the initial MWCNT loading of the nanocomposite samples from 3 wt% to 10 wt%, the percolation threshold of the nanocomposite decreased from 0.55 vol% to 0.36 vol%.

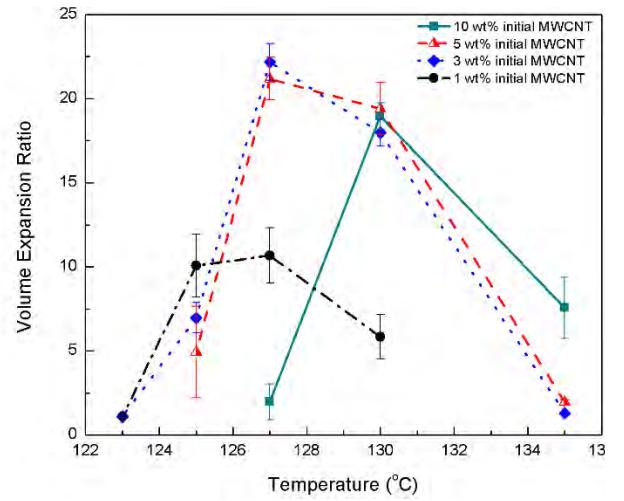

Figure 4. Effects of  $T_{sat}$  on Volume Expansion of HDPE/MWCNT Nanocomposite Foams with Different Initial MWCNT Loadings

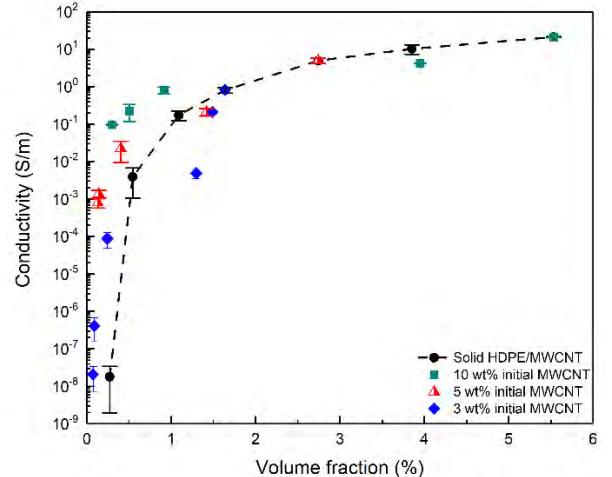

Figure 5. Effects of Volume Fractions of MWCNT on the Electrical Conductivity of HDPE/MWCNT Nanocomposites and Their Foams at different initial MWCNT loadings

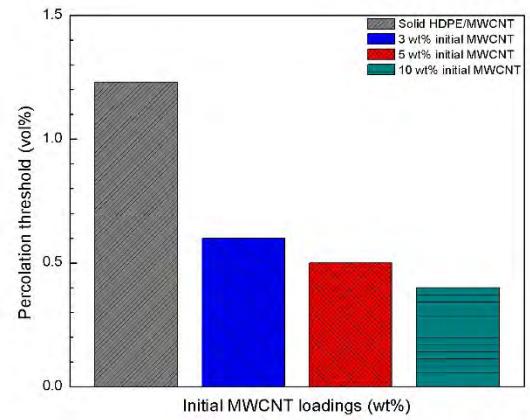

Figure 6. Percolation threshold for foams prepared with different initial MWCNT loadings vs that of solid nanocomposite

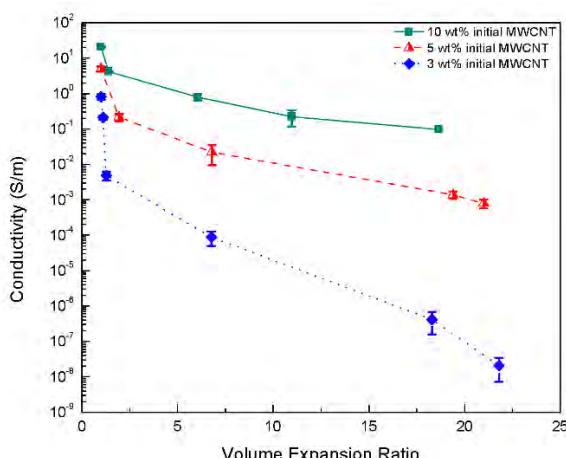

Figure 7. Effect of Volume Expansion Ratio on the Electrical Conductivity of HDPE/MWCNT Nanocomposites and Their Foams at different initial MWCNT loadings

Fig. 7 shows the dependence of electrical conductivity on the volume expansion ratio of HDPE/MWCNT nanocomposite foams. At the same initial MWCNT content, the higher expansion ratio would lead to smaller volume fractions of MWCNT, which decreased the electrical conductivity value for the foamed samples. Similar behavior was observed for all nanocomposite samples with different MWCNT initial loadings. However, it must be noted that larger volume expansion would also reduce the effective MWCNT loading in the nanocomposite foam. Overall, experimental results demonstrated that foaming was a promising strategy to increase the electrical conductivity of HDPE/MWCNT nanocomposites and to reduce the percolation threshold.

#### IV. CONCLUSION

In this study, the effects of physical foaming on the electrical conductivity and the percolation threshold of HDPE/MWCNT nanocomposites were investigated. By changing the saturation temperature, one of the governing physical foaming parameters, the effects of foam morphology and volume expansion ratio on the electrical conductivity of the foamed samples were also explored in this research. The foam morphology and volume expansion ratio of nanocomposite foams were crucially dependent on both saturation temperature and initial loadings of MWCNTs in nanocomposites. The electrical conductivity of foamed samples was significantly higher than their solid counterparts, especially at low MWCNT volume fraction. The enhancement in the electrical conductivity was more pronounced for nanocomposites with higher initial MWCNT loadings. This

also led to lower percolation thresholds than their solid nanocomposites.

**I. Abstract**— The effect of porosity on elastic modulus in low porosity materials is investigated. First, several models used to predict the reduction in elastic modulus due to porosity are compared with a compilation of experimental data to determine their ranges of validity and accuracy. The overlapping solid spheres model is found to be most accurate with the experimental data and valid between 3-10% porosity. Next, a FEM is developed with the objective of demonstrating that a macroscale plate with a center hole can be used to model the effect of microscale porosity on elastic modulus. The FEM agrees best with the overlapping solid spheres model and shows higher accuracy with experimental data than the overlapping solid spheres model.

**Keywords-porosity, elastic modulus, FEA**

## II. INTRODUCTION

### A. Background

Porosity can cause changes to a material's behaviour under loading that is different than predicted. In the extreme case, these changes, if unaccounted for, could lead to major safety and economic concerns. Therefore, the ability to accurately and easily model the effect of porosity is of paramount importance during the design and testing stages. While metals are typically not intended to contain significant pores, micro pores can be present due to manufacturing defects. These pores, which at first glance may appear inconspicuous, can increase in size during service in harsh environmental conditions. For example, in oil and gas pipelines and in hydrogen fuel tanks (typically found in aerospace), materials can be subject to high concentrations of hydrogen. Over time, hydrogen can diffuse into the material and recombine into H<sub>2</sub>, increasing the size of the initial voids and thus raising the porosity to a level that may effect the elastic modulus of the material [1-2]. However, while the effect of low levels of porosity on the yield stress has been comprehensively studied and captured in finite element software, the effect on the elastic modulus requires further research [3].

### B. Porosity and its Effect on Modulus

Significant research has been completed on the relationship between porosity and elastic modulus. Models typically agree that the relationship falls into categories based on the level of porosity. For example, the work of Zhang and Wang in [4] has

recommend subdividing porosity levels into low, medium and high porosity. Where low porosity is less than 10%, medium porosity is 10-70% and, finally, high porosity is greater than 70%. Therefore the approach taken to predict the effect of porosity on elastic modulus depends first on the degree of porosity in the material. It is important to remember that the numbers in these ranges are not necessarily exact and could possibly be better described as extremely low porosity, extremely high porosity, and then the large middle level [5]. In low porosity materials (<10% porosity) there are several suggested relationships between porosity and elastic modulus that depend only on porosity. However, they do not predict the same influence of porosity and create a potential confusion when attempting to model a porous material. Therefore, this study attempted to clarify this confusion by evaluating these models and then demonstrating the applicability of a finite element model (FEM) to accurately predict the change in elastic modulus due to porosity.

#### 1) Low Porosity Materials

For materials of low porosity there have been both analytical and experimental studies that developed a relationship to predict the elastic modulus in terms of the porosity. In this porosity level the elastic modulus is typically determined based on the assumption that voids are not interacting and that void fraction, and not void orientation, effects the materials behaviour [6]. As a result, models in the low porosity level are independent of the material and depend only on the degree of porosity.

For example, it has been suggested that a more simplified approach to modelling the elastic modulus of a porous material can be to consider the rule of mixtures used in composites to relate the modulus of two phases based on a volumetric fraction. In this case, one of the phases is considered as the solid non porous material and the other phase is the empty voids [5, 7]. However, there is a lack of research on the validity of this model or its ranges of accuracy as compared to experimental data. As another example, Coble and Kingery in [8] developed a model to describe materials with spherical pores through testing of cast alumina with porosity from 5-50%. Elastic modulus was then measured using samples in transverse bending and a model was generated that best fit experimental findings. Similarly, Maiti et al. in [9] developed a relationship between modulus and porosity by measuring the mechanical properties of three types of cellular solids as a

function of density. An analytical model was then developed based on the concept that the loading of foam first causes deflection in the cells walls, which can be calculated by relating the densities of the foams to the cell walls. While this study was initially developed to model properties as a function of density, the ratio of the densities can also be related to a porosity ratio; allowing for the subsequent development of a model to predict the behaviour of porous materials. Finally, in [10] Lu et al. studied the effect of porosity on common industrial materials such as carbon rods, woods, ceramics and foams. Based on these experimental results a micromechanical theoretical model was then developed that related the elastic modulus to the porosity for porosity less than 30%. This model considered the material as an isotropic matrix with n spherical voids of varying sizes. Average shear strains were then calculated for a given shear stress, allowing the shear and elastic modulus to be calculated as a function of porosity. The theoretical model showed good agreement with the experimental data presented.

## 2) Intermediate Porosity

It is important to note that some models developed for the intermediate porosity level have also shown accuracy with experimental values in the low porosity level. As a result, some of these analytical models were also considered for their accuracy in predicting the elastic modulus in low porosity materials. In medium porosity materials pores can interact and lead to stress redistribution in the material. Moreover, there exists a critical porosity fraction that, when reached, the material loses all stiffness and load carrying capability. Accounting for this critical porosity value, data Bert et. al. in [11] presented (1) to predict the elastic modulus of medium porosity materials through an empirical observation of trends in experimental data. This model was developed based on the assumption that the ratio of porous material property to the solid material property is proportional to the ratio of minimum solid contact area to total cross-section area in the porous material [12]. The parameters  $\phi_0$  and  $n$  must be determined for each model/material by best fitting to experimental/analytical results.

$$E(\phi) = E_0 (1 - (\phi/\phi_0))^n \quad (1)$$

Where  $E_0$  is the elastic modulus of the material without pores,  $\phi_0$  is the critical porosity value for the given material (between .37 and .97),  $\phi$  is the porosity of the material, and  $n$  is a power exponent that must be determined for each model/material.

Building on this model, in [13] Roberts and Garboczi used finite element analysis to study the influence of porosity and pore shape on the elastic properties of model porous ceramics. The study developed three different FEMs by placing spheres/ellipses in a unit cell to create various pore shapes and then best fitting the results to the model suggested by Bert in [5] to determine the  $\phi_0$  and  $n$  parameters. Predicted elastic moduli agreed well with experimental data and several models also accurately predicted the elastic modulus of materials with porosity below 10%. Therefore these models will also be considered as potential models for the low porosity level.

Similarly, Hardin and Beckermann in [5] used a FEM to determine the best fit parameters for cast steel. First, a simple

tension test and radiographic measurement was performed and a FE mesh was mapped onto an object in Abaqus. However, due to the microscopic nature of the pores, a small representative volume with a defined porosity fraction was used. A relationship for porosity was then determined by minimizing the difference between the FEM and experimental values and best fitting the results to the model suggested by Bert in [5]. Results demonstrated that this method was accurate in the prediction of strains but had significant error in predicting the elastic modulus. The paper concluded that there was no correlation between average porosity and elastic modulus and that the reason for this error in modulus was because the FEM was a representative sample of the total porosity [5]. However, while the results may not be as useful in the prediction of elastic modulus, they serve to shed light on the importance of a FEM fully accounting for variations in porosity in the material.

## C. Finite Element Models

Perhaps the most commonly referenced FEM for porous metals is the porous plasticity model found in Abaqus [14]. This model is based on the Gurson-Needleman-Tvergaard (GTN) model originally developed by Gurson in [15] and later extended by Tvergaard in [3] for the failure of ductile materials due to void coalescence. This model defines a yield potential based on an isolated spherical void and forms the basis of the porous plasticity model currently used in Abaqus to predict the behaviour of mildly voided materials. However, while the model is able to accurately predict micromechanical parameters such as yield stress, it is unable to account for the macro scale effects of the micro scale pores. For example, Hardin and Beckermann in [16] investigated using the porous plasticity model to model the influence of porosity on the yielding of cast steel. As porosity was changed the only observable difference in the stress strain curves was a change in yield stress [16]. Therefore, because there was no change in the slope of linear portion of the plot, the model does not predict a change in elastic modulus due to porosity. This finding serves to highlight the confusion at hand. While studies and intuition dictate that porosity should effect the modulus, the most commonly used models appear to ignore or not account for the effect on elastic modulus.

## D. Purpose of Study

As can be seen from the above review, several models exist to predict the influence of porosity on elastic modulus. However, because there is no study on the ranges of validity and relative accuracy of these models there is a potential confusion when attempting to predict the elastic modulus of a low porosity material. Moreover, the GTN model, a popular microscale model in Abaqus for low porosity materials, only adds to the confusion by predicting a change in the yield stress and no change in the elastic modulus. As a result, Abaqus does not have the capability to accurately predict the elastic modulus of a porous material. To help eliminate this gap in knowledge this study focused on the evaluation of models used for materials in the low porosity level. The first objective of this study was to compare the present models and to clearly identify their validity when compared to experimental data. Next, a FEM was developed with the objective of demonstrating that a

macroscale plate with a center hole can be used to the effect of microscale porosity on elastic modulus.

### III. PROCEDURES

#### A. Evaluation of Existing Models

The first step in this study was to examine experimental data to verify that there was indeed an effect of porosity on elastic modulus. This was achieved by compiling a set of previously conducted experimental data on the elastic modulus of materials with porosity ranging from 0-10%. Next, this experimental data was used to evaluate the previously suggested relationships between porosity and elastic modulus to determine their relative accuracy.

#### B. Finite Element Model Study

After determining which relationship best predicted the effect of porosity on elastic modulus a simplified FEM was then developed using the finite element software Abaqus. First, a large 2D stainless steel plate in plane stress was developed and a pressure load was applied on its right edge. The plate was fixed in the U1 direction on its left edge to model a tension test. A simulation was then run to produce a stress strain curve using the applied pressure and change in length of the plate. Finally, the slope of this curve was used to obtain an effective elastic modulus of 200 GPa; matching the inputted value and therefore verifying the model.

Next, python scripting was used to investigate the effect of pore orientations on elastic modulus. The pores simulated various degrees of porosity in the material. The above test was replicated for a range of pore orientations and stress strain curves were used to calculate the elastic modulus at 2,4,6 8 and 10% porosity. A summary of the pore orientations tested is shown in Figure 1.

Finally, based on the findings of pore orientation, python scripting was used to test plates with a center pore accounting for 1-10% of the total surface area of the plate. The center pore simulated various degrees of porosity in the plate based on the assumption that total pore volume, and not pore orientation, effects the modulus for low porosity materials. The slope of the stress strain curve was then used to obtain the effective elastic modulus for the steel at various degrees of porosity. These results were then compared with experimental data and the most accurate models from above to demonstrate that a macroscale FEM accurately predicted the influence of porosity on elastic modulus.

### IV. RESULTS AND DISCUSSION

#### A. Effect of Porosity on Elastic Modulus

While several models exist to predict the change in elastic modulus due to porosity, their relative accuracy and ranges of validity remains unknown. To close this knowledge gap a comparison between several models and experimental data was conducted. Figure 3 compiles a set of experimental data on the percent reduction in elastic modulus for a range of porous materials. The data observed a linear trend of increasing percent reduction in elastic modulus with increasing porosity ( $R^2 = .77$ ). Therefore, it is clear that porosity has a direct effect

on the elastic modulus of a material. The wide range of materials and preparation techniques for the experimental data also shed light upon the variables that should be considered when modelling porosity. For example, alumina values were obtained from two different sources [17-18]. In [18], Asmani et. al shaped alumina pellets via uniaxial pressing and then sintered these pellets at various temperatures to produce closed porosity shapes. The elastic modulus was then measured using a pulse echo method that calculated the transit time and longitudinal/transverse wave velocities. In contrast, the data provided by Knudsen in [17] was a compilation for a range of tests on the elastic modulus of alumina. Samples were prepared via cold and hot pressing and elastic modulus was determined both statically and dynamically. Therefore, given that both data sets closely follow the same trend, it appears that preparation/measuring techniques do not influence the reduction in elastic modulus. While the majority of materials closely followed this trend, porosity in HfO<sub>2</sub> resulted in a lower reduction in elastic modulus than other materials. The HfO<sub>2</sub> samples were prepared using a dried powder that was formed calcined, and then stabilized with approximately 30% Er<sub>2</sub>O<sub>3</sub> [19]. However, this additive was shown to change the microstructure and effect the baseline elastic modulus [19]. As a result, the stabilizer may have changed the porosity of the material and lead to less of a reduction in elastic modulus. Moreover, when the data for HfO<sub>2</sub> is ignored the linearity of the experimental values raises to and R-squared value of .87. Overall, because the data for several different materials followed the same linear trend it supports the conclusion that models for low porosity materials do not need to be material specific and that the pore volume is critical parameter.

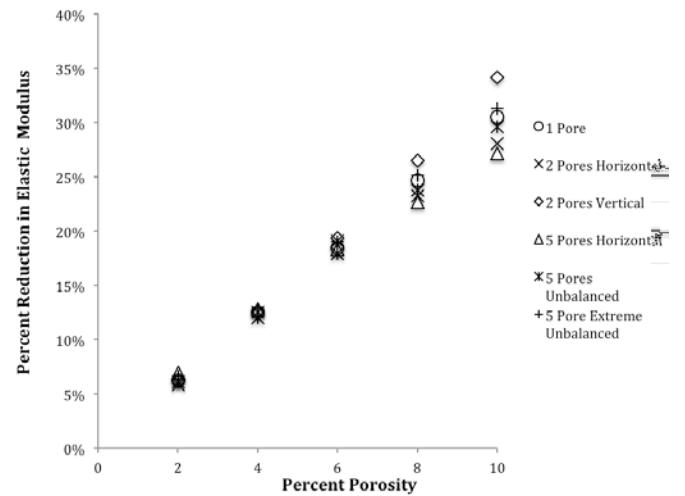

Fig. 1 – A compilation of experimental data for the percent reduction in elastic for various materials with porosity between 1-10% (Alumina 1 [17], Alumina 2[18], thermoset polyester resin [20], HfO<sub>2</sub> [19], sintered Iron [21] , MgAl<sub>2</sub>O<sub>4</sub> ([22])

#### B. Evaluation of Existing Models

Next, 6 models for low porosity materials were evaluated against the experimental data above. First, the three

relationships modelled by Roberts and Garboczi in[13] based on various pore orientations were considered (2-4). These equations were developed by placing either spheres or ellipses into a unit cell such that the orientations of these pores created various pore shapes. Results were then best fit to (1) to determine the  $\phi_0$  and  $n$  parameters.

$$E(\phi) = E_0 (1 - (\phi/0.652))^{2.23} \quad (2)$$

$$E(\phi) = E_0 (1 - (\phi/0.818))^{1.65} \quad (3)$$

$$E(\phi) = E_0 (1 - (\phi/0.798))^{2.23} \quad (4)$$

Where (2) was developed for overlapping solid spheres by placing solid spheres at random points in a unit cell, (3) was developed for overlapping spherical pores by interchanging the roles of the solid and pore phase of the overlapping solid sphere model and (4) was developed for overlapping ellipsoidal pores by changing to spherical pores to overlapping oblate ellipsoidal pores bound by a surface.

In addition to these models, the rule of mixtures (5) in [7], the model for materials with spherical holes developed by Coble and Kingery (6) in [8], the model for closed cell porous materials developed by Maiti et al. (7) in [9], and the micromechanical model suggested by Lu et al. (8) in [10] were also considered.

$$E(\phi) = E_0 (1 - \phi) \quad (5)$$

$$E(\phi) = E_0 (1 - 1.86\phi + 0.86\phi^2) \quad (6)$$

$$E(\phi) = E_0 (1 - (\phi))^3 \quad (7)$$

$$E(\phi) = E_0 (1 - 2\phi)(1 + 4\phi^2) \quad (8)$$

Figure 4 presents the predicted percent reduction in elastic modulus for each model as compared to the experimental data for low porosity materials. First from an overall perspective, all analytical models considered captured the trend of increasing percent reduction in elastic modulus with increasing porosity demonstrated by the experimental values. Between 0-2% porosity (Figure 2A) it is difficult to discern a clear trend and the range of predicted values was closely clustered between a 2-6% reduction in elastic modulus. However, as the porosity increased (Figure 2B) the range of predicted percent reduction grew to over 20% and there were stark differences in the models.

First, for the FEMs presented by Roberts and Garboczi in [13] it can be seen that the overlapping solid spheres model and ellipsoidal pores model both fell within the range of experimental values and were more accurate than the spherical pores model. Moreover, when compared to line of best fit of the experimental data the overlapping solid spheres model was the most accurate model tested. However, the micromechanical geometries of these models create potential limitations to the respective ranges of validity. For example, in the overlapping spherical pores model pores only become macroscopically connected at porosities above 30%. Therefore, an overlapping solid spheres microstructure is not applicable for low porosity materials, potentially explaining the inaccuracy with the experimental. Similarly, pores in the

overlapping ellipsoidal pores model only become macroscopically connected at porosities above 20%. However, while the range of validity for this model was also outside the porosity level in question, its validity was closer to the 0-10% level than the overlapping solid spheres model. This may help explain why it followed the experimental line of best fit closer than the overlapping solid spheres model. Finally, the overlapping spherical pores model was the most accurate of the three and, unlike the other models, has a microstructure that becomes macroscopically connected at porosities above 3%. Therefore, this model is valid within the majority of the low porosity range and was most accurate when compared to the experimental line of best fit.

When examining the other models considered it can clearly be seen that (5), the rule of mixtures model, drastically under predicted the percent reduction in elastic modulus and did not agree with any experimental data. Similarly, the models suggested by Coble and Kingery (6) and Lu (8) both under predicted the reduction in elastic modulus and agreed only with the experimental data for  $HfO_2$  presented by Dole et al. in [19]. Therefore, these models are not recommended to predict the effect of porosity on elastic modulus. In contrast, (7), the model for closed cell porous materials developed by Maiti et al., also closely followed the experimental data and was the second most accurate model when compared to the line of best fit. This model was actually derived during the development of a model to predict mechanical properties of a cellular material in compression. The initial model predicted the elastic modulus of a foam through the ratio of the relative densities and the elastic modulus of the solid cell wall. (7) was then derived by replacing the ratio of the densities of foam to solid by one minus the porosity, and by then replacing the elastic modulus of the cell wall with the elastic modulus of the solid material.

### C. Finite Element Model

#### 1) Effect of Pore Orientation on Elastic Modulus

After comparing and evaluating the existing models, the next step was to examine the applicability of a FEM for low porosity materials in Abaqus. Although porosity is a microscale phenomenon, its effect can be seen on both the yield stress (a microscale property) and on elastic modulus (a macroscale property). Therefore, the fundamental question asked by this FEM was whether microscopic pores can be approximated as one bulk macroscopic hole and then be used to accurately obtain the elastic modulus, a macroscopic property. The first step to answering this question was to investigate the effect of pore orientation on elastic modulus. This was achieved by measuring the slope of the stress strain curve of a macroscopic plate in tension in Abaqus with various pore orientations accounting for 0-10% porosity.

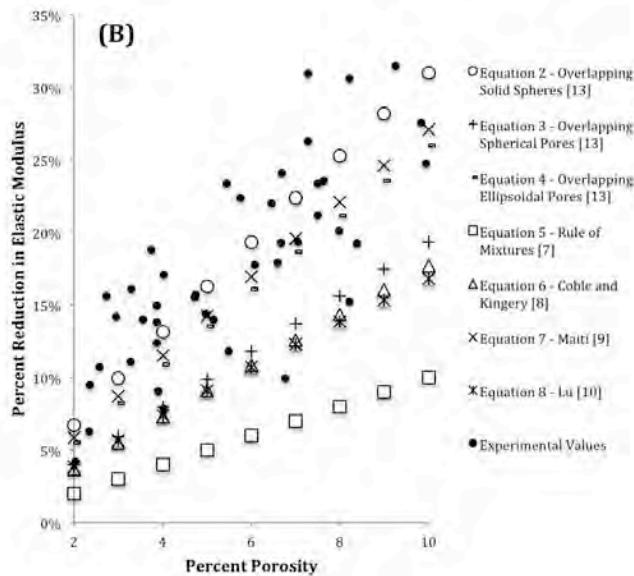

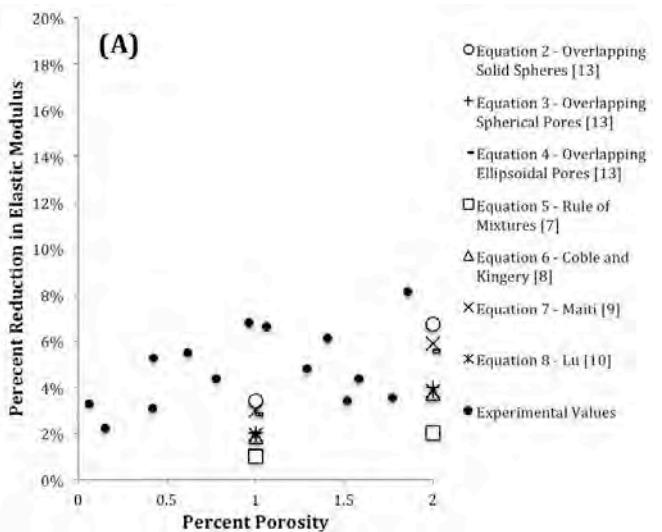

Fig. 2 - Predicted reduction in elastic modulus for various analytical models compared with experimental data for materials with porosity between 0-2% (A) and 2-10% (B)

The effect of porosity on elastic modulus for various pore orientations was compared in Figure 3. Several different pore orientations were considered that varied the size, number, and location of the pores. The maximum error between orientations occurred at 10% porosity (8.32%), while all other errors were below 6%. Therefore, changing pore orientation did not appear to cause a significant effect of the percent reduction of elastic modulus. However, it is important to note that as porosity increased the standard deviation between the various orientations also increased. For example, at 2% porosity the standard deviation between all orientations was only 0.004 and the range in predicted reduction in elastic modulus was 5.9%-6.9%. However, as the porosities increased so did the gap in the predicted reduction of elastic modulus. For example, by simply looking at Figure 3 it is clear that data at 10% porosity the results are significantly

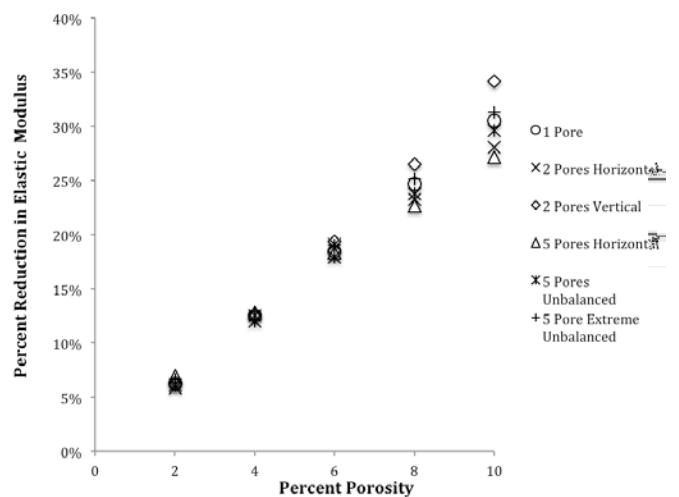

Fig. 3 - Effect of pore orientation on reduction of elastic modulus for low porosity materials.

more spread out than the at the lower porosities. At 10% porosity the standard deviation was raised by approximately seven times to 0.025 and range in values was between 27-34%. Therefore, while the assumption that pore orientation does not effect change in elastic modulus for low porosity materials was supported, there is more error in the assumption as the material nears 10% porosity. In addition, it can be seen that the 1 center pore always fell within the middle of the ranges of percent reduction in elastic modulus. Therefore, to ensure that the results were not biased by orientation, the center pore was used for comparison with analytical and experimental results.

## 2) Comparison of Finite Element Model with Analytical Models and Experimental Values

After investigating the effect of pore orientation in a FEM, the next step was to compare the FEM with analytical and experimental results. First, Figure 4 compares the predicted reduction in elastic modulus for porosities between 0-10% for the proposed FEM with the analytical models. The FEM produced a highly linear relationship between porosity and elastic modulus between 1-10% porosity ( $R^2 = .9983$ ). Over the entire porosity range the overlapping solid spheres model had the lowest average error when compared to the FEM (average error of -4.38% with standard deviation of .0216) followed by (7) (average error of 8.67% with standard deviation of .0199). Therefore, the two models shown to be most accurate to the experimental data also matched best with the proposed FEM.

Next, Figure 5 compares the results of the FEM with experimental data from several different low porosity materials. The experimental data and FEM both closely followed a similar linear trend with the FEM falling within the range determined by the various experiments. When comparing the FEM to a linear trend line of experimental data it can be seen that the FEM followed the experimental data

better than all other models for porosities between 5-10% and was second only to the overlapping solid spheres model for all other porosities. Moreover, because the overlapping solid spheres model is not valid between 0-2%, the FEM was both more accurate and applicable over a larger range of validity. Therefore, a macroscale plate with a hole was shown to successfully predict the elastic modulus of materials with micro pores.

## V. CONCLUSIONS

An accurate relationship between elastic modulus and porosity is critical to safely using materials with porosity. However, while several models exist to predict the effect of porosity on elastic modulus for low porosity materials, these relationships predict varying effects of porosity. This can create confusion for engineers looking to predict the behaviour of a porous material. Therefore, this study compared commonly used models against a compilation of experimental values. While several models did not match well with experimental values, the overlapping solid spheres model (2) best agreed well with the data. Next, this paper considered a large plate with a center pore in tension to demonstrate the validity of a using a macroscale model to predict the effect of microscale pores on the elastic modulus using FEA. The FEM matched with experimental data better than the overlapping solid spheres model and, unlike this model, was applicable for the entire low porosity range. Therefore, this study successfully demonstrated the most accurate relationship between porosity and elastic modulus and then used a FEM to improve upon this model.

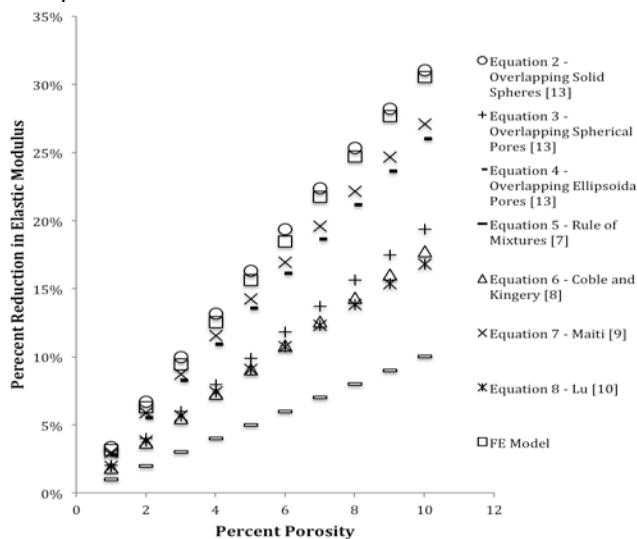

Fig. 4 – The predicted reduction in elastic modulus for porosities between 0-10% for the proposed Finite Element model as compared to analytical models.

**Abstract**— Ice accumulation on aircraft, wind turbines and power lines can have detrimental effects, including efficiency reduction, mechanical failures and the creation of safety hazards. The aim of this study is to investigate the ice adhesion and wear resistance of three hydrophobic and icephobic coatings applied onto an aluminum substrate. Ethylene-tetrafluoroethylene (ETFE) coating was deposited using a plasma spray method while advanced liquid glass (ALG) and silicone R-2180 were both applied using dipping followed by furnace curing. Water was applied and frozen between both bare and coated surfaces using a custom built jig at -20 °C for 24 hours. The ice adhesion strength was measured using a lap shear test done inside an insulated chamber. The results showed low ice adhesion strengths for both ALG and silicone R-2180 coatings when compared to the bare surface. It was also found the silicone R-2180 coating had a higher wear rate than both the ETFE and ALG coatings. By combining icephobic coatings with an ultrasonic de-icing system, the power required by the system can be reduced, creating a low-powered active approach to the de-icing problem.

**Keywords** - anti-icing, coatings, ultrasonic de-icing system, ice adhesion

## I. INTRODUCTION

Ice accumulation and wet-snow adhesion to solid outdoor surfaces can cause severe accidents and large economic losses. Such problems are present in many fields, from aeronautics [1] to off-shore oil platforms [2] and from power lines [3] to wind turbines [4]. On aircraft, ice accumulation can result in decreased lift, increased drag, decreased thrust, reduced stall angle, altered stall characteristics and even engine failure due to ice shedding. Aircraft icing can occur both during flight and on the ground. It has led to many reported aircraft accidents including Air Florida Boeing 737 (1982) and the American Eagle ATR 72 (1997). To ensure aircraft safety, regulatory bodies such as the FAA, JAA and EASA have established regulations for anti-icing and de-icing measures.

Present-day anti-icing and de-icing strategies can be chemical, thermal, electrical, and mechanical. Chemical methods belong to the passive techniques and can be used for anti-icing and

de-icing. They can be categorized into freezing point depressants or icephobic/hydrophobic coatings. Freezing point depressants lower the freezing point of water which prevents the freezing of supercooled water droplets or creating a thin film of water between the aircraft surface/ice interface to assist ice-shedding. Viscous icephobic/hydrophobic coatings adhere to the surface, creating a thin film promoting ice-shedding. Chemicals can only be employed as an effective anti-icing strategy when being applied just prior to takeoff and reapplied for whenever the possibility of ice accretion exists on the ground. Corrosion becomes an issue with sodium chloride based inorganic freezing point depressants while organic anti-icing and de-icing chemicals (such as propylene glycol) have the potential to provide better snow and ice control performance and are less corrosive. However, organic materials are generally more costly and may be subject to dilution and pose environmental concerns.

The active methods depend on an external action being applied such as thermal, electro-thermal, electro-mechanical, or electromagnetic, and, as for passive methods, rely on the physical properties of the solid surface [5]. Thermal methods are based on the extraction of hot air from the engine, but this bleed reduces the efficiency of the engine. An electro-thermal de-icing system was adopted by Boeing in the B787 but this solution is energy-intensive. Mechanical devices such as pneumatic boots which break the accumulated ice by inflating can be implemented but these boots have a significant impact on the aerodynamics of the aircraft and a low durability. Finally, electromagnetic technologies based on the deformation of a winding are penalized by the weight of the power supply.

All of these existing methods entail disadvantages (cost, environmental concerns, large amount of power required). As such, the aviation industry is searching for a more efficient and cost-effective means for de-icing and anti-icing [6].

The authors advocate the use of hydrophobic and icephobic coatings in conjunction with electro-mechanical ice protection systems. The active ice protection systems generate shear stresses at the interface between the ice and the structure to break the accumulated ice and this shear stress required for ice shedding is reduced by the coating, which reduces the power

required by the actuators, and also the size and weight of the overall system. Based on the published literature, two main coating types can lessen the effect of ice accumulation. The first type contributes to the so called icephobic materials [7-10]. Such material reduces the shear forces required to break the accumulated layer of ice on the solid surface. The second type focuses on hydrophobic features. Surfaces coated with hydrophobic materials have a high tendency in repelling water due to the high contact angle between the water droplet and the solid surface. Hence this method eliminates the accumulation of water before water freezes and ice formation occurs. In the present study, two hydrophobic coatings (Ethylene-tetrafluoroethylene (ETFE), advanced liquid glass (ALG)) and one icephobic coating (silicone R-2180) were applied onto the aluminum (Al) 2024 substrate and tested for ice adhesion strength and wear resistance. These coatings were selected to experiment with different coating application methods and surface properties.

## II. MATERIALS AND EXPERIMENTAL PROCEDURES

### A. Sample Preparation

The substrate material used in this study was Al 2024-T3 cut to a size of 75 mm by 25 mm for ice adhesion testing and a 25 mm by 25 mm section for the wear test. Four different surface conditions were investigated. A sandblasted (SB) coupon with no coating, a SB coupon with ethylene-tetrafluoroethylene (ETFE from Dupont) plasma sprayed coating, a SB coupon with an Advanced Liquid Glass (ALG, from Liquid Glass Shield) coating, and a SB coupon with silicone R-2180 (Nusil Technology). ETFE is similar to PTFE as they are both hydrophobic and composed of a carbon chain with fluorine reaction groups while ALG is a hydrophobic low friction coating with added silica particles. For ice adhesion tests, coating was applied only to 25 mm by 25 mm section of the coupon.

During the plasma spraying of ETFE, a mixture of 20% nitrogen gas and 80% argon was used as the carrier gas. The aluminum coupons were preheated for two minutes by the plasma stream before spraying. Other spraying parameters for ETFE coupons consisted of 190 A arc current, 220 slm argon gas flow rate and 100 mm offset distance between the nozzle and the coupons. After coating, all ETFE coupons were baked at 274°C for 20 minutes as recommended by the supplier [11].

The other two coatings, ALG and silicone R-2180, were applied using dipping application. Samples were dipped into a beaker containing ALG for 5 seconds and were cured in an air furnace at 250 °C for 1 hour. For the silicone R-2180 coating, the samples were dip coated and allowed to cure at room temperature for 30 minutes, then were placed in a furnace at 75 °C for 45 minutes and subsequently the temperature was increased to 150 °C and cured for another 135 minutes.

### B. Ice Adhesion Test

A freezing jig was manufactured to hold the coupons in place during the freezing process. The jig was designed such that the

gap clearance between the top and bottom coupons remains constant at 1 mm. The jig shown in Figure 1 uses slots to keep the coupons aligned and can hold six test specimens at once (a total of 12 coupons). A layer of parafilm was placed on top of the jig to prevent the coupons from sticking to the surface of the jig during the freezing process. Using a 1 mL syringe, 0.6 mL of deionized water was then injected into the hole in the lap shear joint (25 mm overlap) and the jig was placed in a freezer for 24 hours. This was done to ensure a complete transition of water to ice between the two coated surfaces. After 24 hours, each specimen was removed and inspected to ensure complete formation of ice between the coated surfaces.

**Figure 1:** (a) As fabricated jig used to align lap shear samples during freezing and (b) jig with sample loaded.

The ice adhesion test was carried out using a Material Testing System (MTS) to measure the force required to break the lap joint. From the measured force, the shear stress at which ice is detached from the surface can be determined. The frozen specimen was placed inside an insulated chamber and gripped by the MTS. The chamber kept the specimens at a temperature of approximately -20 °C for the duration of the test. The test setup can be found in Figure 2(a) while the inside of the chamber is shown in Figure 2(b). An axial displacement rate of 1 mm/min was used to pull the joint apart. The maximum load was then recorded for each sample.

**Figure 2:** (a) Insulated chamber shown in the MTS and (b) cross-section of the insulated chamber with a loaded sample.

In order to compare the results obtained, the adhesion reduction factor (ARF) was used and is calculated using the following equation:

$$ARF = (\tau_{aluminum}/\tau_{coating}) \quad (1)$$

where  $\tau_{aluminum}$  is the shear stress of the bare aluminum sample and  $\tau_{coating}$  is the shear stress in the coated sample being investigated. A high ARF value corresponds to a coating that has a low ice adhesion strength when compared to aluminum [12].

### C. Maintaining the Integrity of the Specifications

A pin-on-disk wear test was carried out to compare the coating's resistance to wear. It was performed under the dry sliding condition, according to ASTM 99-05 using a wear tester with model No: NEO-TRIBO MPW110 provided by NEOPLUS. This apparatus uses a rotating pin pressed under a normal force of 24.5 N against a static coating sample. The pin used was a Teflon ball with a radius of 2.5 mm. During the test, the specimen was placed horizontally with its center at a distance of 5 mm away from the vertical axis of the pin shaft. The pin (ball) was spinning at a constant speed of 50 RPM. As the result of friction/wear, a 10 mm diameter circular wear track was generated on the specimen surface. Wear loss of the coating material was measured based on the track depth. A new Teflon ball was used for each test to eliminate cross contamination between samples.

## III. RESULTS

### A. Ice Adhesion Strength Results

The lap shear test results are presented in Table 1. The bare, sandblasted aluminum samples required on average 447 kPa to shear the ice between the two coupons. This indicates that the bare sand blasted coupons exhibited a stronger adhesion to ice than the other coatings tested in this study.

**Table 1: Adhesion strength for tested coatings**

Coating	Adhesion Strength (kPa)	ARF
Sandblasted Al	447 ± 71	-
ALG	151 ± 69	2.96
ETFE	357 ± 72	1.25
R-2180	187 ± 26	2.39

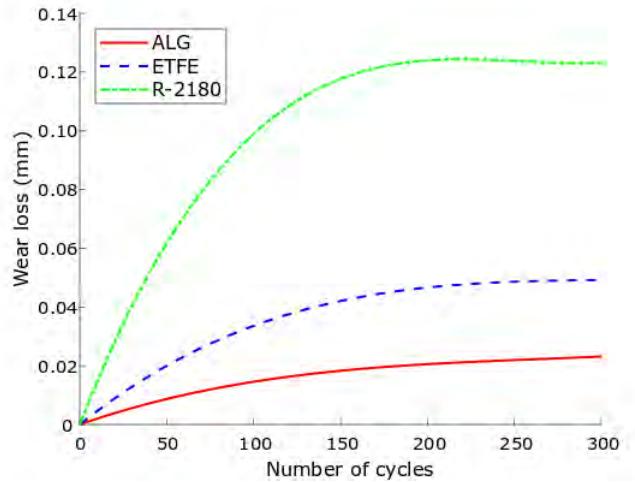

A total of six samples were shear tested for each type of the coatings. A large variation was observed in the results obtained from this study. However, these variations in adhesion strength for each coating group are similar and also comparable that from previous tests conducted by other researchers. The ice adhesion strength of aluminum has been measured as low as 242 kPa [13] and sandblasted aluminum has been measured at 610 kPa [14]. In a similar experiment carried out using a lap joint shear test conducted in an MTS, the ice adhesion strength of the bare aluminum 2024 sample

was 399.7 kPa [15] which closely resembles the 447 kPa obtained in this study. Although the results of this study do not closely match previous work [2], the ARF instead acts as a comparison tool for the tested coatings. ALG had the highest tested ARF of 2.96, followed by R-2180 (2.39) and ETFE (1.25).

There are several variables that could not be controlled during the testing and lead to deviations in the results. Any deviation in terms of actual ice temperature would have an impact on the required shear force. Another variable is the clamping pressure used during freezing. While the position of the clamps was constant for freezing each sample, the pressure exerted on each sample could be different due to the effects of the surface tension exerted by the water. Since each surface is different in the surface tension can vary significantly and cause a difference in the adhesion of ice to the sample.

### B. Wear Resistance Results

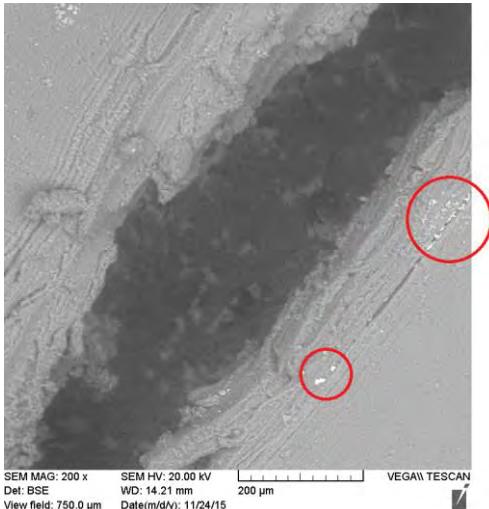

A pin on disc wear test was used to evaluate the wear resistance of the three coatings using the procedure described previously. After the wear testing was conducted, SEM images were obtained to assess the damage to the coatings. The amount of wear was dependent on the type of coating and the duration of the test. Each coating was tested for durations of 1, 2, 4 and 8 minutes. A graph showing the wear loss, in terms of wear depth tracked by the location of the pin, of the three coatings plotted against the number of cycles can be found in Figure 3. ETFE wears at a rate of approximately twice the rate of the ALG samples while the silicone R-2180 samples wear out approximately six times more than the ALG samples.

**Figure 3: Wear loss for the ALG (red), ETFE (blue) and silicone R-2180 (green) samples.**

As the test duration increased, the wear rate of each coating decreased. This can be expected as the longer the test lasts, the Teflon ball comes into contact with more coating surface area and a larger force is required to displace the coating. ALG coating, being a primarily SiO<sub>2</sub> based, was the most resistive to wear. The silicone R-2180 is an elastomer-based coating

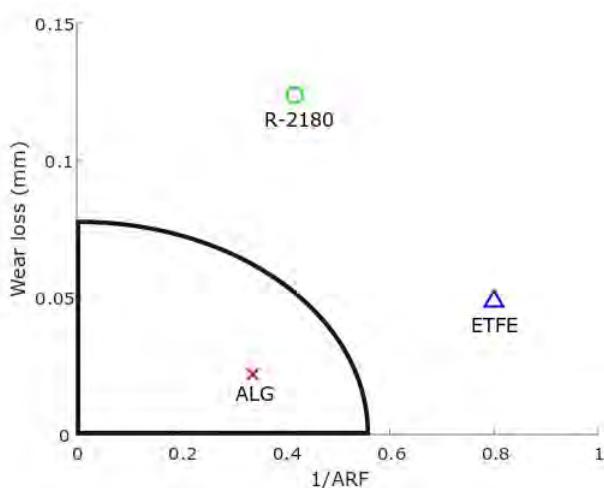

and is fairly soft so the ball could easily displace the coating along the wear track. There was also a net mass increase in each sample due to the deposition of Teflon flakes from the pin onto the sample. As the surface of the pin was in contact with the coating, flakes wore off from the tip and were left along the wear track. Figure 4 shows the flakes that were deposited into R-2180 coating that was tested for 4 minutes.

**Figure 4: Teflon flakes were deposited into the wear track.**

### C. Feasibility for anti-icing applications

A composite plot was created in order to aid the selection process of anti-icing coatings for industrial applications. This plot is shown in Figure 5. As can be seen on the plot, ALG has the combination of the highest ARF and the lowest wear loss making it the most suitable coating for anti-icing applications. Coatings in the contained region possess a high ARF and low wear rate relative to other tested coatings. Coatings outside of this region are not suitable for aircraft as they possess either an ARF that is low when compared to other coatings or can wear quickly, exposing the surface of the aircraft.

**Figure 5: Composite plot of ARF and wear loss for the tested coatings.**

### D. Potential for combined anti-icing coating and ultrasonic de-icing systems

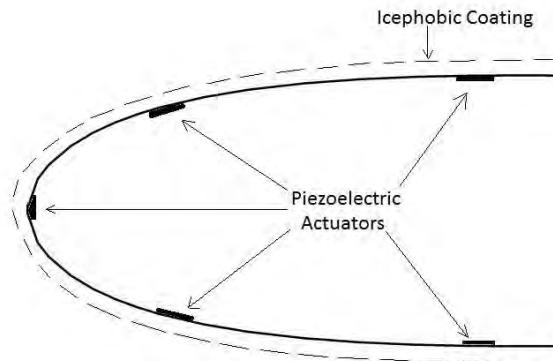

The potential exists to combine icephobic coatings with pre-existing de-icing systems to reduce the ice adhesion strength on the surface, which results in lower power consumption. Budinger *et al.* experimented with ultrasonic de-icing systems and developed a model to calculate the stress in the piezoceramic and the required voltage and current needed to delaminate a sheet of ice [16]. It was shown that the voltage and current required for delamination are linearly related to the ice adhesion strength [6]. Thus, the power required to delaminate a sheet of ice is proportional to the square of the ice adhesion strength, which means that an ARF of two would cause the power to decrease by a factor of four, reducing the size of actuator needed for the system.

Listed in Table 2 are the ARF of the tested coatings and the theoretical reduction in power due to the coating being used in conjunction with the ultrasonic de-icing system. Further decreases in the power can be achieved using icephobic coatings with a higher ARF.

**Table 2: Power reduction factor when the coating is combined with an ultrasonic de-icing system**

Coating	ARF	Power Reduction Factor
ALG	2.96	8.76
R-2180	2.39	5.71
ETFE	1.25	1.56

The proposed system is shown in Figure 6. Several piezoelectric actuators are positioned on the inside of the leading edge of the aircraft while an icephobic coating is applied on the exterior. The size and quantity of the actuators is dependent on the ARF of the selected coating. The system is similar to the Low Frequency De-Icing system (LFDI) proposed by Endres *et al.* [17] with the surface having a lower ice adhesion strength due to the icephobic coating.

**Figure 6: Proposed ice protection using both icephobic coating and piezoelectric actuators.**

#### IV. CONCLUSIONS

Ice accretion on aircraft can have catastrophic consequences and the aviation industry is looking for both passive and active approaches to prevent and eliminate ice accretion. Ice adhesion was studied on four types of surfaces with different characteristics in order to analyze their icephobic properties. Ice adhesion strength measurements were obtained using an MTS and a constant axial displacement rate. The ALG coating decreased the ice adhesion by a factor of 2.96 and the silicone R-2180 reduced the ice adhesion strength by a factor of 2.39 when compared to an uncoated aluminum substrate. In addition to analyzing the icephobic characteristics of coatings, the durability in terms of wear was also assessed to validate its continuous effectiveness against ice. The R-2180 coating wore off easily compared to the ETFE and ALG coatings. As such, ALG coating was found to be a more suitable coating for the anti-icing application as it would not need to be consistently reapplied while having the highest ARF.

By selecting a coating with a high ARF and a low wear rate, the coating can be coupled with ultrasonic de-icing systems and provide an effective solution to de-icing. The relationship between the ARF and reduction in power is exponential, which makes the ARF a critical factor when selecting a coating.

#### ACKNOWLEDGMENT

The authors would like to acknowledge Ayman Ibrahim and Fred Barrett for developing the plasma spray process used to coat ETFE samples.

# Low-Velocity Impact Response and Experimental Optimization of Modified Fiber Metal Laminates with Integrated Mechanical Interlock Bonding System

Tran-Vu Nong, M.S.A ElSayed\*

Dept. of Mechanical and Aerospace Engineering  
Carleton University  
Ottawa, Canada  
\*Mostafa.elsayed@carleton.ca

**Abstract**— This paper presents a modified version of fiber metal laminates with integrated mechanical interlock bonding system for aerospace applications. Sheet metals of Al 2024-T3 with surface machined infinitesimal hooks are used along with impregnated glass fiber composites to manufacture a modified version of GLAss REinforced aluminum (GLARE). Low-velocity impact responses of the modified GLARE is examined using a drop weight impact testing machine at an impact energy of 7.5 J. To optimize the geometry of the machined hooks to maximize the modified GLARE low-velocity impact resistance, we developed and tested four configurations of modified GLARE with four variants of hooks' geometry, including two hook sizes, namely, nano and micro and two hook profiles, namely, curved and straight. Impact tests show that modified GLARE with Straight Nano Hooks (SNH) have comparable dynamic responses to the standard GLARE (without hooks), while experiencing much less delamination and fiber damage. Microscopic inspection of the four configurations of modified GLARE also illustrates that SNHs generate modified GLARE with minimal manufacturing defects. The results obtained indicate that SNH is the optimum hook geometry for the development of modified GLARE. It can be considered as an alternative surface treatment for sheet metals in FML development process as it offers a modified version of the material with comparable impact responses to those manufactured by the industrial standard methodology but at a fraction of production cost.

## I. INTRODUCTION

Increasing demands in aerospace industries for high-performance and lightweight structures with cost-effective manufacturability have stimulated a strong trend towards the development of refined models of hybrid materials such as Fiber-metal laminates (FMLs). While FMLs possess better specific mechanical properties compared to traditional aerospace materials, it is also several times more expensive.

Thomas Letellier

École Nationale Supérieure de Mécanique et d'Aérotechnique (ISAE-ENSMA)  
Poitou-Charentes, France  
thomas.letellier@etu.isae-ensma.fr

This can be attributed to the costly surface treatments and manufacturing processes designed to improve the adhesion bonding between FML layers to minimize its consistency failures. Particularly, surface topology optimization is a key element to maximize adhesion bonding between FML layers.

Developed during the late 1980s at Delft University, GLARE was the second generation of FMLs. Through its high-strength glass Fiber Reinforced Polymers (FRP) layers, GLARE possesses better impact behavior compared to monolithic aluminum alloys and FRPs [1, 2, 3]. GLARE also possesses superior tensile strength compared to monolithic aluminum alloys [3]. In addition, GLARE is extremely resistant to environmental factors such as moisture, fire, corrosion, and lightning, and can be machined and repaired using common techniques used for aluminum alloys [4, 5, 6]. With its low density compared to monolithic aluminum alloys, GLARE can offer weight savings of up to 25% [1, 7, 8]. Given these promising properties, GLARE has been used in a variety of applications in the aerospace industry, such as in the cargo floor of the Boeing B777, the upper fuselage of the Airbus A380, and as bonded repair patches [3, 4, 8, 9].

Given that low-velocity impacts are common in aerospace structures during operation, improving the low-velocity impact response of GLARE is very important [10]. This can be done by preventing the common modes of failure that occur during impact. From existing literature [11, 12], delamination and debonding tend to be among the most important failure modes for laminated structures such as GLARE [11]. Studies have been done to prevent this type of failure by improving the adhesion at the internal interfaces between layers through metal surface treatments. Botelho et al. [12] investigated the effects of sulphuric chromic acid etching and chromic acid anodizing on the interfacial adhesion of GLARE and found that both surface treatments improved the adhesion between the aluminum and the FRP layers compared to non-treated aluminum. Ostapiuk et al. [13] found similar results with regards to sulphuric acid anodizing as well. However, these surface treatments are

expensive and/or require specialized equipment. Since one of the main disadvantages of

GLARE is its high unit cost compared to aluminum, a more cost-effective solution should be found [7, 8, 9].

In this study, the low-velocity impact behavior of a novel GLARE variant using a low-cost technology, developed by our industrial partner, is investigated. Here, machined hooks are created on the surface of sheet metal aluminum. During the curing cycle of the GLARE, those hooks penetrate the FRP layers creating an integrated mechanical interlock bonding system. While the modified GLARE possesses mechanical properties similar or comparable to those of GLARE build using the standard methodology available in the aerospace industry, the hook formation process is less costly compared to other surface treatment methods used to improve consistency failure. Moreover, we used the hot-press method to build our samples which is very cheap compared to the infrastructure required for the autoclave manufacturing process which further reduces the cost.

This paper is organized in five sections. After this introduction, the manufacturing process of the modified GLARE is explained in section 2. The test setup, procedures and results for impact testing are presented in section 3. Mechanical characterization results obtained through tensile testing are presented in section 4. The paper is concluded in section 5.

## II. MODIFIED GLARE

### A. Lay-up

We based the lay-up of the modified GLARE on those of GLARE-3 [14]. The lay-up of the modified GLARE is formed of three layers of aluminum 2024-T3 (two external layers with single-sided hooks and one middle layer with double-sided hooks) alternating with two pre-impregnated (pregregs) glass fiber layers. We used fiber layers consisting of 0.008" (0.20 mm) thick of 8H satin glass fiber weaved prepregs supplied by ACP Composites [15]. This is chosen due to availability, cost, and storage requirements.

To optimize the geometry of the hooks, four configurations of modified GLARE are considered in this study. The different configurations are based on geometry variants of the machined hooks including two hook sizes as well as two hook profiles. Table 1 summarizes the lay-up specifications of the four configurations of modified GLARE considered as well as those of the standard GLARE (with no-hooks).

### B. Hooks Development

0.016" (0.40 mm) thick ALCLAD 2024-T3 aluminum sheet metals are used. Nano and micro hooks with straight and curved profiles are machined on the surface of sheet metals using the manufacturing services at our industrial partner. Due to tooling limitations, we are able to machine the hooks on only a 6" wide sheet metal strips. The sheet metal strips are cut into 12" in length to fit within the hot-press available

for the manufacturing of GLARE. Fig. 1 shows microscopic images of the machined sheet metal with straight and curved hooks.

TABLE I. LAY-UP SUMMARY OF THE STANDARD AND MODIFIED GLARE

	Standard (No-Hooks)	Modified GLARE			
		Straight Nano Hooks (SNH)	Straight Micro Hooks (SMH)	Curved Nano Hooks (CNH)	Curved Micro Hooks (CMH)
Metal Layer	2024-T3 ALCLAD aluminum	2024-T3 ALCLAD aluminum	2024-T3 ALCLAD aluminum	2024-T3 ALCLAD aluminum	2024-T3 ALCLAD aluminum
Metal Thickness	0.016" (0.40 mm)	0.016" (0.40 mm)	0.016" (0.40 mm)	0.016" (0.40 mm)	0.016" (0.40 mm)
No. of No- Hooks Layer	3 sheets	—	—	—	—
No. of Hooked Layer	—	2 single- sided, 1 double- sided	2 single- sided, 1 double- sided	2 single- sided, 1 double- sided	2 single- sided, 1 double- sided

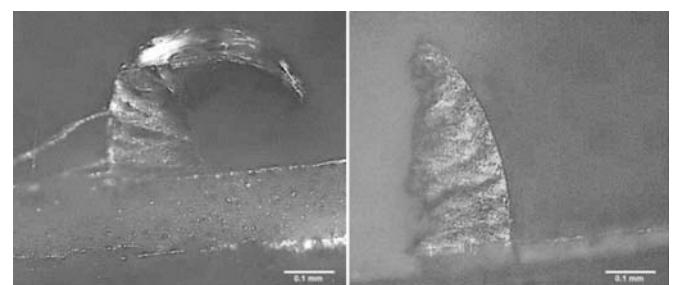

Figure 1. Microscopic view of CMH (left) and SMH (right) using AmScope Inverted Trinocular Metallurgical Microscope

### C. Manufacturing

The GLARE manufacturing process can be summarized into four distinct stages, namely, cleaning, lay-up, curing, and cutting. Prior to lay-up and curing, the prepreg layers are cut to  $152 \times 304 \text{ mm}^2$  ( $6 \times 12 \text{ in}^2$ ) and debulked in a cold hydraulic press at 1.4 metric tons of pressure for 12 hours to remove any air pockets before lay-up.

The sheet metals are then degreased with methyl ethyl ketone (MEK) followed by cleaning in an ultrasonic bath using 100 mL of soap and 20 L of water for 15 minutes, before being thoroughly rinsed with tap water and wiped down with isopropyl alcohol, as shown in Fig. 4.

Following industry standards for the manufacturing of standard GLARE, prior to lay-up, no-hook sheet metal layers, used to manufacture the standard GLARE, are further treated with grit blasting using silica sand at 110 psi and then sprayed with 40 mL of AC-130-2 Sol-Gel, produced by 3M [16]. The Sol-Gel is then left to dry for 1 hour before beginning the lay-up of the standard GLARE. Sol-Gel forms an organic layer which promotes bonding between layers.

Prior to curing, the laid-up panels are debulked once again in a hydraulic press at 1.4 metric tons of pressure for 1 hour at room temperature to promote adhesion and to remove any air trapped during lay-up. Curing was done in house using a heated Carver pneumatic press at a pressure of 1.6 tons, as shown in Fig. 4. The temperature was increased from room temperature to  $310^\circ\text{F}$  at an approximate rate of  $5^\circ\text{F}/\text{min}$ , then cured for an hour at  $310^\circ\text{F}$  before being left to cool to room temperature. Cured samples are then removed from the press once their temperature fell below  $140^\circ\text{F}$  (after approximately four hours).

Test samples are cut from the manufactured GLARE panels using a UHAP Smart Cut 6100 composite wet saw to the dimensions described in Section 3.2. The saw uses a nickel bond diamond wafering blade lubricated with distilled water to accurately cut samples to size with a precision of 0.13 mm (0.05 in).

### D. Microscopic Investigation

To check the quality of the modified GLARE panels, pre-testing microscopic analysis is conducted. Cross-sections are cut from a random selection of the manufactured panels and inspected using an optical microscope, as shown in Figs 2-5.

As shown in Fig. 2, GLARE with SNH showed the best manufacturing quality. It is observed that SNHs are able to penetrate well into the fiberglass composite which resulted in a very good integration at the interface of the different layers of the material. However, in few locations the hooks are found not penetrating the fibers and instead, the fibers are bending around the hooks creating potential gaps and fiber breakage, as shown in Fig. 2. A potential solution to this includes using a fiberglass weave with lower fiber density as well as redesigning the hooks with straight, sharper, pin profile.

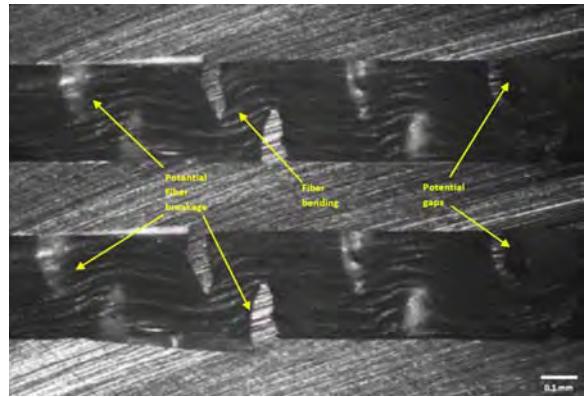

Figure 2. Microscopic view of modified GLARE with SNH using AmScope Inverted Trinocular Metallurgical Microscope

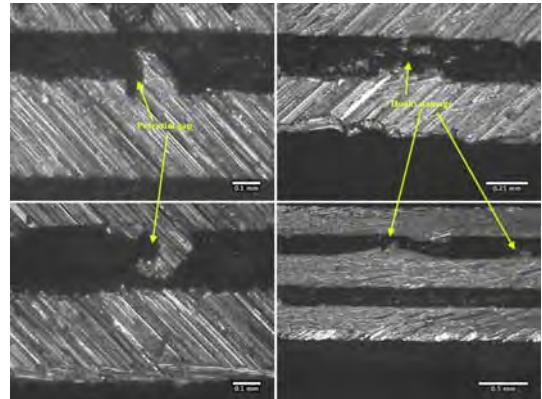

Figure 3. Four microscopic views of modified GLARE with CNH using AmScope Inverted Trinocular Metallurgical Microscope

As shown in Fig. 3, microscopic inspection of modified GLARE with CNH showed several manufacturing flaws including hooks crushing and breakage as well as development of gaps and fiber breakage. This can be attributed to the curved hook profile which significantly reduce the penetration capability of the hooks into the composite layers.

Modified GLARE with micro hooks showed the worst manufacturing quality. As shown in Fig. 4 and 5, most of the SMH and CMH are either crushed under pressure during curing or resulted in fiber breakage and development of several gaps.

## III. LOW-VELOCITY IMPACT TESTING

### A. Test Setup

Low velocity impact tests were performed using an Instron Dynatup 8200 drop weight impact tower following ASTM D7136/D7136-M [17]. A hemispherical impactor with a diameter of 25.4 mm and a mass of 10.1 kg was used in all tests. Samples were clamped using a custom-built impact fixture modelled after the impact fixture used by Laliberte et al. [18], shown in Fig. 6. The impact fixture had a filleted circular opening with a diameter of 112 mm (4.4 in) to

prevent corner and edge deformations. Three samples of each GLARE configuration are tested at 7.5J energy level, including one configuration of standard GLARE with no-hooks and four configurations of modified GLARE. Samples were cross-sectioned and examined under an optical microscope post-impact to determine internal damages.

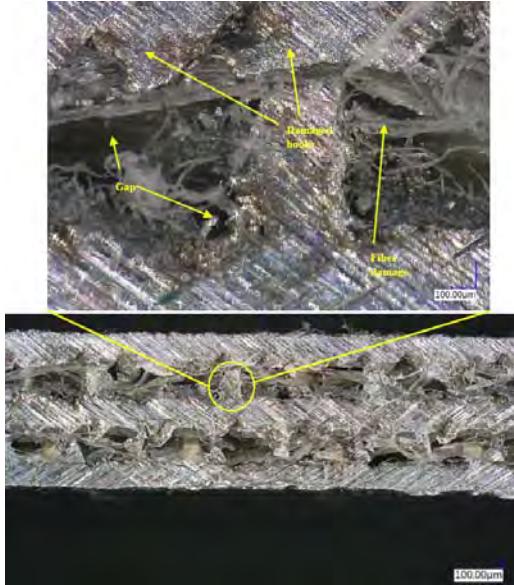

Figure 4. Microscopic views of modified GLARE with SMH using Keyence Digital Microscope VHX-6000 Series

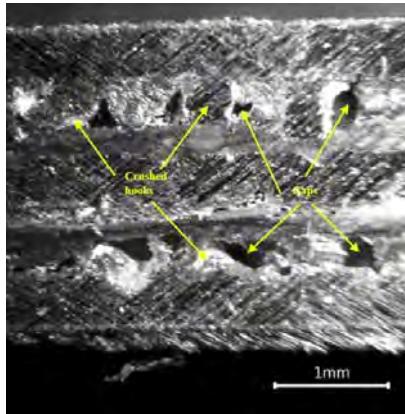

Figure 5. Microscopic view of modified GLARE with CMH using AmScope Inverted Trinocular Metallurgical Microscope

### B. Impact Response

The averaged load versus time curves for each test configuration are shown in Fig. 7. The averaged maximum load of each test configuration is shown in Table 2. As shown in Fig. 7, samples of modified GLARE with nano hooks have similar impact responses to those of standard GLARE. While the modified GLARE with SNH supports a lower maximum load than standard GLARE, as shown in

Table 2, a drop of 2% is deemed insignificant compared to cost savings during metal sheet surface preparation.

Modified GLARE with micro hooks had worse impact responses compared to modified GLARE with nano hooks and standard GLARE. Despite supporting similar maximum loads to the other GLARE configurations, modified GLARE with micro hooks experienced significant internal failure during impact, as shown by the sharp drop in supported load in Fig. 7. This is attributed to the significant presence of voids and internal defects in the micro-hooked samples, as shown in Figs. 4 and 5.

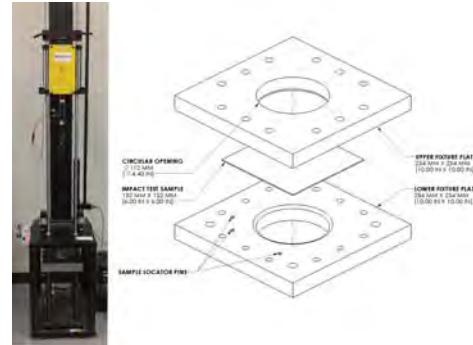

Figure 6. Drop tower (left) and custom impact fixture (right)

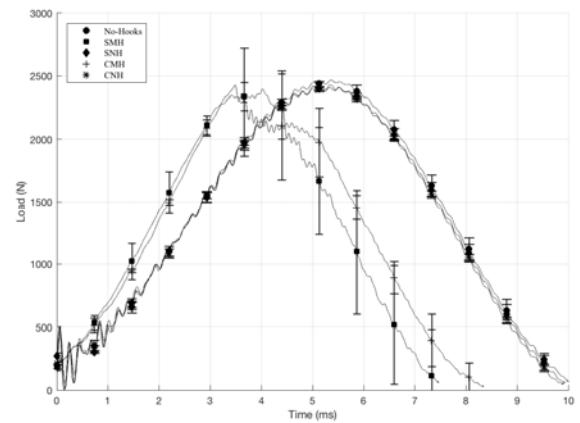

Figure 7. Averaged load v. time curves for each test configuration

TABLE II. AVERAGED MAXIMUM LOAD OF GLARE

Specimen	Averaged Maximum Load (N)
No-hooks	2571.7±19.6
SNH	2256.5±0.8
SMH	2552.0±19.6
CNH	2529.6±21.0
CMH	2588.3±156.4

### C. Damage Assessment

Fig. 8 shows a representative internal cross-section of each test configuration. As shown in Fig. 8, modified GLARE

with nano hooks experienced significantly less delamination and fiber breakage than standard GLARE.

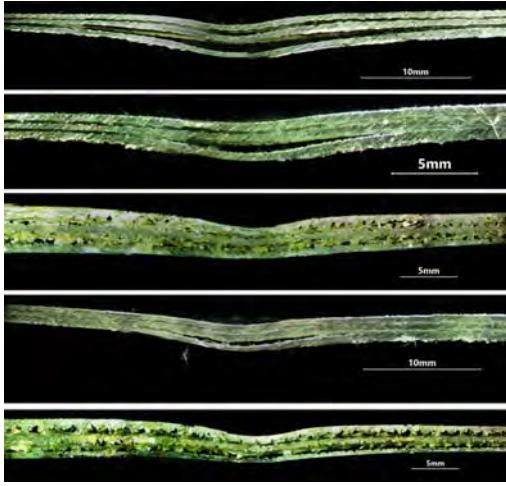

Figure 8. Internal cross sections of samples at 7.5 J, in the following order from top to bottom: standard GLARE, SNH, SMH, CNH, CMH

Standard GLARE samples also possess a larger internal damage area, as internal damages extend far beyond the impactor dent. This can be attributed to the superior interlocking behavior of the nano hooks. The modified GLARE with micro hooks experience significantly more damage than the other test configurations. In addition to experiencing major fiber breakage near the impactor dent, the modified GLARE with micro hooks are the only test configurations that experience observable cracks in the metal surfaces, as shown in Fig. 8. This is due to the reduction in strength in the metal layers due to hooks machining. Since the hooks are made directly from the sheet metal surfaces, larger hooks would remove more material, reducing its strength. Since nano hooks have smaller hooks, it would not experience as significant of an issue.

#### IV. MECHANICAL CHARACTERIZATION

Tensile tests were performed to mechanically characterize the modified GLARE. Tensile tests are performed using 810 Materials Testing System (MTS), shown in Fig. 9. Rectangular test samples are manufactured following ASTM D3039/D3039M [19] with dimensions of  $216 \times 22 \text{ mm}^2$  ( $8.5 \times 0.85 \text{ in}^2$ ) and grip lengths of 47 mm (1.85 in). Five samples of each GLARE configuration are tested including one configuration of standard GLARE with no-hooks and four configurations of modified GLARE. Samples are tested at a constant load rate of 2.0 mm/min. Test data was recorded at a frequency of 5.0 Hz.

The averaged stress versus strain curves for each test configuration are shown in Fig. 10. The averaged elastic modulus, yield strength, ultimate tensile strength, and elongation to fracture of each test configuration are shown in Table 3.

All tensile samples of modified GLARE with micro hooks as well as those of standard GLARE experienced significant fiber breakage and edge delamination upon tensile failure, as shown in Fig. 11.

Figure 9. 810 Material Testing System (MTS) (left) and a mounted tensile test sample (right)

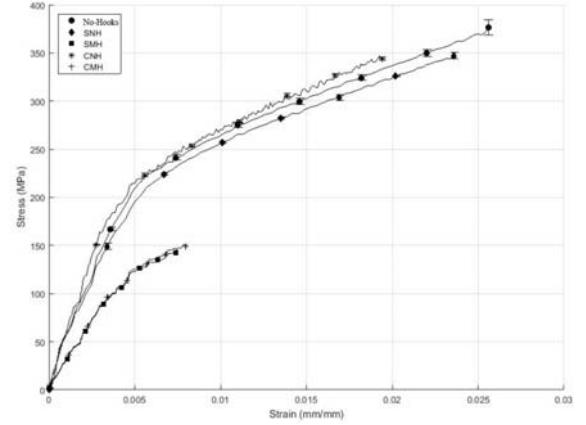

Figure 10. Tensile test results of GLARE

Also, their samples experienced full rupture upon failure, as shown in Fig. 12. Samples of modified GLARE with nano hooks tended to partially fracture, leaving the back metal sheet intact, as shown in Fig. 13. Despite earlier failure of modified GLARE samples with CNH and at lower ultimate stress level compared to standard GLARE and modified GLARE with SNH, the difference in strength between them lie only within 10% - 20%. As shown in Fig. 10 and Table 2, modified GLARE with SNH experienced drop of 4.5% and 3% in elastic modulus and yield strength, respectively, compared to the standard GLARE.

TABLE III. TENSILE MECHANICAL PROPERTIES OF GLARE

Specimen	Elastic Modulus (GPa)	Yield Strength (MPa)	Ultimate Strength (MPa)	Elongation to Break (%)
No-hooks	$42.3 \pm 0.3$	$243.4 \pm 2.3$	$378.5 \pm 8.8$	$2.69 \pm 0.1$
SNH	$40.4 \pm 1.6$	$236.8 \pm 4.6$	$362.3 \pm 16.8$	$2.63 \pm 0.29$
SMH	$28.0 \pm 0.02$	$141.5 \pm 2.3$	$143.2 \pm 2.6$	$0.75 \pm 0.02$
CNH	$53.1 \pm 1.4$	$229.9 \pm 0.8$	$352.2 \pm 2.8$	$2.02 \pm 0.07$
CMH	$28.3 \pm 0.5$	$145.7 \pm 1.8$	$156.0 \pm 6.0$	$0.93 \pm 0.15$

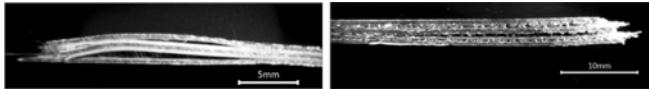

Figure 11. Fiber breakage and delamination in standard GLARE (left) and modified GLARE with CMH (right)

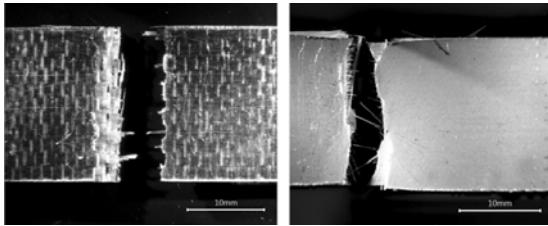

Figure 12. Top view of fractured samples of modified GLARE with CMH (left) and standard GLARE (right)

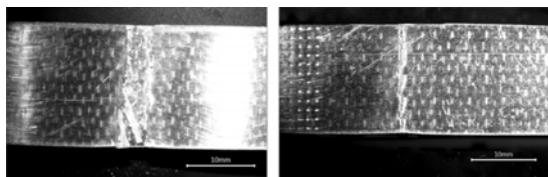

Figure 13. Partial fracture in samples of modified GLARE with SNH (left) and CNH (right)

The results from the tensile tests agree with the conclusions from the impact tests, namely comparable mechanical responses between the modified GLARE with SNH and standard GLARE, and the superior internal damage resistance of modified GLARE with SNH.

## V. CONCLUSION

The low-velocity impact response of GLARE samples with and without hooks are experimentally investigated to determine whether machined hooks can be considered as a low-cost alternative to expensive industry-standard methods of improving adhesion in FML manufacturing. Hooks of different sizes and profiles are tested to determine the optimal hook size and profile. The following conclusions are made:

Modified GLARE with SNH samples had comparable dynamic impact responses to standard GLARE samples, while outperforming the standard GLARE samples in terms of the severity and extent of internal damages. While modified GLARE with CNH had comparable behavior to that with SNH, microscopic analysis revealed that CNHs do not penetrate the fibers in the composite layer due to the shape of its profile.

Micro-hooked samples perform significantly worse compared to all other test configurations in terms of both dynamic response and internal damages. This is due to the high number of voids and internal defects in the micro-hooked samples, which stem from the composite layer being too thin to fully encompass the larger hooks. In addition, the

micro hooks are deformed or damaged due to the clamping pressure exerted on it during manufacturing.

Based on these conclusions, modified GLARE with SNH has the potential to be a viable, low-cost alternative to traditional methods of improving consistency failure in FMLs.

**Abstract**—Micro-arc oxidation (MAO) technology is attractive for the surface treatment of Mg alloys for diverse applications because it can be used to form adherent coatings with superior wear and corrosion resistance. In the present study, the corrosion protective MAO coatings were prepared on the AZ31B, AZ80 and ZK60 cast magnesium alloy at a constant current mode in an alkaline silicate electrolyte. Analysis of the surface and cross-section morphology, phase composition and microstructures of the MAO coatings and these three kinds of substrates was conducted utilizing scanning electron microscope (SEM) and X-ray diffraction (XRD) techniques. The corrosion properties of the uncoated and MAO coated Mg alloys were investigated using advanced electrochemical methods including the open circuit potential (OCP) measurement and electrochemical impedance spectroscopy (EIS). To further characterize the protectiveness of the MAO coating, the scribed MAO coated AZ31B and ZK60 alloy coupons were exposed to the continuous salt spray corrosion testing (SSCT) for 168 h. The experimental results show that the phase composition, the thickness and the microstructure of MAO coatings on different kinds of Mg alloys did not show any differences between them. While the MAO coating provides the best robust protection on the ZK60 Mg alloy substrate in the aqueous salt solution and continuous salt spray environments, the corrosion resistance increased by nearly three orders of magnitude as compared to uncoated Mg alloy.

## I. INTRODUCTION

In the automotive industry, magnesium and magnesium alloys have been given priority to be the structural components

to reduce the weight and decrease the fuel emissions [1]. As the application of magnesium alloys becoming mature, they are not only applied in the internal and unloading components, but also serviced in the external and loading parts [2,3]. However, magnesium alloy is prone to corrosion during services, which is a major factor in obstructing its application [4,5].

This paper discusses a promising surface treatment, micro-arc oxidation (MAO), to form the ceramic coatings on Mg and their alloys [6]. Up to now, the MAO coatings are widely used on different kinds of the magnesium alloy, which makes the perfect combination of the base material [7]. In this work, we chose two Mg-Al alloys (AZ31B and AZ80) and one Mg-Zn alloy (ZK60) as the substrate. Inclusion of Al can improve the corrosion resistance of magnesium alloy[8], and the zinc element with zirconium in Mg alloy has successful grain refinement and better anti-corrosion behavior [9]. For a better understanding of the correlations of MAO coatings, different substrate element alloys, corrosion kinetics in simulated service environment of automotive applications, the microstructure and corrosion properties of uncoated and MAO coated AZ31B, AZ80 and ZK60 were studied by the microscopic analysis and corrosion methods.

## II. MATERIALS AND EXPERIMENTS

### A. Materials

The materials were commercially available AZ31B [10,11], AZ80 [12] and ZK60 [9] cast Mg alloys (see Table 1). These alloys were cut into flat coupons with the dimensions of 50 mm\*25 mm\*3 mm. And then all the specimens were ground with emery paper to achieve lower surface roughness.

The processing parameters for the MAO treatment are listed in Table 2. All MAO coatings were performed at Xi'an University of Technology. After the MAO treatment, the

specimens were first cleaned with distilled water and then air dried for further analysis.

TABLE 1 Chemical composition of the substrate alloys

Alloys	Compositions (wt.%)						
	Al	Zn	Zr	Mn	Si	Cu	Mg
AZ31B	3.1	1.05	0.54	0.02	0.0008	Balance	
AZ80	8.4	0.48	0.2	0.026	0.0026	Balance	
ZK60	5.2	0.47	0.09	0.03	0.005	Balance	

TABLE 2 Processing parameters for the MAO treatment

Electrolyte composition	Na <sub>2</sub> SiO <sub>3</sub> -5 g/L; KF-8 g/L; KOH-10 g/L
Electrolyte pH	13
Current density (mA/cm <sup>2</sup> )	34
Power supply pulse width (μs)	80
Processing time (min)	5
Power supply average current(A)	1

### B. Specimen examination and test methods

For metallographic characterization of the base alloys, optical microstructure of the specimens were studied using the etching reagents, and the etching procedure was immersing specimen face up with gentle agitation until face turns brown. The surface and cross-section morphologies of the MAO coated different substrate were investigated by XL30 SEM. And phase composition of uncoated and MAO coated specimens was identified by XRD analysis.

The electrochemical measurements including open-current potential (OCP) and electrochemical impedance spectroscopy (EIS) were obtained using a Solartron Analytical 1287A potentiostat/galvanostat and Solartron 1255B Frequency Response Analyzer controlled by a personal computer at room temperature in the corrosive medium 3.5 wt.% NaCl solution.

The scribe test were conducted in the Singleton Corp.SCCH-salt fog chamber to a static environment of continuous salt spray with a concentration of 5 wt.% NaCl at 36 °C, 100% relative humidity according to ASTM B117 [13]. MAO coated AZ31B and ZK60 contained a vertical scribe parallel to major long axis (about 3.5 cm in length) down the centerline. Scribing was performed by rounded tip scribing tool to make sure that fresh Mg alloy substrate metal was exposed. The rust creepage along the scribe after corrosion testing was evaluated.

## III. RESULTS AND DISCUSSION

### A. Materials characterization

Fig.1 shows the optical micrographs of the internal structure for the AZ31B, AZ80 and ZK60 cast magnesium alloys. For AZ31B, the volume fraction ratio of the  $\beta$ -Mg<sub>17</sub>Al<sub>12</sub> is low and it is diffused in the matrix  $\alpha$ -Mg because of the low aluminum content as shown in the Fig.1a. In the AZ80 alloy, the higher content of Al element, the richer  $\beta$ -phase formed a continuous network and precipitated along the grain boundaries. There are MgZn<sub>2</sub> and Zn<sub>2</sub>Zr intermetallic compound in the

ZK60 alloy (shown in Fig.1c,d). The zirconium in ZK60 magnesium alloys can refine grain and purify the composition of alloy [14].

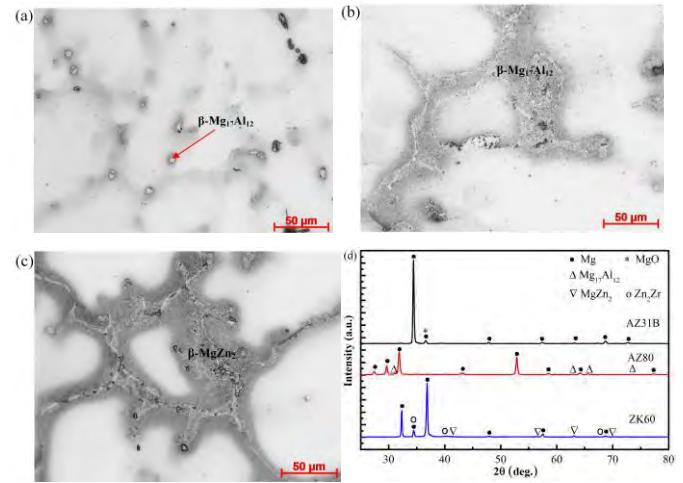

Figure 1. Optical micrographs (a,b,c) and XRD patterns (d) of the AZ31B, AZ80 and ZK60 Mg alloys

SEM images and phase compositions of the typical surface of the MAO coated magnesium alloys are shown in Fig.2. The surface of the MAO treated different Mg alloys under same processing parameters were featured by a porous morphology with lots of volcano top-like micro-pores which diameter is about 1 μm, dense and uniform ceramic coating with strong adhesion to substrate are formed on the substrates. There is no obvious difference between the surface micrographs of these three specimens. The thickness of the MAO coatings is about 5.5 μm, and a typical amount of micro-pores and micro-cracks can still be found in the coatings. Seen from the XRD spectra, it is clear that the surface of all treated specimens are mainly composed of Mg phase, MgO, MgF<sub>2</sub> and Mg<sub>2</sub>SiO<sub>4</sub>. And they also contained some complex silicate compounds Mg<sub>3</sub>Al<sub>2</sub>(SiO<sub>4</sub>)<sub>3</sub> and Mg<sub>x</sub>F<sub>y</sub>(SiO<sub>4</sub>)<sub>z</sub>.

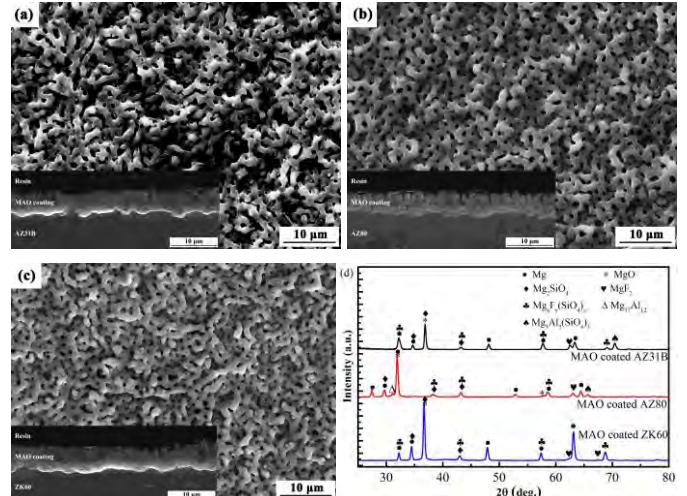

Figure 2. SEM images of the surface, cross-sectional morphology and the corresponding phase compositions (d) of the MAO coated (a) AZ31B, (b) AZ80 and (c) ZK60 Mg alloys

## B. Electrochemical corrosion test

### 1) OCP

Fig.3 shows the OCPs of these different specimens. After 30 min of immersion, all these specimens were reached to the relatively stable values of electrode potentials. Compared with the bare substrate, the OCPs of the specimens with MAO coated Mg alloys were shifted towards the noble direction. The uncoated Mg specimens had a low average OCP value of -1.54, -1.52 and -1.49 V for AZ31B, AZ80 and ZK60 Mg alloy, respectively. In contrast, all the MAO coated AZ31B, AZ80 and ZK60 specimens showed more noble average OCP values, which were -1.29, -1.28 and -1.26 V, respectively. These results suggest that MAO deposited on magnesium alloys showed a better thermodynamically stable and can improve the corrosion resistance of magnesium alloys in a dilute chloride solution.

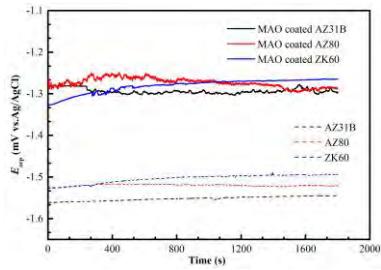

Figure 3. OCPs vs. immersion time curves in 3.5 wt% NaCl solution for uncoated and MAO coated different Mg alloys

### 2) EIS

Fig.4 shows the plots of impedance modulus vs. frequency and phase angle vs. frequency measured after the OCP test for the MAO coated and bare magnesium alloys. The equivalent circuits seen in Fig.5 were used to simulate the measured impedance data of the uncoated and MAO coated Mg alloys, and it shows the charge transfer between the reference electrode and working electrode during the corrosion process.

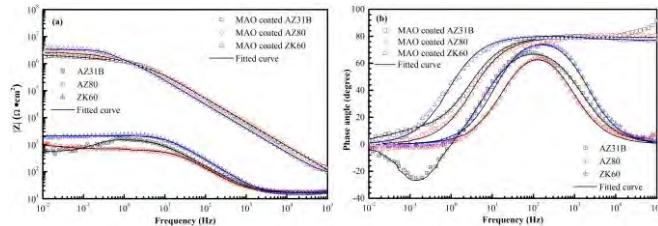

Figure 4. EIS experimental data and simulated curves for coated and uncoated Mg alloys specimens in the form of Bode plots: (a) impedance modulus vs. frequency, and (b) phase angle vs. frequency plots

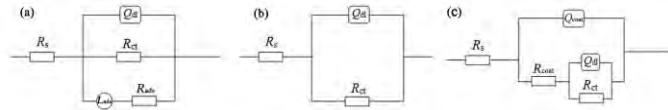

Figure 5. Equivalent electrical circuits for (a) AZ31B, (b) AZ80 and ZK60 and (c) MAO coated AZ31B, AZ80 and ZK60 alloys

For the substrate AZ31B Mg alloy, Fig.5 shows the adsorption inductance behavior in the low frequency range (less than 100 Hz) of the spectrum. Its equivalent circuit (Fig.5a) is made up of the electrolyte resistance ( $R_s$ ), charge transfer resistance ( $R_{ct}$ ) of the double-layer capacitor and

double-layer capacitance ( $Q_{dl}$ ) which are attributed to the Faradaic processes [15], adsorption resistance ( $R_{ads}$ ) and adsorption inductance ( $L_{ads}$ ) which are associated with either the corrosion products such as  $MgO/Mg(OH)_2$  formed on the surface of Mg alloy or Mg dissolution in chloride containing solution. In AZ80 and ZK60 alloy, their equivalent circuit includes  $R_s$ ,  $R_{ct}$  and  $Q_{dl}$ . The proposed equivalent circuit of MAO coated Mg alloys is shown in Fig.5c. It consists of  $R_s$ ,  $R_{ct}$  and  $Q_{dl}$ , coating resistance ( $R_{coat}$ ) and coating capacitance ( $Q_{coat}$ ) which is the virtual properties of MAO coating [16]. It can be seen from Fig.4 that the simulated curves fit very well with the experiment data. The fitting results are summarized in Table 3.

TABLE 3 Results of fitting EIS data for the uncoated and MAO coated Mg alloys specimens

Specimen	$R_{ct}$ ( $\Omega \cdot cm^2$ )	$Q_{dl}$ ( $\mu F/cm^2 \cdot s^{1-n}$ )	$n_{dl}$	$R_{ads}$ ( $\Omega \cdot cm^2$ )	$L_{ads}$ ( $H/cm^2$ )	$R_{total}$ ( $\Omega \cdot cm^2$ )	
AZ31B	$1.59 \times 10^3$	23.59	0.864	870	1415	$2.459 \times 10^3$	
AZ80	$3.31 \times 10^3$	18.92	0.901			$3.307 \times 10^3$	
ZK60	$6.34 \times 10^3$	8.72	0.938			$6.335 \times 10^3$	
Specimen	$R_{coat}$ ( $\Omega \cdot cm^2$ )	$Q_{coat}$ ( $\mu F/cm^2 \cdot s^{1-n}$ )	$n_{coat}$	$R_{ct}$ ( $\Omega \cdot cm^2$ )	$Q_{dl}$ ( $\mu F/cm^2 \cdot s^{1-n}$ )	$n_{dl}$	$R_{total}$ ( $\Omega \cdot cm^2$ )
MAO coated AZ31B	$7.97 \times 10^5$	0.066	0.885	$1.34 \times 10^6$	0.186		$0.856 \quad 2.141 \times 10^6$
MAO coated AZ80	$8.28 \times 10^5$	0.040	0.859	$2.10 \times 10^6$	0.103		$0.883 \quad 2.929 \times 10^6$
MAO coated ZK60	$2.10 \times 10^6$	0.010	0.847	$3.54 \times 10^6$	0.068		$0.895 \quad 5.645 \times 10^6$

In this work, a  $R_{ads}$  of 870  $\Omega \cdot cm^2$  was obtained for the uncoated AZ31B alloy specimen. In comparison, 3-4 orders of magnitude higher coating resistance  $R_{coat}$  ( $7.97 \times 10^5 \sim 2.10 \times 10^6 \Omega \cdot cm^2$ ) than the  $R_{ads}$  of uncoated AZ31B Mg alloy were obtained for the MAO coated specimens. It is suggested that the formation of complex compounds consisting of mainly  $Mg_2SiO_4$  and  $MgF_2$  on the alloy surface during the MAO process improved the corrosion resistance of the alloy significantly. The high  $R_{coat}$  and low  $Q_{coat}$  indicate a small number of ionic conducting pathways (pores and micro-cracks) in the MAO coating, especially for the MAO coated ZK60 Mg alloy. It should be noted that for all coated specimens the charge transfer resistance  $R_{ct}$  obtained is always higher than coating resistance  $R_{coat}$ , indicating that the charge transfer through the electrical double-layer at the coating/substrate interface is also pronouncedly impeded by the MAO coating, leading to improve the corrosion resistance of the MAO coated Mg alloy specimens.

For the charge transfer resistance ( $R_{ct}$ ), it can be acquired from the high-frequency range and correspond to the dissolution of magnesium alloy and can directly characterize the corrosion resistance of the specimens. As shown in Table 3, the MAO coated ZK60 Mg alloy specimen has a very high  $R_{ct}$  ( $3.54 \times 10^6 \Omega \cdot cm^2$ ) and low  $Q_{dl}$  ( $0.068 \mu F/cm^2 \cdot s^{1-n}$ ) compared with other coated specimens. This can be attributed to the more compact coating microstructure and elements with more positive potential obtained under such a processing condition. It is worth noticing that the polarisation resistance  $R_{total}$

( $R_{\text{total}}=R_{\text{coat}} + R_{\text{ct}}$  for MAO coated Mg alloys specimens,  $R_{\text{total}}=R_{\text{ads}} + R_{\text{ct}}$  for uncoated AZ31B specimen, and  $R_{\text{total}}=R_{\text{ct}}$  for uncoated AZ80 and ZK60 specimens) measured by EIS, as listed in Table 3, follows such an order: MAO coated ZK60 > MAO coated AZ80 > MAO coated AZ31B; for bare alloys: ZK60 > AZ80 > AZ31B. The polarisation resistance from EIS has been widely used to account for the kinetics of electrochemical corrosion process [17]. The higher polarisation resistance, the better corrosion resistance the coated specimen exhibits.

### C. Scribe testing

Fig. 6 shows the photographs of the MAO coated AZ31B and ZK60 specimens after 0 h, 72 h and 168 h exposure in the ASTM B117 test environment. After 72 h, visual corrosion damage associated with the scribe was observed on the MAO coated AZ31B alloy. None of the MAO coated ZK60 alloy exhibited any visual corrosion damage associated with the scribe. As the corrosion continues (168 h), MAO coated AZ31B specimen exhibited significantly more corrosion products relative to the MAO coated ZK60 alloy. And there are some corrosion areas occurred on the MAO coated AZ31B alloy. The visual extent of the adherent corrosion product was significantly less than the MAO coated ZK60.

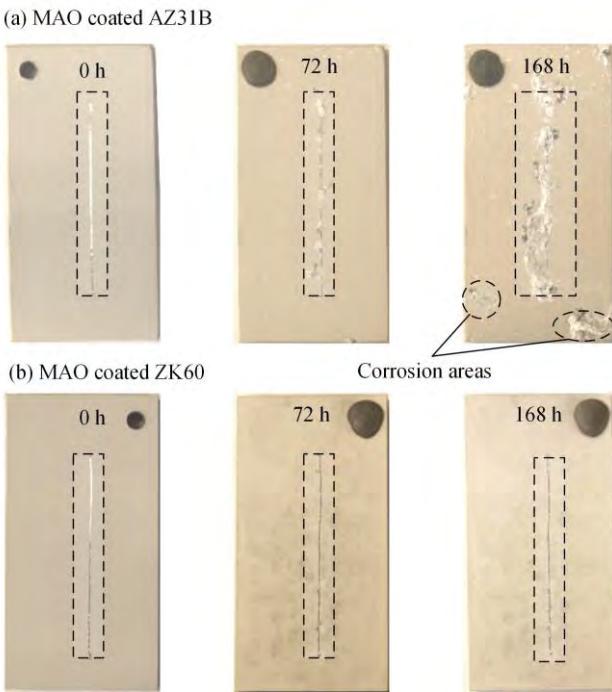

Figure 6. Photographs of the scribed MAO coated (a) AZ31B and (b) ZK60 specimens before corrosion and after ASTM B117 testing for 72 h and 168 h

It seems that the spread of corrosion from scribe was influenced more by the difference in the coating substrate. Combining the microstructure and electrochemical corrosion results, in AZ series and ZK60 alloys, the corrosion mechanism was more influenced by the Al, Zn distribution and morphology of the formed  $\beta$ -phase. The highest corrosion resistance of ZK60 among these three alloys is related to Zn and Zr elements which can form the compounds of  $\text{MgZn}_2$  and  $\text{Zn}_2\text{Zr}$  [18]. For MAO coating, the MAO coated Mg alloys

exhibited excellent corrosion performances due to the protection of the MAO coatings containing  $\text{Mg}_2\text{SiO}_4$  and  $\text{MgF}_2$  phases that have relatively stable chemical properties [19]. Under the same MAO processing parameters, there is not much difference between the thickness and density of the coating on different substrate. When the coating is broken down, its corrosion is mainly depended on the substrate properties. After the scribe testing, the MAO coating on ZK60 specimen exhibited better corrosion protection in the continuous salt spray environment than that synthesized on the AZ31B alloy.

### IV. CONCLUSIONS

In this work, the significance of the microstructure and corrosion properties of the MAO coated different kinds of magnesium alloys were evaluated using advance microstructural and surface analysis techniques, electrochemical testing method and scribe testing exposure in the ASTM B117 test environment. The conclusions can be summarized as:

- 1) The corrosion behavior of the three kinds of cast magnesium alloy of AZ31B, AZ80 and ZK60 has shown that the ZK60 Mg alloy is better than AZ80 and AZ31B.
- 2) Adherent, dense and uniform MAO coatings are grown on AZ31B, AZ80 and ZK60 Mg alloy substrates in an alkaline silicate electrolyte. SEM and XRD analysis has shown that the MAO coating is a complex mixture of compounds including  $\text{MgO}$ ,  $\text{Mg}_2\text{SiO}_4$  and  $\text{MgF}_2$ , etc. The variation of different substrate materials did not result in any marked change in the compositional or phase composition and the thickness, microstructure of the MAO coating.
- 3) MAO coatings provide robust protection of the AZ31B, AZ80 and ZK60 Mg alloys substrate in both electrochemical and scribe salt spray corrosion tests. The MAO coated ZK60 exhibited better anti-corrosion performance among these specimens.

**Abstract**— Elemental powders of Atomized Iron (Fe), Carbon (C) and Molybdenum (Mo) were weighed and mixed in a pot mill to yield the composition of C45, C45-1%Mo and C45-2%Mo Steels, then compacted and sintered. The Sintered preforms had a density- 75% of the Theoretical Density. Then the Sintered preforms were subjected to densification to get two densities- 80% and 85% of the theoretical density through Forging. The sintered and densified preforms of alloy steels are subsequently machined to get the required test specimens. The experiments were conducted on a pin-on-disc Tribometer, conforming to ASTM G99 standards, on a rotating EN32 disc. Using Minitab 16 software, the Dry Sliding wear experiments were planned using L27 Orthogonal Array. The % Theoretical Density of the Specimens, % Mo Addition, Load and Sliding Speed were taken as input parameters, mass loss was the output parameter. It was observed that the increasing density of alloy steels adversely affects the wear resistance of the alloy steels and mass loss is increased. It was found that the addition of Mo significantly improves the wear resistance of the alloy steels irrespective of the densities due to hard phase carbides present in the microstructure. Empirical correlations for mass loss with respect to input parameters had been developed using Regression Analysis. In the case of Mo added alloy, Mo particulates embedded between the ferrite-pearlite grains are observed from the microstructure.

**Keywords-** Powder Metallurgy, Wear, Sintered Steels

## I. INTRODUCTION

Tribology is a field of science which applies an operational analysis to problems of great economic significance such as reliability, maintenance and wear of technical equipment ranging from household appliances to aircraft. Derived from the Greek word ‘Tribos’, which means sliding or rubbing, the term deals with friction, wear and lubrication of the interacting surfaces in relative motion. Wear is an inevitable phenomenon and occurs at all places where there exist interacting surfaces in relative motion such as gears, bearing, coupling, sealing, cams, clutches, etc. Wear is the major cause of material wastage and loss of mechanical performance and any

reduction of which can result in considerable savings. Friction is the principle cause of wear and energy dissipation. It is estimated that one third of world’s energy resources in present use is needed to overcome friction in one form or another. One effective way to friction and wear is lubrication. Another convenient method is to devise special Tribo materials, which is more wear resistant as well as economically affordable

## II. LITERATURE SURVEY

Molinari and Straffelini [1] investigated the wear behaviour of Fe-C-Ni-Mo and Fe-C-Mo steels in three states namely steam treated, sintered and heat treated (oil quenching and stress relieving). Due to their high resistance to plastic flow, the heat-treated steels exhibited lesser wear rates. Oxidative wear is commonly observed in all the three states. The Molybdenum alloyed steel had a higher wear resistance compared to the other steels due to the evenly distributed bainite structure. Molinari and Straffelini [2] investigated the dry sliding wear behaviour of sintered and steam treated Fe-2%Cu and Fe-0.3%C alloy steels. They found that the wear rate is independent of the chemical composition of steels as long as the oxide layer forms on the outer surface and the wear rate is lesser. The Copper and Carbon alloyed steels exhibit improved wear resistance because to the domination of delamination wear mechanism. Wang and Danner [3] found that the Sintering temperature affects the wear behaviour of sintered steels with 1% Carbon and 3.5% Molybdenum addition. At a Lesser sintering temperature (11200C) the wear rate of the steels is lesser when compared with Steels subjected to the higher sintering temperature (12200C). Razavizadch and Davies [4] reported that the addition of copper as alloying element to iron based alloys significantly improves the wear resistance of the alloy steels due to predominant delamination wear process. Ceschin et al [5] have found that the increase in Molybdenum addition to Fe-C steels and higher a sintering temperature lead to significant improvement in the sliding wear resistance of Fe-C-Mo because to the formation of bainite microstructure. Gopinath [6] studied the influence of speed on the wear of sintered iron-based materials. The wear rates of sintered Fe-Cu alloys got reduced with increasing

sliding speed upto a particular threshold value, after which the trend got reversed. Zhang et al [7] observed that the addition of Sulphur (S) to Fe-Mo alloy steels contributes to reduction of the wear rate due to the chemical reactions of Sulphur with Molybdenum, which leads to the formation of Sulphide of Molybdenum, which forms adherent film on the wear surface. Murakami et al [8] observed that the Fe-Mo Steel specimen exhibited higher wear resistance at the non-annealed state when compared to the annealed specimen of the same alloy steel because of higher fracture toughness and hardness. The formation of oxides of Molybdenum during the wear test lead to lower coefficient of friction. Adhesive wear mechanism was identified as the predominant in the wear of alloy steel. Tekeli et al [9] experimentally found that the wear rate of Annealed Fe-0.3%C P/M steel, followed by water quenching was lower compared to that of as sintered state. This is due to the transformation of pearlite into martensite microstructure during quenching process. The wear mechanism found in the alloy specimen is a mixture of adhesive and abrasive wear due to high volume fraction of martensite in microstructure. Tekeli and Gural [10] have investigated the effect of microstructure and heat treatment on dry sliding wear behaviour of Sintered steels with 0.3% Carbon and 2% Nickel additions. They have experimentally found that the Tempered-Quenched specimens had lower wear resistance when compared to the Inter-Critically Annealed specimens of same composition. It was due to the detachment of surface platelets (wear debris) by micro ploughing and subsequently the predominant abrasive wear mechanism is taking place on the surface. The specimens subjected to Lower Inter-Critical annealing temperature (7280 C) exhibited lesser wear rate when compared to the specimens annealed at the higher Inter-Critical Annealing temperature (9000 C) due to the transformation of martensite from the rich austenite microstructure. Caloco et al [11] experimentally found that though the Laser Surface Melted- Sintered AISI M42 exhibited higher hardness when compared with as sintered AISI M42 specimens. The Laser Surface Melted- Sintered specimens exhibited poor wear resistance compared to sintered specimens. It was due to the complete elimination of residual porosity and formation of super saturated martensite that lead to the dominance of abrasive wear. Anton et al [12] found that the addition of 0.7% Carbon to plain carbon steels enhances their wear resistance when compared with 0.3% Carbon addition. They have also found that the addition of Manganese (Mn) alone to the 0.7% Carbon steels showed improved wear behaviour than combined Nickel-Manganese addition, due to the formation of higher percentage of martensitic-bainitic structure in a ferritic-pearlitic matrix. Abrasion-adhesion wear mechanism was found to be dominant in these alloy steels, that lead to higher wear rates. Leheup et al [13] investigated the effect of density on wear behaviour of sintered iron specimens. They have experimentally found that the wear behaviour of the sintered preforms is dependent upon the sliding amplitude rather than the density. At the higher sliding amplitude, the higher density sintered preforms are subjected to the higher wear loss compared to the lower

density specimens. Lim and Brunton [14] investigated the predominant wear mechanism of the Sintered and Non-Sintered steels were ploughing and delamination. The open pores on the sliding surfaces of sintered iron preforms acted as a site for the generation and collection of wear debris. Lim et al [15] have investigated the wear properties of unlubricated specimens of sintered and non-sintered medium and low carbon steels. They found that the wear behaviour of both the non-sintered and sintered steels were similar. Mild oxidation wear producing fine oxide debris and oxide plateau, with delamination as a secondary mechanism at higher load and speed has been reported. Kang [16] has investigated the wear behaviour of Copper based and Iron based sintered alloy materials. At mild sliding conditions Cu-based alloy had better frictional properties. On the other hand, for the severe sliding conditions Fe-based sintered material was better. At the lower load condition, the softening effect of Cu in the Cu-based alloy could prevent the wear without material transfer and the delamination wear is found predominant at the higher load and speed conditions. Dhanasekharan and Gnanamoorthy [17] found that the addition of Molybdenum Disulphide (MoS<sub>2</sub>) to Fe-C-Cu and Fe-C-Cu-Ni Sintered Steels improves the wear behaviour of alloys.

### III. SPECIMEN PREPARATION

Due to their high strength and hardness, the P/M Low alloy steels under the present study could be potential candidates for high-wear applications. Therefore, the need for studying their wear behaviour was strongly felt. Atomized powders of Iron (Fe), Carbon (Graphite Form) and Molybdenum (Mo) were weighed separately in a 4 decimal Mitutoyo Digital Balance. Then the powders were mixed according to their weight composition in pot mill and allowed to mix well for about 8 hours. Few drops of Liquid Paraffin was added as a binder to these powders. After 8 hours, the powders were taken out, weighed separately and packed for the preparation of each specimen. Compaction of premix was carried out at different pressures from 400 Mpa to 600Mpa by using Hydraulic compacting press of capacity 100 tons. Aspect ratio for samples was maintained less than 1 (L/D<1). The Die & Punch design and fabrication were carried accordingly, such that they should withstand the sufficient Load. A High Chromium High Carbon Steel Die was selected for the Compaction process as shown in Figure 3.1. The Die must be fixed and does not escape from the base plate while applying load. Initially the lower punch was inserted in the die case and placed properly in the base plate of hydraulic press. Zinc Stearate was applied over the die cavity, upper punch and lower punch. Powder was poured into the die cavity carefully. Load was applied after the contact has been made between the upper punch and upper plate of hydraulic press for the compaction of powders as shown in Figure 3.2. The load was applied gradually until required pressure has attained. After that the upper plate is moved upside and carefully the upper punch were removed for obtaining the Green Compact as shown in Figure 3.3. The Green Compact was given a coating

to prevent it from oxidation. Sintering of the coated samples was carried out in a muffle furnace. Sintering furnace of rectangular cross section (max Temp. 1250°C) with a provision for necessary reducing atmosphere was chosen for Sintering, where the loosely packed Green Compact will be transformed into metallurgically bonded sample. Samples were placed in heating zone and heated to its sintering temperature ( $T_s = 0.7 - 0.8$  Melting Point) as shown in Figure 3.4. In the first step of Sintering, the coating was removed and burned. This step is popularly known as ‘de lube’ or ‘dewax’ step. In the Second step the powder particles fuse together. The Third Step of the sintering cycle is the cooling step. Both sintering and cooling were done in controlled atmosphere. The details of the Sintering Parameters is given in Table 3.1. The Sintered Specimens had a Density about 75% of the theoretical density. Figure 3.5 shows the Sintered Specimens. Then the sintered specimens were subjected to densification through Forging. The specimens were subjected to two different loads in order to get two different densities for each alloy, namely 80% and 85% of theoretical density. The theoretical and the actual densities obtained, along with the Vicker’s Hardness is given in Table 3.2

S.No.	Sintering Parameters	Values
1	De-Lube/ De-Wax temperature	$475 \pm 30^\circ\text{C}$
2	Sintering temperature	$1100 \text{ C} \pm 10^\circ\text{C}$
3	Sintering time	120 min
4	Cooling way	Furnace cooled
5	Atmosphere used	Argon
6	Gas Flow Rate	$0.4 \text{ m}^3/\text{hr}$

#### IV. WEAR TESTING

In this work, a dry sliding wear behavior of P/M Steels were studied using a pin on-disc apparatus (DUCOM™ make). Figure 4.1 shows the arrangement of pin-on-disc apparatus. The disc material was made of EN-32 steel with a hardness of 65 HRC. The pin specimen is pressed against disc at a specified load usually by means of an arm and attached weights. The dry sliding wear tests were carried out at room temperature ( $30^{\circ}\text{C} \pm 3^{\circ}\text{C}$ , RH 55 %  $\pm 5\%$ ) under dry sliding condition in accordance with the ASTM G 99 standard. Cylindrical pins of 10 mm diameter and 25 mm long were machined and polished by metallographic method. Immediately prior to testing, were cleaned and dried using acetone to remove all dirt and foreign matter from the specimens. Initial and final weight of the specimen was measured using a Mitutoyo™ make electronic weighing machine with an accuracy of 0.0001 grams. Wear measurement is carried out to determine the amount of materials removed (or worn away) after a wear test, (and in reality after a part in service for a period of time). The material worn away can be expressed either as weight (mass) loss, volume loss, or linear dimension change depending on the purpose of the test, the type of wear, the geometry and size of the test specimens, and sometimes on the availability of a measurement facility [4]. The specimen was fixed in the arm and the disc was made to rotate below the pin. Mass of the specimen before and after the test is measured using digital balance and mass loss is found out for each set of input parameters. Wear track images and SEM images were taken to analyze the maximum wear.

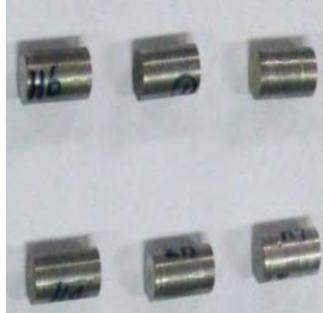

Fig 4.2: Wear Test Specimens

#### V. RESULTS AND DISCUSSIONS

The Experiments were conducted according to the Taguchi's L27 Orthogonal Array- 3 level and 4 Factors. The Input Parameters and their Levels is given in Table 5.1. The result of the output parameter Mass loss is given in Table 5.2. Minitab 16 software was used for further analysis.

Input Parameter	Level 1	Level 2	Level 3
% Theoretical Density	75	80	85
% Mo Addition	0	1	2
Load (N)	10	20	30
Sliding Speed (m/s)	1	2	3
Sliding Distance (m)	3000 m		

Table 5.1 Input parameters for Wear Test

Calculating the Signal-to-Noise ratio ( $\eta$ ) [5]: Mass Loss has to be minimized; it is smaller- the better type of quality characteristics. Hence, S/N ratio for Mass Loss is computed from the following equation:

$$\text{Smaller the better } \eta = -10 * \log\left(\frac{1}{n} * \sum_{i=1}^n y_{ij}^2\right) \quad (1)$$

S.No	% Theoretical Density	% Mo Addition	Load (N)	Sliding Velocity (m/s)	Mass Loss (g)	S/N Ratio

$$\text{Mass Loss} = 3.17363 - (0.0898507 * \% \text{ TD}) + (0.35593 \% \text{ Mo}) - (0.0257828 * \text{Load}) + (0.151944 * \text{SV}) + (0.000704889 * \% \text{TD} * \% \text{TD}) + (0.0712389 * \% \text{Mo} * \% \text{Mo}) - (2.46111e-005 * \text{Load} * \text{Load}) - (0.0179111 * \text{SV} * \text{SV}) - (90.00785467 * \% \text{TD} * \% \text{Mo}) + (0.000393511 * \% \text{TD} * \text{Load}) - (0.00129911 * \% \text{TD} * \text{SV}) - (0.00149511 * \% \text{Mo} * \text{Load}) + (0.00456444 * \% \text{Mo} * \text{SV}) + (0.000616 * \text{Load} * \text{SV})$$

$$S = 0.0700912 \quad R-\text{Sq} = 92.16\% \quad R-\text{Sq}(\text{adj}) = 83.01\%$$

The lowering in wear rate of P/M Steels can be raised due to the addition of Molybdenum and which reduces the wear rate of the P/M Steels. The decrease in the Mass loss can also be correlated by role of Molybdenum as spacers that prevent direct contact between rough surfaces. The thermal mismatch between the Iron and Molybdenum increase the dislocation density that increases the resistance of the materials to plastic deformation. The formation of solid film Oxide and Sulphides of Molybdenum, makes the C45 Steel wear resistant. At a higher loads, the thermal softening and the plastic deformation tends to prevail. From the Table 5.3, it is very clear that the % porosity (Inverse of % Theoretical Density) also plays a significant role in reducing the Wear rate of both the Steels. It is due to the fact that the pores acts as site, where there are no material present, thereby reducing the Mass Loss considerably. For the lower density preforms, the plastic deformation of material can be accommodated by the pores by reducing the volume and subsequently the effective number of

asperities is getting reduced and makes the surface smooth. This in turn leads to the reduction in wear loss. In contrast, the plastic deformation with fewer pores in higher density preforms with asperities opposing on the surfaces, which in turn makes the specimen subjected to higher wear loss.

Fig 5.2.b C45 Steel-80%TD

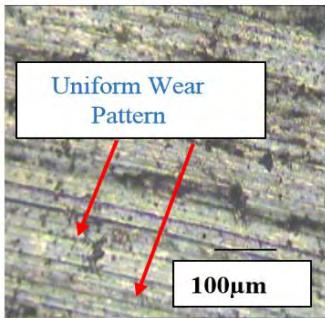

Fig 5.2.c C45 Steel-85%TD

Figure 5.2.a, b and c shows the Optical Microscope images of Maximum Worn surfaces of C45 Steel at 75%, 80% and 85% Theoretical Density (TD).

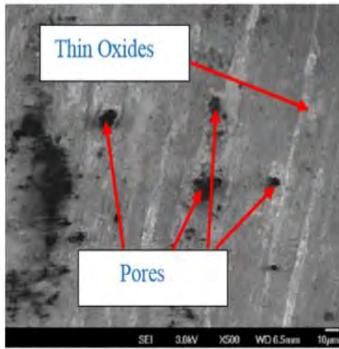

Fig 5.3.a C45 Steel-75%TD

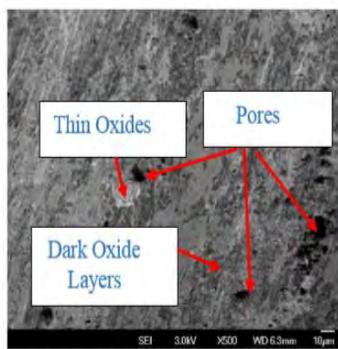

Fig 5.3.b C45 Steel-80%TD

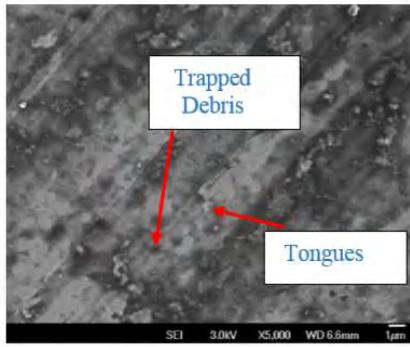

Fig 5.3.c C45 Steel-85%TD

Figure 5.3.a, b and c shows the SEM images of Maximum Worn surfaces of C45 Steel at 75%, 80% and 85% Theoretical Density(TD). It is observed that the C45 steel is subjected to uniform wear throughout the wear region and makes it uniform mass loss over the contact surface. The bright areas of thin oxide layer are visible throughout the entire wear surface micrograph and the dark areas are probably the areas fully covered by oxide [9]. The alternate white and dark areas may be the hill and groove of the wear track [10]. Few bright

particles are also observed in the image and this could be the metallic debris embedded in the pores [11]. As the plain carbon steels consists of soft ferritic-pearlitic structure, the wear loss is observed to be uniform [12]. This is evident from the uniform wear track of the surface. The wear loss is observed to be uniform. This is evident from the uniform wear track of the surface.

## REFERENCES

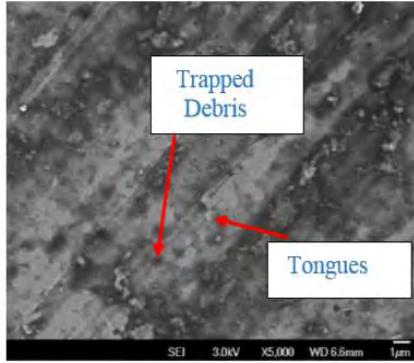

Fig 5.5.c C45-2% Mo Steel-85% TD

Figure 5.5 a, b and c shows the SEM images of Maximum Worn surfaces of C45-2% Mo Steel at 75%, 80% and 85% Theoretical Density(TD). It is clearly evident from the SEM image of Mo alloyed steels that the layered appearance shows the removal of flakes due to delamination process [14]. The trapped wear asperities in the open pores, found in some places, significantly enhance the wear resistance of the alloy steel [14]. Appearance of tongues at some places in the SEM image could be the effect of deep metallic flow of steel due to deformation, which could further contribute to the reduction of wear rate of alloy steel and consequently enhance the friction at the interface [13]. The Wear of Mo alloyed steels, irrespective of densities is Non-Uniform.

## VI. CONCLUSION

The wear resistance is increased by addition of Molybdenum to C45 Steel. Irrespective of alloy steels as density increases wear resistance decreases and mass loss increases. The C45 Steel is found to undergo uniform wear due to the soft nature of the ferritic-pearlitic micro structure, while Mo alloyed steel is subjected to non-uniform surface wear due to the presence of hard particulates. Delamination is found to be a common mode of wear for carbon and alloy steels. Addition of Mo to plain carbon steel increases the hardness [16]. Hardness of As Sintered preforms is found to be decreased when compared to densified preforms. In the case of As Sintered preforms large no. of pores are observed when compared to densified preforms [17]. Confirmation Experiments were carried with the Empirical Equation obtained. The deviation from the Actual Readings were around 20%.

## VII. ACKNOWLEDGEMENT

The Authors are thankful to Mr.N.Ramanan, Senior Engineer-R&D Division, Sharda Motors Industries Ltd, Chengalpattu-Tamil Nadu State, India, for his valuable support and guidance throughout this work.

# **Effect of the Interlacing Pattern on the Compaction Behavior of 3D Carbon Fibre Textile Reinforcements**

R. Salekrostam, F. Robitaille

Department of Mechanical Engineering

University of Ottawa

Ottawa, Canada

[Rsale051@uottawa.ca](mailto:Rsale051@uottawa.ca)

**Abstract**— 3D reinforcements were introduced to mitigate and overcome limitations arising from the use of traditional textile reinforcements in the construction of polymer matrix composites (PMC), in terms of their resistance to impact and inter-laminar shear strength (ILSS), both resulting from delamination.

Many thick interlaced textile structures were developed towards that end but many more possibilities exist in terms of yarn interlacing patterns, leading to different types of 3D textiles that may potentially be built. The effect of different interlacing patterns on the compaction behaviour of such interlaced 3D textiles is probed in this paper. Trends and differences in the compaction behaviour were observed for 5 series of 3 consecutive compaction cycles applied to 16-layers interlaced 3D reinforcements. Those trends and differences are presented and discussed.

Overall, the maximum recorded volume fraction ranged from 0.58 to 0.86. Values of the volume fraction reached in the first cycle  $C_1$  were always lower than in following cycles  $C_2$  and  $C_3$ . Although some elements of behaviour were common to all samples and tests, differences also emerged between samples featuring different interlacing patterns.

**Keywords-** *3D reinforcement fabrics; compaction; interlacing pattern; volume fraction*

## I. INTRODUCTION

3D textile reinforcements featuring relatively few through-thickness yarns may be constructed from 2D fabrics, stitching them together using structural thread to enable some level of local load transfer between layers in addition to assembling the 2D layers into a 3D textile. 2D textile layers can also be held together using technologies such as tufting or z-pins [1]. Advantages of such methods for producing simple 3D textile reinforcements include reduced labour and level of uniformity that are largely maintained, without the need for complex textile manufacturing processes. However, a suitable joining method for assembling different layers together is critical for handling of the fabrics, and for the mechanical properties of

the final PMC part [2]. For example, Quan et al. reported a multi-layer 3D textile reinforcement consisting of 2D layers of plain weave,  $0^\circ$  unidirectional non-crimp fabric,  $90^\circ$  unidirectional non-crimp fabric, and plain weave laid either side of a foam core and held together by 4 pins [3].

3D reinforcements featuring more interlacing can be produced through dedicated weaving, braiding and knitting processes using specially designed automated looms. These reinforcements are better in the sense that yarn interlacing between layers is more pervasive, more consistent, and it is effectively part of the textile design. Many interlaced fabrics featuring different yarn interlacing patterns can be designed, resulting in numerous types of 3D woven fabrics that could theoretically be built. The University of Ottawa composites group has developed its Steered Preforming Technology (uO-SPT) which enables the design and manufacturing of thick, net-shape, flat drapable 3D reinforcement fabrics featuring variable spacing between either straight or curved yarns [4, 5]. Different yarn interlacing patterns in uO-SPT reinforcements result in different properties in the dry fabrics and final composite parts made from them [3,5]. Comparing with 2D woven fabrics, different yarn interlacing patterns have led to a number of classic patterns becoming standard constructions including plain weaves, 4-harness, 5-harness and 8-harness satin weaves, and twill weaves. These patterns are used routinely in composites construction and constitute the vast majority of 2D weaves used, even as many other patterns could be created. 3D reinforcements can also be built based on a large array of possible interlacing patterns [6]. Some 3D interlacing patterns are referred to more frequently in the literature such as orthogonal and interlock constructions.

The behaviour of different reinforcements subjected to compaction normal to their plane is very important to numerous aspects of the processing of reinforcements into composite parts. Compaction controls the permeability which largely dictates how resin flows through the reinforcement during processing, and it also controls the fibre volume fraction which influences the mechanical properties of the composite parts. A number of 3D reinforcements featuring different

interlacing patterns were manufactured and their compaction behaviour are reported and compared.

## II. MATERIALS

The uO-SPT was used for manufacturing 16-layers 3D carbon fibre reinforcements featuring 3 different interlacing patterns. The aim of choosing different interlacing patterns was to probe the effect of yarn interlacing on the compaction behaviour of the reinforcements: one of the reinforcements featured limited interlacing, one featured a high level of interlacing, and one was between these extremes.

Diagrams representing these fabrics were produced using textile modeling software TexGen from the University of Nottingham [7]. It should be noted that vertical dimensions in computer models were magnified for clarity. Stitching lines do not feature in the diagrams. The interlacing patterns of the 3D reinforcements were explained through illustrations of the yarn paths in the reinforcements, also generated using TexGen.

The reinforcement shown in “Fig 1” was labelled preform #1. Preform #1 features no interlacing. Yarn paths for preform #1 are shown in “Fig 2”. “Fig 3” illustrates the second 16-layers 3D reinforcement which features highly interlaced yarns. The reinforcement shown in “Fig 3” was labelled preform #2. The yarn paths of preform#2 are shown in “Fig. 4”. The third reinforcement, which features moderate interlacing is labelled preform#3 and is shown in “Fig. 5”. “Fig. 6” illustrates the yarn paths for preform#3.

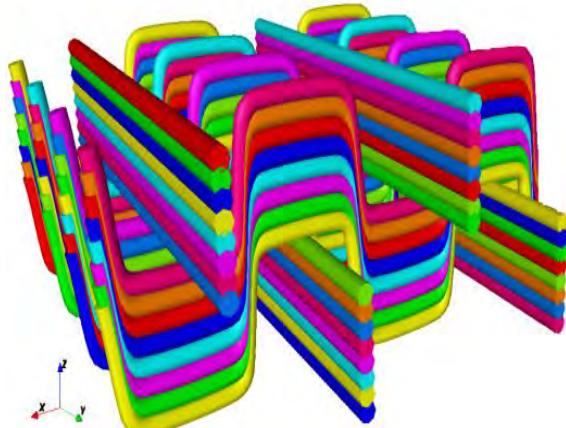

Figure 4. Yarn paths, preform #2

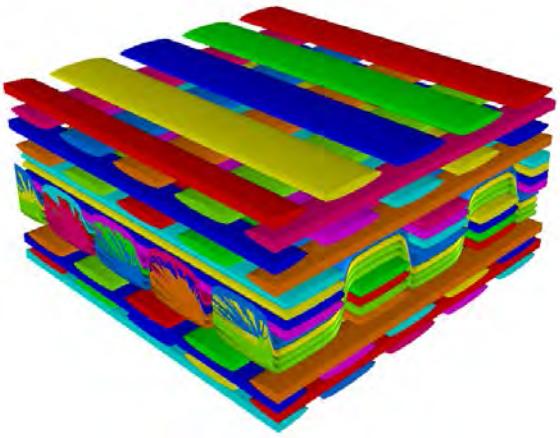

Figure 5. Preform#3, 16-layers, moderate interlacing

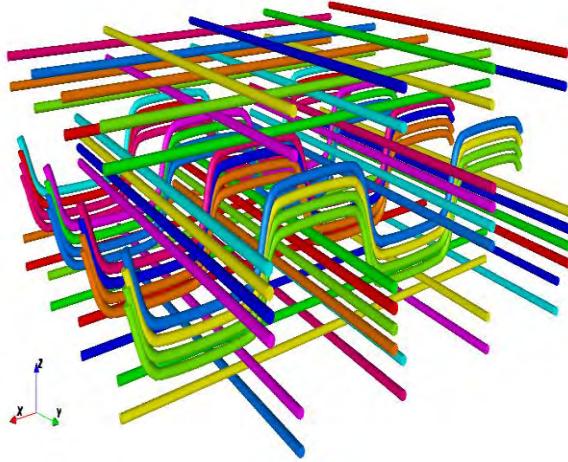

Figure 6. Yarn paths, preform #3

### III. Experimental

All compaction tests were conducted using an Instron 4482 universal testing frame equipped with a 100KN load cell, with an accuracy of 0.25% of maximum load. Compaction tests were conducted using a circular cross-section test rig. “Fig 7” shows the compaction test rig throughout compaction test of preform #2. The test rig includes a lower platen and an upper platen with a diameter of 50mm. Tests were conducted up to a pressure of 0.12 Mpas. All compaction tests were performed by moving the upper platen onto the surface of the reinforcement at a fixed displacement rate of 0.1 mm/min, recording the reaction force applied by the compacted reinforcement on the platen.

Successive compaction cycles were conducted in each test, to investigate the effect of repeated loading cycles on the compaction behaviour of all 3D preforms. Each series of cycles was repeated 4 times to quantify the reproducibility of the data. Recorded values were converted to fibre volume fractions as a function of the compaction pressure, and graphs of average curves were produced. All compaction tests are conducted in room temperature.

Figure 7. Compaction test on preform#2

### IV. RESULTS AND DISCUSSION

Compaction graphs showing the behaviour of 3D reinforcements in different successive compaction cycles are derived. “Fig 8” shows the compaction behaviour of preforms #1, #2 and #3 in the first compaction cycle. “Fig 9” and “Fig 10” show the compaction behaviour of all three 3D reinforcements in the second and third successive cycles. “P#1 / C1” means total average of data obtained for preform#1 in the first cycle. The error bars on the graphs show the variability of the data.

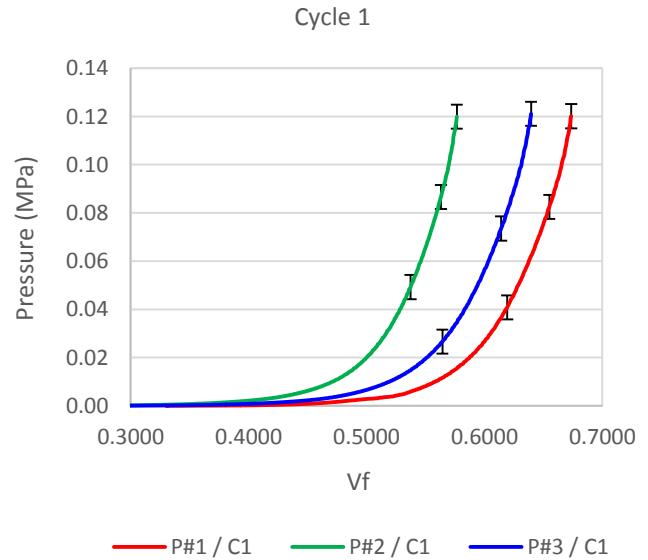

Figure 8. Compaction behaviour, 3 fabrics, cycle 1

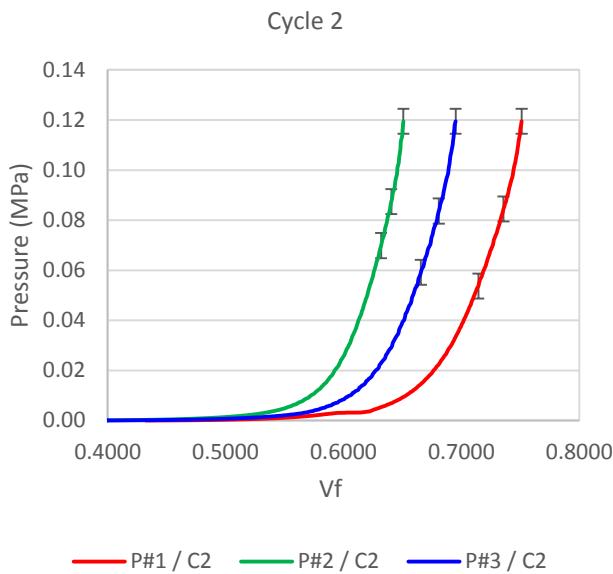

Figure 9. Compaction behaviour, 3 fabrics, cycle 2

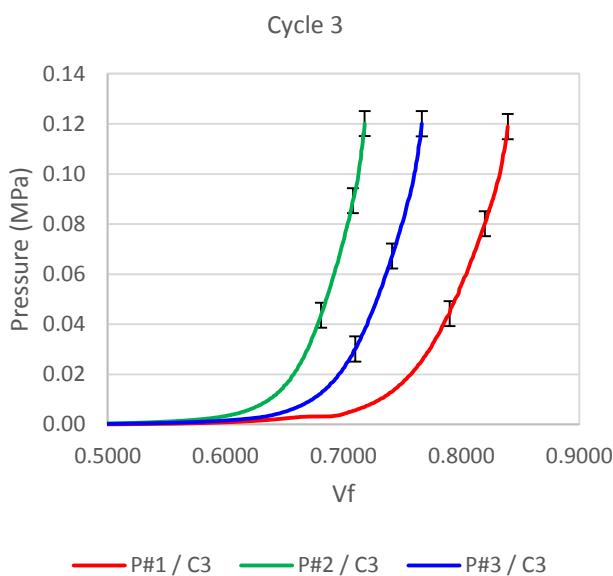

Figure 10. Compaction behavior, 3 fabrics, cycle 3

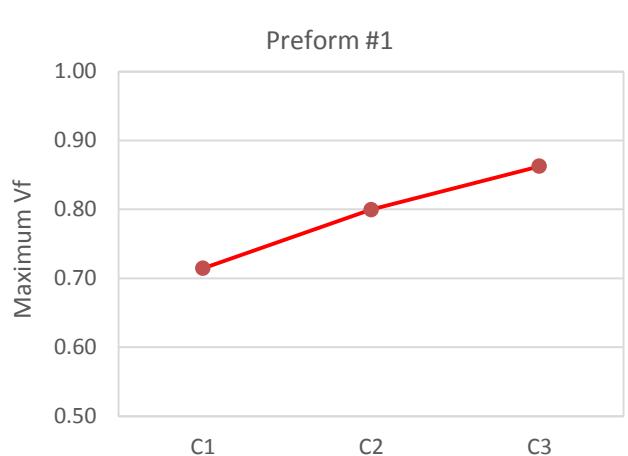

Figure 11. Effect of number of cycles on compaction behaviour, preform #1

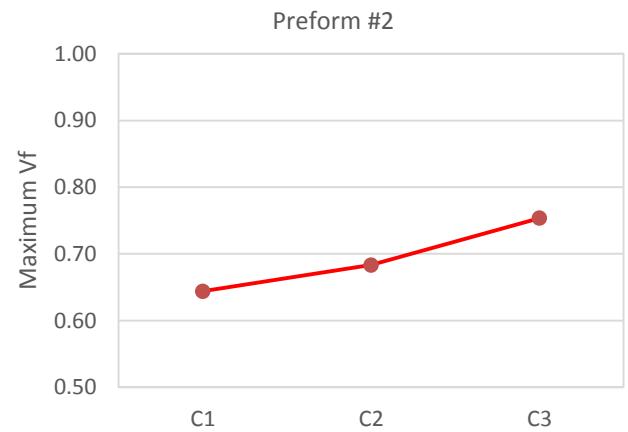

Figure 12. Effect of number of cycles on compaction behaviour, preform #2

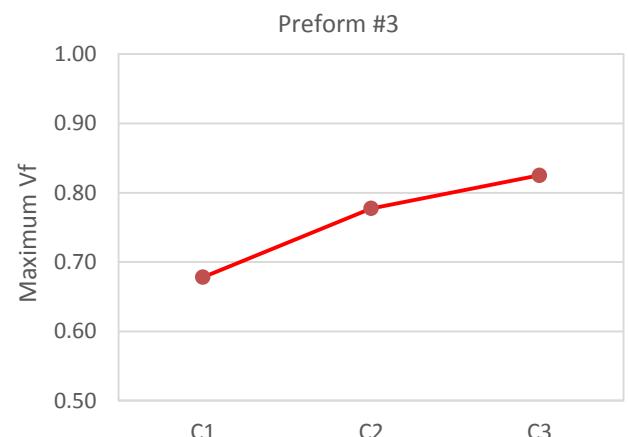

Figure 13. Effect of number of cycles on compaction behaviour, preform #3

Different internal interlacing patterns in the reinforcements affect their compaction behaviour and volume fraction.

"Fig 11", "Fig 12" and "Fig 13" show the effect of compaction cycles on the maximum fibre volume fraction.

An increase in the  $V_f$  of all three preforms was observed from conducting successive compaction cycles as seen in “Fig 11”, “Fig 12” and “Fig 13”.

## V. CONCLUSIONS

An experimental study of the compaction behaviour of three different 3D carbon fibre reinforcements with different interlacing patterns is presented. The influence of interlacing on the final volume fraction of the reinforcements was analysed.

3D reinforcements featuring more interlacing show lower volume fractions. Their volume fraction at any pressure is lower than 3D reinforcements featuring lower interlacing. This shows direct effect of the quantity of the interlacing of 3D reinforcements on their compaction behaviour and volume fraction.

The effect of repeated compaction cycles on the different interlaced 3D reinforcements was also probed. The volume fraction of all 3D reinforcements increased for higher compaction cycles.

# Investigation of Fraying in Textile Reinforcements for Composites

Yousef Badripour, François Robitaille  
Department of Mechanical Engineering  
University of Ottawa  
Ottawa, Canada

**Abstract**—This paper discusses the fraying of textile reinforcements upon preforming. The paper also introduces a method for quantifying the fraying characteristics of fabrics. Six different fabrics including three carbon fabrics and three glass fabrics were tested. Digital microscopy was also used for measuring the structures of the fabrics tested. The relation between the structures and fraying is discussed.

**Keywords-** *textiles; composites; fraying; yarn loss*

## I. INTRODUCTION

Fibre reinforced polymer matrix composites are increasingly used in numerous applications. However, a lack of established standard characterization methods for the dry fabrics used in manufacturing these composites preclude the use of quantitative methods for analyzing and predicting the manufacturing operations. Upon preforming, different fabrics behave in different ways, making it difficult to plan manufacturing efficiently. Each element of the behaviour of these textiles demands a reproducible testing method. Some elements have been investigated thoroughly [1]; however, others still lack proper testing methods. Knowledge of the fraying characteristics of carbon and glass fabrics upon cutting and handling is important in manufacturing; however, no established testing method exists for assessing it. Although some work was done towards that aim, leading to the yarn pull-out test [2] or the inter-yarn friction test [3], such tests mostly measure friction between yarns when subject to pulling or shear; however, yarns fraying from the edges upon draping on moulds is a recurring phenomenon. This paper introduces a reproducible test method for measuring fraying in industrial reinforcement fabrics.

## II. INDUSTRIAL CONTEXT

When draped, industrial fabrics can show fraying around the edges. The amount of fraying can vary with the fabric type, fabric architecture and mould geometry. A typical situation when fraying can occur is the darting of a fabric, which is done to facilitate the draping of a mould of complex

geometry [4]. “Fig. 1” and “Fig. 2” show two different fabrics after being cut and draped on a mould. More complex mould geometries result in higher shear and more fraying, eventually making the draping process more problematic.

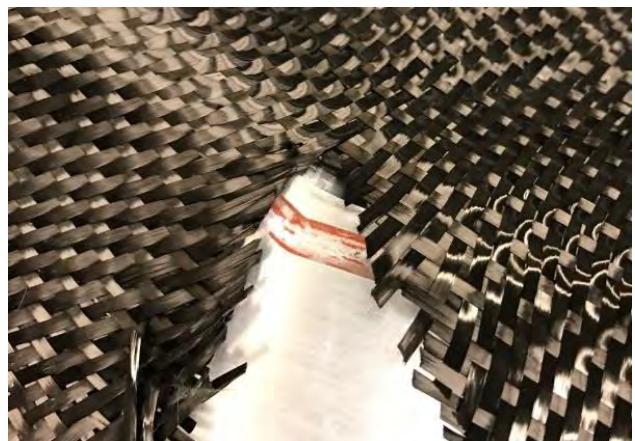

Figure 1. Fraying around edges after cutting and draping, 5-harness carbon fabric

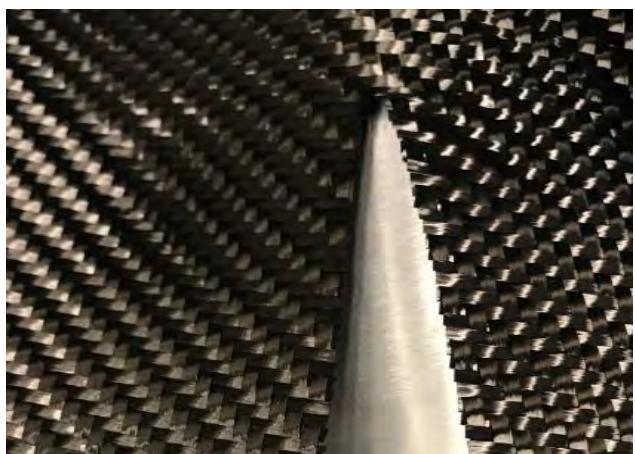

Figure 2. Fraying around edges after cutting and draping, twill carbon fabric

### III. APPARATUS AND METHODOLOGY

A testing rig featuring a 3.81 cm (1.5 in) circular platen supported by a 0.95 cm (3/8 in) rod is mounted into a spinner with an adjustable speed. Tests reported in this paper were conducted at a spinning speed of 1500 RPM. Circular fabric specimens measuring 15.24 cm (6 in) in diameter were placed on the platen. Double-sided General Sealants Inc tape covered the whole surface of the circular platen and held the fabric onto it. Samples were spun at the aforementioned speed for 3 seconds. Inertial forces caused some yarns to dislodge from the edges. Lost yarns were quantified using mass and area loss. Tests were run 5 times for each fabric and average losses are reported in Table 1 and Table 2.

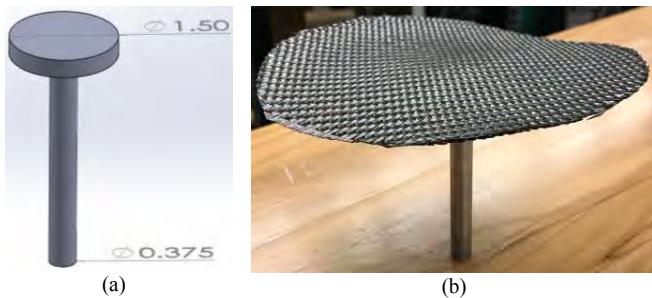

Figure 3. Test rig (a) and fabric specimen mounted on the rig (b)

Figure 4. 8-harness glass fabric specimen, before test

Figure 5. 8-harness glass fabric, after test

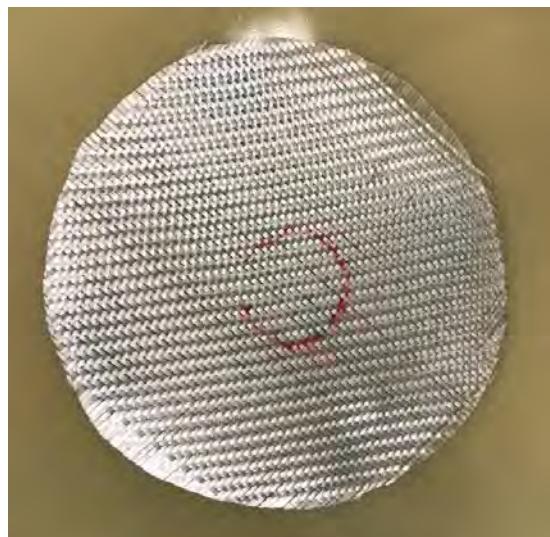

Figure 6. Twill glass fabric after test

The mass of each specimen was measured before and after the test, using a Smart weight dual platform scale with 200 g capacity and  $\pm 0.001$  g accuracy. Mass loss is reported as an average.

The area of the specimen before the test and the non-frayed area after the test were measured using the ImageJ software. Area loss is reported as an average for each fabric.

Topographies were determined using Keyence VHX-6000 series digital microscope. Effects of maximum height and textiles patterns are assessed.

#### IV. RESULTS

Table 1 and Table 2 give fabrics information such as architecture, surface density as well as yarn count. It also lists results for mass loss, area loss and standard deviations for both measurements.

"Fig. 7" to "Fig. 12" illustrate topographies for the fabrics tested. These topographies returned maximum value of 192  $\mu\text{m}$  in the twill glass and 195  $\mu\text{m}$  in the twill carbon with regard to their surface pattern range in the z axis direction. The value was 237.2  $\mu\text{m}$  for the 8-harness glass fabric. Higher values indicated a higher crimp factor for a given fabric.

TABLE 1. TEST RESULTS FOR GLASS FABRICS

Fabric	Glass	Glass	Glass
Architecture	Plain	Twill	8-harness
Surface density (g/m <sup>2</sup> )	304	300	296
Yarn count (yarn/cm)	5.55	6.45	22.42
Mass loss (%)	43.15	1.39	11.23
Area loss (%)	77.07	6.04	20.68
Mass loss standard deviation (%)	5.63	15.83	10.24
Area loss standard deviation (%)	6.25	20.70	14.46

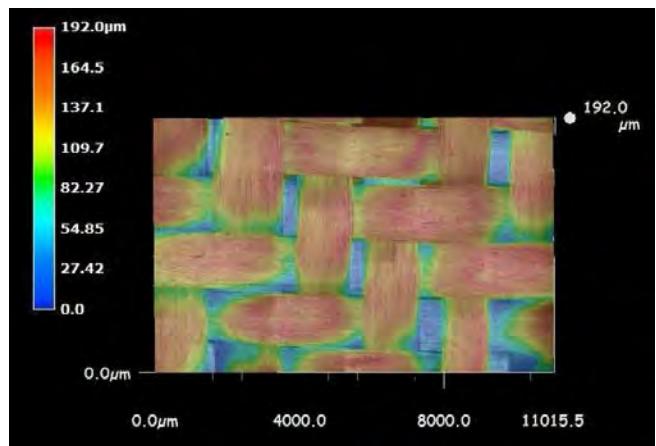

Figure 7. Topography of twill glass fabric

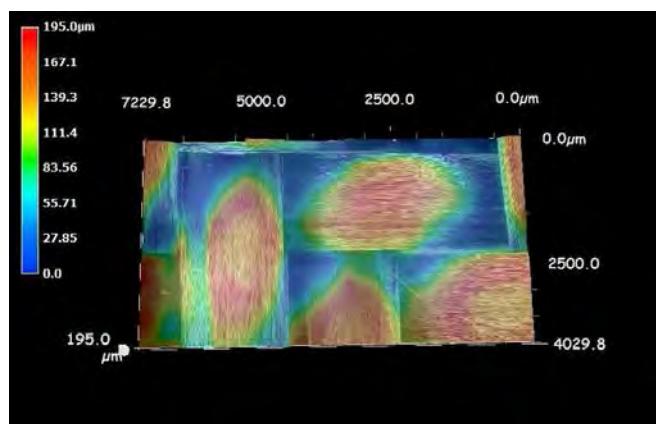

Figure 8. Topography of twill carbon fabric

TABLE 2. TEST RESULTS FOR CARBON FABRICS

Fabric	Carbon	Carbon	Carbon
Architecture	Twill	5-harness with binder	Stitched
Surface density (g/cm <sup>2</sup> )	408	368	288
Yarn count (yarn/cm)	5	4.54	2
Mass loss (%)	3.03	1.84	1.09
Area loss (%)	7.20	4.75	3.39
Mass loss standard deviation (%)	17.82	17.39	9.17
Area loss standard deviation (%)	18.89	33.68	26.84

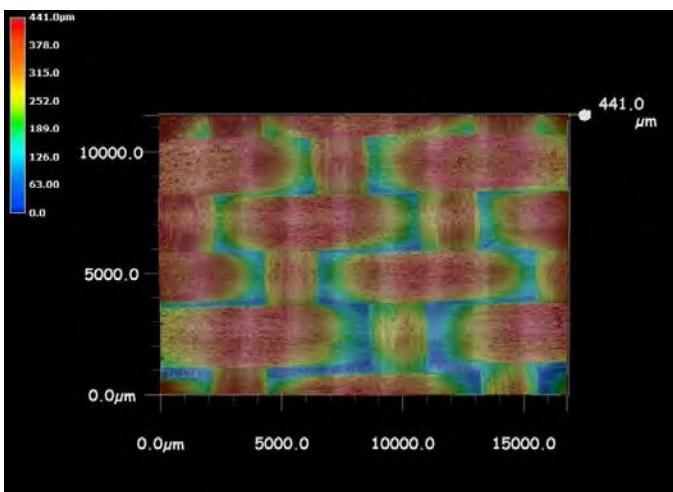

Figure 12. Topography of 5-harness carbon fabric with binder

"Fig. 13" shows the results from Table 1 and Table 2 comparing the mass loss (%) and area loss (%) for all fabrics.

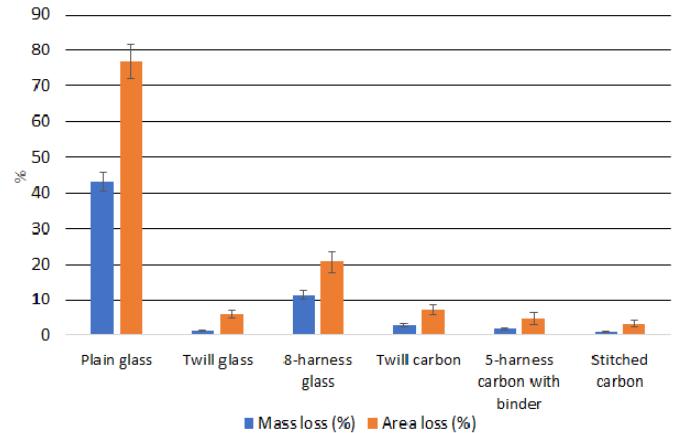

Figure 13. Mass loss and area loss chart for all tested fabrics

## V. DISCUSSION

Test results for twill glass fabric, twill carbon fabric, 5-harness carbon fabric with binder and stitched carbon fabric show limited yarn loss. On the other hand, results for the 8-harness glass fabric, showed moderate amounts of yarn loss, and the plain glass fabric showed high amounts of yarn loss. This high amount of yarn loss in plain glass fabric could be due to low amount of inter-yarn friction as well as the plain structure itself. It can be concluded that twill fabrics show a high resistance to fraying. Also, the use of a binder on the fabric and the presence of stitching in fabrics prevent edge fraying efficiently.

The stitched carbon fabric used in testing had fibers extending along 45° and -45° directions with a stitch along the 0° direction. This fabric predictably returned the minimum amount of yarn loss, confirming that stitching can be a potent solution to the occurrence of fraying in some cases [5].

The analysis of fabric topography delivered information regarding each fabric crimp factor. Twill structured fabrics showed less crimp than the 8-harness one. Varying amounts of crimp can lead to differences in triggering of yarns sliding relatively to each other [6]. Tables 1 and 2 support this claim, as higher mass and area losses are seen for the 8-harness fabric compared with the twills, and similar figures were seen for both twill carbon and twill glass fabrics.

"Fig. 1", which illustrates noticeable fraying for the 5-harness carbon fabric, and Table 1 which reports the second highest yarn loss for the 8-harness glass fabric, it can show that yarns in satin fabrics are more likely to slip from the edge.

Results for each fabric showed limited variability notably for the mass loss measurements. However, using an automated

cutting machine [7] for preparing the specimens, would lead to more accurate specimens resulting in more repeatable results.

## VI. CONCLUSION

This work introduced a reproducible testing method for measuring yarn loss in carbon and glass fabrics with minimum variability in results aiming at quantifying fraying. The impact of some fabrics attributes such as architecture, stitching and presence of a binder on yarn loss was observed and discussed.

# Modelling Viscoelastomers With Nonlinear Viscosity

Jianyou Zhou, Liying Jiang and Roger E. Khayat

Department of Mechanical and Materials Engineering

The University of Western Ontario

London, Ontario N6A 6B9, Canada

lyjiang@eng.uwo.ca

**Abstract**— Consisting of highly mobile and flexible polymer chains, elastomers are known to exhibit viscoelastic behavior. Adopting concepts from the theory of polymer dynamics and finite-deformation viscoelasticity, this work presents a micro-macro constitutive model to investigate the viscoelastic behavior of elastomers, in which the material viscosity varies with the macroscopic deformation. The developed model is then applied to study the stress response of elastomers. From the simulation results, it is observed that the developed model exhibits strong capability of capturing the typical response behaviors of elastomers (e.g., strain-softening behavior). A comparison of the stress responses between linear and nonlinear viscosity is also considered in this work. The modeling framework in this paper is expected to provide a general approach and a platform to analyze the viscoelastic behavior of rubber-like materials with nonlinear viscosity.

**Elastomers; viscoelasticity; finite-deformation; nonlinear viscosity;**

## I. INTRODUCTION

Elastomers, capable of sustaining exceptionally large deformation, have extensive applications in engineering and industrial fields, such as flexible joints, automotive products, soft robots, artificial muscles and vibration isolators [1]. Formed by the cross-linking of highly mobile and flexible polymer chains, elastomers are hyperelastic and highly viscoelastic. These two major characteristics strongly affect the response of elastomers and have attracted much interest from the research community.

In the literature, numbers of constitutive models have been developed to capture the hyperelastic behavior of elastomers. These available models are established mainly based on two approaches: continuum mechanics treatments and statistical mechanics treatments. Developed through continuum mechanics framework, the phenomenological models assume that the hyperelastic properties of the material can be described by a strain energy function [2-3]. On the other hand, the hyperelastic constitutive models based on statistical treatments link the macroscopic response of the materials to their microstructure [4-5].

This work is supported by Natural Sciences and Engineering Research Council of Canada (NSERC).

As for modeling the viscosity of elastomers, extensive research is also available in the literature. For example, phenomenological models that adopt thermodynamics evolution laws have been developed to tackle the inelastic deformation and viscous effect of elastomers, where the time-dependent strain variables are determined by the evolution laws [6-7]. Nevertheless, in these phenomenological models, details of the microstructure of the material related to the viscosity are not involved. Therefore, to reveal the physical mechanisms of the viscosity of the material, concepts from polymer dynamics [8] have been adopted later to develop the micromechanism inspired viscoelasticity models [9-10]. Although both the phenomenological models and the micromechanism inspired viscoelasticity models work well for fitting certain experimental data, they cannot capture the nonlinear viscosity of the material (viscosity varies with the deformation).

This motivates us to revisit the theory of polymer dynamics and the state-of-the-art theoretical framework of finite-deformation viscoelasticity to develop a micro-macro constitutive model, which aims to capture the viscoelastic deformation of elastomers with consideration of their nonlinear viscosity.

## II. THEORETICAL FRAMEWORK

### A. Continuum Mechanics Framework

Following the pioneering works of Sidoroff [11], and Reese and Govindjee [7], it is assumed that the elastomer comprises an elastic polymer ground network and a viscous polymer subnetwork, which can be represented by the rheological model shown in Figure 1. Polymer network A is a purely elastic network, while network B is a viscous network. Consider a material point P in the reference configuration denoted by its position vector  $\mathbf{X}$ . When the elastomer is subject to external loads, point P moves to position  $\mathbf{x}$  in the current configuration. Then the total deformation gradient tensor  $\mathbf{F}$  is defined as  $\mathbf{F} = \nabla \mathbf{x}(\mathbf{X}, t)$ . Since the deformation is applied to both polymer networks,  $\mathbf{F}_A = \mathbf{F}_B = \mathbf{F}$ . Borrowing a concept from finite-deformation plasticity, the deformation gradient tensor of network B can be further multiplicatively split into two parts, i.e.,  $\mathbf{F}_B = \mathbf{F}_B^e \mathbf{F}_B^i$ . Here,  $\mathbf{F}_B^e$  represents the deformation gradient of

the spring and  $\mathbf{F}_B^i$  denotes the deformation gradient of the dashpot. Adopting the rheological model in Fig. 1, the total Helmholtz free energy density of the elastomer is expressed as

$$W(\mathbf{F}_A, \mathbf{F}_B^e) = W_A(\mathbf{F}_A) + W_B(\mathbf{F}_B^e), \quad (1)$$

where  $W_A$  and  $W_B$  are the strain energy densities of the springs of network A and B, respectively [12-13]. Then the Cauchy stress tensor  $\boldsymbol{\sigma}$  and the first Piola-Kirchhoff stress tensor  $\mathbf{P}$  are given as

$$\mathbf{T} = J^{-1} \frac{\partial W_A(\mathbf{F}_A)}{\partial \mathbf{F}} \mathbf{F}^T + J^{-1} \frac{\partial W_B(\mathbf{F}_B^e)}{\partial \mathbf{F}} \mathbf{F}^T \quad (2)$$

and

$$\mathbf{P} = J \mathbf{T} \mathbf{F}^{-T}. \quad (3)$$

Moreover, the internal variables  $\mathbf{F}_B^e$  and  $\mathbf{F}_B^i$  must satisfy the following thermodynamic evolution equation, i.e.,

$$-\frac{1}{2} \mathbf{F}_B \frac{d[(\mathbf{C}_B^i)^{-1}]}{dt} (\mathbf{F}_B^e)^T (\mathbf{b}_B^e)^{-1} = \gamma^{-1} : \boldsymbol{\tau}_B. \quad (4)$$

Here,  $\boldsymbol{\tau}_B = 2\mathbf{F}_B^e \frac{\partial W}{\partial \mathbf{C}_B^e} (\mathbf{F}_B^e)^T$ ,  $\mathbf{b}_B^e = \mathbf{F}_B^e (\mathbf{F}_B^e)^T$ ,  $\mathbf{C}_B^i = (\mathbf{F}_B^i)^T \mathbf{F}_B^i$

and  $\gamma^{-1}$  takes the form

$$\gamma^{-1} = \frac{1}{2\eta_B} \left( \mathbf{I}^4 - \frac{1}{3} \mathbf{I} \otimes \mathbf{I} \right), \quad (5)$$

where  $\eta_B$  is the viscosity of the viscous polymer subnetwork B,  $\mathbf{I}^4$  is the fourth order symmetric identity tensor and  $\mathbf{I}$  is the second order identity tensor [7].

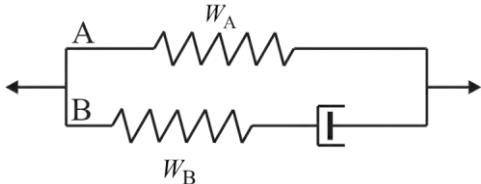

Figure 1. The rheological model of viscoelastic elastomers under finite-deformation.

### B. Nonlinear Viscosity

To obtain the stress with (2), (3), (4) and (5), the viscosity  $\eta_B$  of the viscous network must be constitutively prescribed first. Following Doi and Edwards [8],  $\eta_B$  can be expressed in terms of the shear relaxation modulus  $G_r$ , i.e.,

$$\eta_B = \int_0^\infty G_r dt. \quad (6)$$

In the short time-scale ( $t < \tau^e$ ),  $G_r$  is related to the microstructural parameters of the polymer network as

$$G_r \cong n_B k_B T \left( \frac{\tau^e}{\tau^R} \right)^{1/2}, \quad (7)$$

where  $n_B$  is the number of chains per unit volume in subnetwork B,  $k_B$  is the Boltzmann constant,  $T$  is the temperature,  $\tau^R$  is the relaxation time of the contour length of the primitive chain, and  $\tau^e$  is the critical time that the Brownian motion is restricted by the topological constraints (tube-like region) of the polymer network.

However, in the long time-scale ( $t > \tau^e$ ), the polymer chains may reptate out of the topological constraints (the tube). When reptation occurs, the shear relaxation modulus  $G_r$  is proportional to the fraction  $\varphi(t)$  of the chain still in the tube, i.e.,

$$G_r \cong n_B k_B T \left( \frac{\tau^e}{\tau^R} \right)^{1/2} \varphi(t). \quad (8)$$

By solving the one-dimensional diffusion equation to obtain  $\varphi(t)$  and integrating the shear relaxation modulus in (6),

$$\eta_B = \frac{\zeta n_B^4 b_0^4}{12 \langle a \rangle^2} \left( \frac{\tau^e}{\tau^R} \right)^{1/2}, \quad (9)$$

where  $a$  is the tube diameter in the current configuration,  $\zeta$  is the monomer friction constant,  $b_0$  is the effective bond length between monomers, and  $\langle * \rangle$  is the expectation operation of parameter \* [13].

Considering nonlinear viscosity,  $\langle a \rangle$  should vary with the deformation. Moreover, the mean diameter  $\langle a \rangle$  is linked to the square end-to-end distance of the primitive chain  $\mathbf{R}_{ee}^2$  and the primitive chain length  $L$  by  $\langle a \rangle = \langle \mathbf{R}_{ee}^2 \rangle / \langle L \rangle$ . Following Li et al. [14],  $\langle \mathbf{R}_{ee}^2 \rangle$  is obtained as

$$\langle \mathbf{R}_{ee}^2 \rangle = \int |\mathbf{F} \cdot \mathbf{R}|^2 f_0(\mathbf{R}) d^3 \mathbf{R}, \quad (10)$$

where  $f_0(\mathbf{R})$  is the statistical distribution function of the end-to-end vector. Also, the mean primitive chain length  $\langle L \rangle$  is given as

$$\langle L \rangle = \int \frac{|\mathbf{F} \cdot \mathbf{u}_0|}{4\pi} L_0 d^2 \mathbf{u}_0, \quad (11)$$

where  $\mathbf{u}_0$  is the initial tangent vector of the primitive chain in the reference configuration. Then the ratio of the tube diameter between the current configuration and the reference configuration is expressed as

$$\frac{\langle a_n \rangle}{a_0} = \frac{\int |\mathbf{F} \cdot \mathbf{R}|^2 f_0(\mathbf{R}) d^3 \mathbf{R}}{\langle \mathbf{R}_{ee}^2 \rangle_0 \int \frac{|\mathbf{F} \cdot \mathbf{u}_0|}{4\pi} d^2 \mathbf{u}_0}. \quad (12)$$

Here,  $a_0$  is the tube diameter in the reference configuration. Therefore, the deformation-dependent viscosity is given as

$$\eta_B = \frac{\eta}{\alpha(\mathbf{F})^2}, \quad (13)$$

where  $\eta = \frac{\zeta n_B^4 b_0^4}{12a_0^2} \left( \frac{\tau^R}{\tau^e} \right)^{1/2}$  is the viscosity of the elastomer in the reference configuration and  $\alpha(\mathbf{F}) = \frac{\int |\mathbf{F} \cdot \mathbf{R}|^2 f_0(\mathbf{R}) d^3 \mathbf{R}}{\langle \mathbf{R}_{ee}^2 \rangle_0 \int \frac{|\mathbf{F} \cdot \mathbf{u}_0|}{4\pi} d^2 \mathbf{u}_0}$  indicates the deformation-dependency.

### III. NUMERICAL SIMULATIONS

To test the modeling capacity of the theoretical framework developed above, the material models (the strain energy densities  $W_A$  and  $W_B$  in (1)) need to be prescribed first. In this work, the Gent strain energy density function [3] is chosen as  $W_A$ , i.e.,

$$W_A = -\frac{G^{EQ} J_{lim}}{2} \ln \left( \frac{J_{lim} - \lambda_1^2 - \lambda_2^2 - \lambda_3^2}{J_{lim}} \right). \quad (14)$$

Here,  $G^{EQ}$  is the shear modulus of polymer network A and  $J_{lim}$  is the material extensibility parameter. Also,  $\lambda_1$ ,  $\lambda_2$  and  $\lambda_3$  are the stretch ratios in three directions. We assume that  $W_B$  takes the same form as  $W_A$ , which gives

$$W_B = -\frac{G^{NEQ} J_{lim}}{2} \ln \left[ \frac{J_{lim} - (\lambda_1^e)^2 - (\lambda_2^e)^2 - (\lambda_3^e)^2}{J_{lim}} \right], \quad (15)$$

where  $G^{NEQ}$  is the shear modulus of polymer network B.

Considering uniaxial tension,  $\lambda_1 = \lambda$ ,  $\lambda_2 = \lambda_3 = 1/\sqrt{\lambda}$ ,  $\lambda_1^e = \lambda^e$  and  $\lambda_2^e = \lambda_3^e = 1/\sqrt{\lambda^e}$ . From (2) and (3), the dimensionless nominal stress is obtained as

$$\frac{P_{11}}{G} = \frac{\chi J_{lim} (\lambda - \lambda^{-2})}{J_{lim} - 2\lambda^{-1} - \lambda^2 + 3} + \frac{(1-\chi) J_{lim} [\lambda (\lambda^i)^{-2} - \lambda^{-2} \lambda^i]}{J_{lim} - 2\lambda^{-1} \lambda^i - \lambda^2 (\lambda^i)^{-2} + 3}, \quad (16)$$

where  $G = G^{EQ} + G^{NEQ}$  and  $\chi = G^{EQ}/G$ . Also, the thermodynamic evolution equation gives that

$$\frac{d\lambda^i}{dt} = \frac{J_{lim} \lambda^i \alpha(\mathbf{F})^2}{3\tau [J_{lim} - 2\lambda^i \lambda^{-1} - \lambda^2 (\lambda^i)^{-2} + 3]} [\lambda^2 (\lambda^i)^{-2} - \lambda^i \lambda^{-1}]. \quad (17)$$

Here,  $\tau = \eta/G^{NEQ}$  is the relaxation time.

Fig. 2 depicts the dimensionless nominal stress  $P_{11}/G$  as a function of the stretch ratio of the elastomer at four different stretching rates, i.e.,  $|\dot{\lambda}| = 0.01/s$ ,  $|\dot{\lambda}| = 0.03/s$ ,  $|\dot{\lambda}| = 0.05/s$  and  $|\dot{\lambda}| = 1/s$ . It can be seen that the loading and unloading curves overlap at large stretch ratios when the stretching rates are relatively low ( $0.01/s \sim 0.05/s$ ). According to (13), the viscosity  $\eta_B$  is inversely proportional to the second power of

$\alpha(\mathbf{F})$ . Therefore, the viscosity of the elastomer is exceptionally low at large stretch ratios, which leads to much faster relaxation of the polymer chains, thus causing the loading and unloading curves to overlap. However, when the stretching rate is high (e.g.,  $1/s$ ), a wider gap between the loading and unloading curves appears since the elastomer has less time to relax during the loading path. To further examine the effect of the nonlinear viscosity on the stress response of the elastomer, Fig. 3 depicts the dimensionless nominal stress  $P_{11}/G$  obtained with  $\eta_B$  and  $\eta$ , respectively. A higher degree of strain-softening behavior is observed from the nonlinear viscosity case. Moreover, as the stretching rate increases, the stress difference between two cases becomes larger. Therefore, it is essential to consider the nonlinear behavior of the material viscosity in analyzing the stress response of elastomers, or it may lead to significant error in calculation. In Fig. 2 and Fig. 3, the material parameters are selected as  $\chi=0.5$ ,  $J_{lim}=110$  and  $\tau=500s$  [12-13].

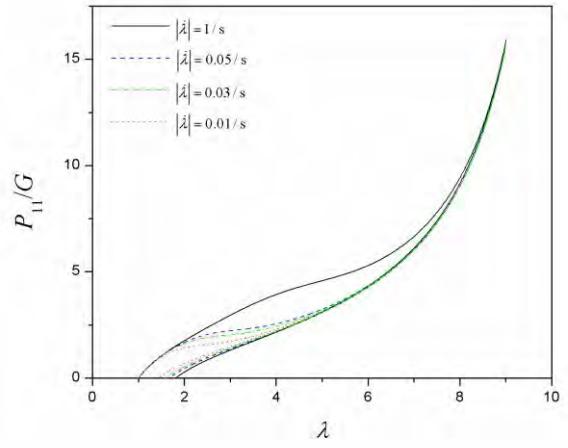

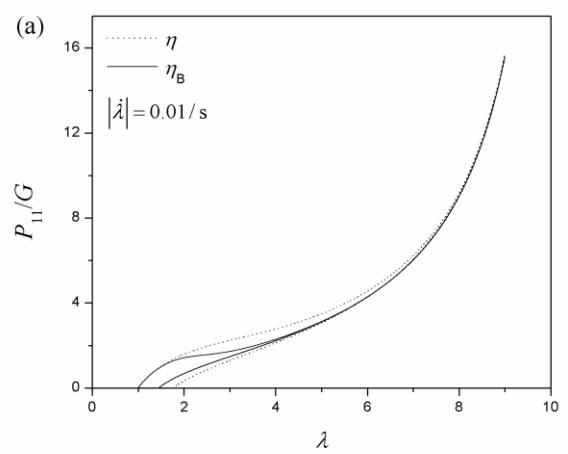

Figure 2. Stress response of the elastomer at different stretching rates.

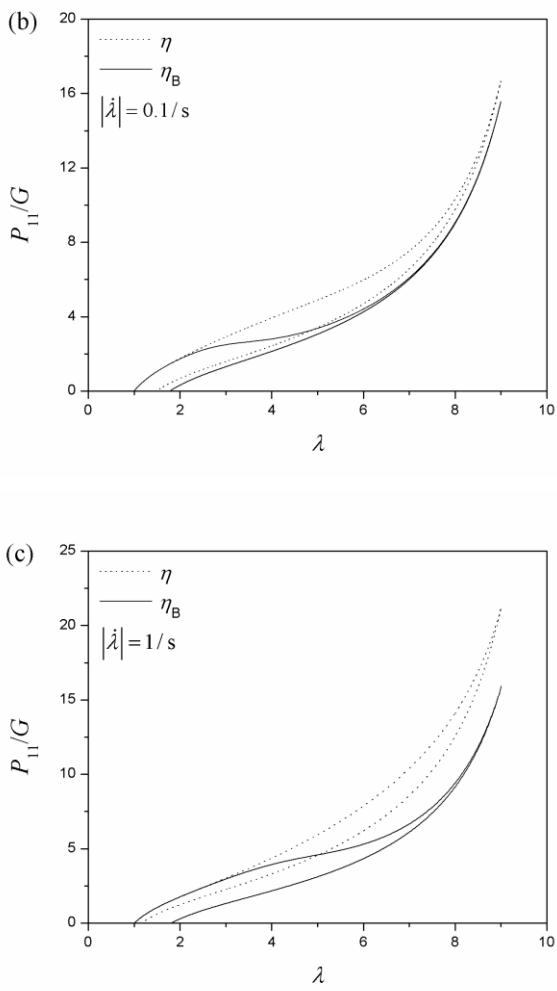

Figure 3. Comparison of the stress response between linear and nonlinear viscosity. (a)  $|\dot{\lambda}|=0.01/\text{s}$ , (b)  $|\dot{\lambda}|=0.1/\text{s}$  and (c)  $|\dot{\lambda}|=1/\text{s}$ .

#### IV. CONCLUSION

Based on the theory of polymer dynamics and finite-deformation viscoelasticity, a micro-macro constitutive model is developed to investigate the stress response and relaxation of elastomers under large deformation. For the developed model, all the material parameters have a microscopic foundation or physical meanings. Moreover, incorporating the nonlinear material viscosity into the continuum mechanics framework for finite-deformation viscoelasticity, the developed model can

adopt most of strain energy density functions for hyperelastic solids and thermodynamics evolution laws of viscoelastic materials. From our simulation results, it is found that the developed model can better capture the strain-softening behavior of elastomers, which could be explained by the nonlinear viscosity of the material. In summary, the developed modeling framework is anticipated to provide significant guidelines for studying the viscoelastic behavior of elastomers.

**Abstract**—The overall objective of this study is the fabrication of defect-free electrospun mats of polysulfone (PSU) for applications as a porous support for proton exchange membranes. Electrospinning of PSU from dimethylformamide (DMF) solution generated mats free of cast formation and over-wetting, but unspun droplets were frequently observed in the mats because the electrospun jet was unstable. A stable jet and a large reduction of beads in the electrospun mats were obtained with a mixture of 20 vol.% acetone in DMF. Subsequent optimization of the flow rate to 1.5 mL/h and the applied voltage to 14 kV generated electrospun mats free of any beads based on SEM analysis.

**Keywords-component;** *Electrospinning; polysulfone (PSU); Dimethylformamide (DMF); Proton Exchange Membrane Fuel Cell (PEMFC)*

## I. INTRODUCTION

Proton Proton Exchange Membrane Fuel Cell (PEMFC) is one of the proposed effective methods to improve the energy conversion in vehicles due to their high efficiency and no hazardous emission [1]. However, there are still several barriers, such as high production cost and low durability, that need to be addressed for commercial development. Several deficiencies are rooted in the performance of the membranes PEMFCs, which is why the improvement of these membranes is a present focus of fuel cell related research [2].

The most broadly applied membrane materials are perflourosulfonic acids (PFSA), which show high proton conductivity at a fully hydrated state. However, they suffer from a high price and low dimensional stability during the starting up and shutting down of a PEMFC when the amount of humidity is varied widely [2, 3]. To overcome this issue, the commercial membranes have relatively high thickness (50–175 $\mu\text{m}$ ) to show enough strength to overcome the changes in dimensions. However, thicker membranes negatively impact the performance of the fuel cell due to their decreased proton conductance [3].

One of the proposed methods for reducing the thickness of the membrane without decreasing the durability of the fuel cell is to build a porous inert reinforcement into the membrane to limit its expansion and contraction when its water content is changed. The enforcement porous support would also improve the mechanical properties of the membrane and is expected to reduce the overall cost of production. The overall cost is likely reduced despite extra processing steps because the porous enforcement material is much less expensive than PFSA and the overall amount of required PFSA is significantly reduced [2].

Among different methods for the fabrication of porous support layers, electrospinning attracts great attention due to its ability to fabricate submicron fibers mats with different morphologies [4]. Typically, a high voltage power supply (usually in the kV range) connects to a collector and the conductive needle of a syringe. The syringe is filled with a viscous liquid (a polymer solution or a molten polymer) to charge it. At a certain critical voltage, the repulsive force of the charged liquid offsets its surface tension and the liquid ejects from the nozzle to the collector. If the polymer solution has enough entanglement, the ejected solution forms fibers and the process is called electrospinning; otherwise, the ejected solution turns into small droplets and the process is called electrospraying [5, 6]. Simplicity, ability to control morphology at different levels makes this method attractive to researchers [4]. Moreover, the uniaxial alignment of polymer chain fibers can improve the mechanical properties of the membrane [7]. Finally, the low packing density of generated electrospun mats and their interconnected pore structure make them excellent substrates for filling with other materials to fabricate a dense membrane. Several polymers, such as polyvinylidene fluoride (PVDF), polyvinyl alcohol (PVA), Polystyrene (PS), and polysulfone (PSU) have been successfully electrospun as the porous support for proton exchange membranes [7]. However, more investigations are required to improve the electrospinning condition of these polymers for their application in a proton exchange membrane.

Reported here is the electrospinning behaviour of PSU in dimethylformamide-acetone mixtures and the effect of the electrospinning parameters on the morphology of the produced mats. Specifically, adjustments of the acetone content, flow rate, and voltage successfully suppressed the formation of macroscopic and microscopic defects observed for not optimized spinning conditions..

## II. EXPERIMENTAL PROCEDURE

*N,N*-Dimethylformamide (DMF, anhydrous, 99.8%) and Polysulfone (PSU, average Mn  $\approx$ 22,000) were purchased from Sigma-Aldrich. Acetone (ACS grade) was also provided from VWR. Solvents with different volume ratios of acetone in DMF (0%, 20%, and 40%) were prepared and used for the preparation of PSU solutions at a concentration of 20wt%. The mixtures were stirred via a magnet stirrer for 6 hours to generate a homogeneous solution at room temperature. The solutions were kept overnight at room temperature to ensure no phase separation occurs. Only solutions that show no macroscopic phase separation were selected for electrospinning test.

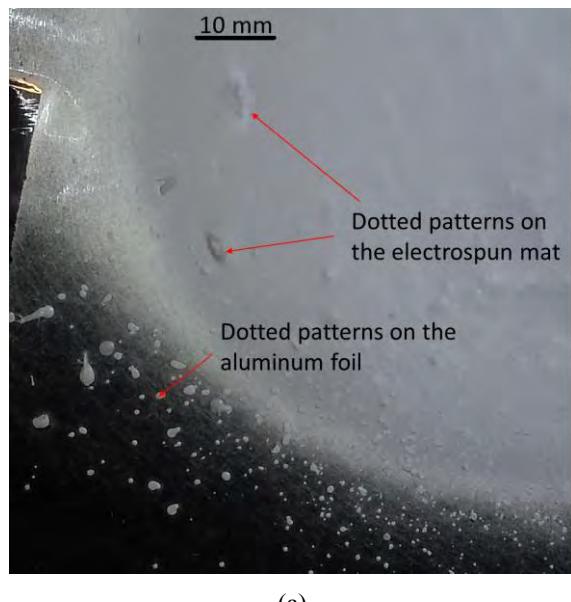

Before electrospinning, the solution was stirred for 2 hours to homogenise again. A 5 cc plastic syringe was filled bubble free and connected to a 22 gauge stainless steel blunt needle. The syringe was loaded onto a syringe pump (KDS, Legato 200) to control the flow rate (0.2 to 1.5 mL/h). To charge up the solution for electropinning, a power supply (ES50, Gamma high voltage research) was connected to the needle and a grounded static steel plate covered by an aluminum foil that served as the current collector. The current collector was placed 10 to 20 cm from the needle tip and the applied voltage was varied between 10 kV and 30 kV. The applied voltage was usually selected based on the critical voltage for ejection of the fluid from the Taylor cone (1 to 2 kV higher than the critical voltage), but in a few cases voltages 7 kV higher than the critical voltage were also examined to stabilize the process and avoid the formation of unspun droplets.

The electrospun samples were dried at 65 °C overnight to remove any possible residual solvent and then coated with gold by sputtering for the observation by SEM (Field Emission Scanning Electron Microscope Quanta FEG 200).

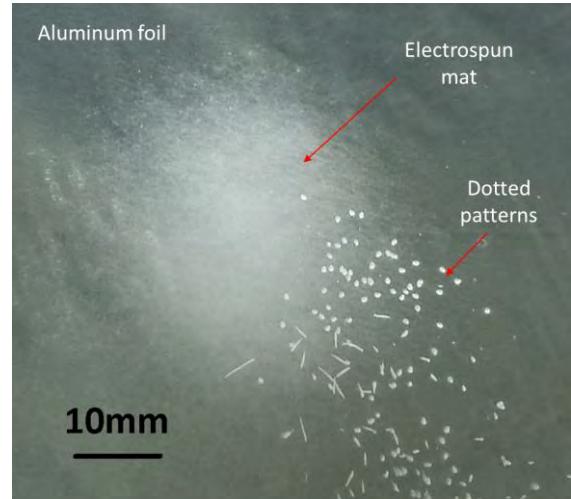

## III. RESULT AND DISCUSSION

Before our first experiments, pure DMF was used as the solvent for PSU. PSU showed appropriate solubility in DMF and clear solutions were obtained easily by stirring at room temperature. Electrospinning of these solutions was also straightforward and no cracking, cast formation, or peeling off was observed in the electrospun mats. However, the electrospun jet was not stable and unspun droplets were frequently observed during the process, which led to the formation of dotted patterns in the electrospun mats (Fig. 1-a). Although the problem was supposed to be addressed by reducing the flow rate [8], it became worse in our hands (Fig. 1-b).

The microstructure of the electrospun mats also suffered from the formation of beads. Fig. 2 shows the microstructure of the fabricated mats when the distance between the needle's tip and the collector was 20 and 15 cm, respectively. Although the number of beads can be reduced effectively by optimizing the tip collector distance (d) the formation of unspun droplets still persisted. To address this issue, DMF-acetone mixtures were applied as the solvent for PSU to reduce the surface tension of the solvent. If the surface tension is reduced, the beads problem can be addressed effectively and the formation of unspun droplets is reduced because the electrospun jet is more stable.

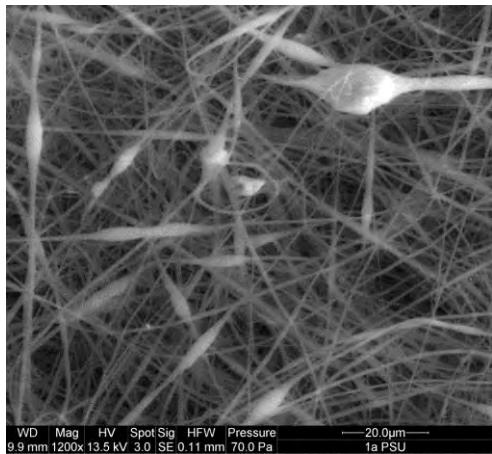

(a)

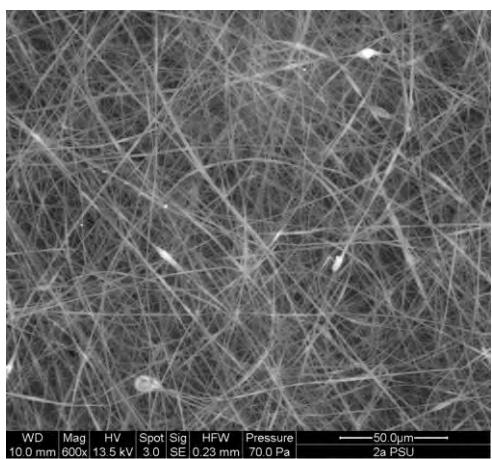

(b)

Figure 1. The PSU electrospun mat from DMF solution when the needle tip to collector distance is 15 cm: (a) flow rate = 0.5 mL/h (b) flow rate=0.2 mL/h.

(a)

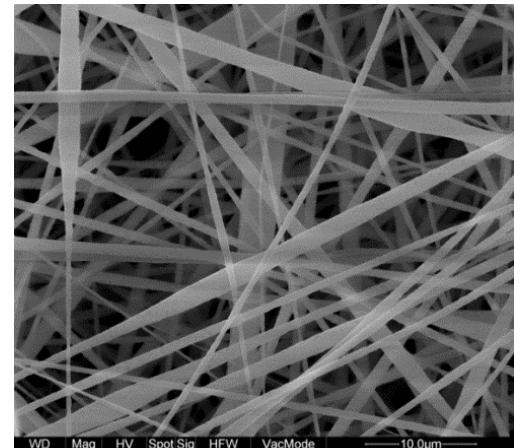

(b)

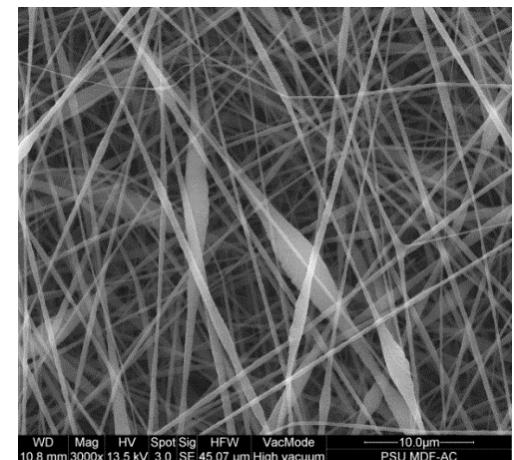

Figure 2. SEM images of the PSU electrospun fibers when DMF is applied as the solvent and the flow rate is 0.5 mL/h: (a) d=20 cm (b) d=15 cm.

PSU did not show proper solubility in 60%DMF-40% acetone (by Vol.) mixture. The solution was not clear and a macroscopic phase separation was observed after one day (a clear solution was on top and a milky solution was in bottom). By increasing the percentage of DMF to 80%, the solubility improved remarkably. Although the prepared solution was milky again, no macroscopic phase separation was observed even within a week.

By replacing the solvent from pure DMF to a mixture of 80% DMF and 20% acetone, some differences were observed in the electrospinning process. Firstly, the critical voltage for the Taylor cone was reduced significantly. The critical applied voltage for pure DMF was around 29 kV when the needle tip collector distance was 15 cm while this value for a 4:1 DMF/acetone mixture was just 8 kV. Since in many mathematical models the critical voltage mostly depends on the surface tension (among other solution parameters such as viscosity and conductivity) [6], reduction of the surface tension by the addition of acetone seemed to play an important role in the reduction of the critical voltage.

(a)

(b)

Figure 3. The SEM images of PSU electrospun fibers when 80% DMF-20% acetone was used as the solvent, the applied voltage was 10kV and d=15cm: (a) flow rate=1.2 mL/h, (b) flow rate=0.2 mL/h.

Addition of acetone also affected the microstructure of the electrospun mats. The beads were almost removed in the microstructure due to reduction of the surface tension of the solution (Fig. 3-a). It should be mentioned that the driving force for the bead formation is the high surface energy of the electrospun fibers during the electrospinning process [9]. Therefore, reduction of the surface energy can address this problem significantly.

Additionally, the electrospun jet became more stable when acetone was added to the solution. It was reported that the jet become more stable when the surface tension of the solution was reduced [9]. The unspun droplets were still persistence, but the number of them was cut down effectively. To diminish this problem totally other electrospinning parameters should be tuned. Reduction of the flow rate is one of the effective strategies that has been recommended to address the formation of unspun droplets [8]. However, similar to the case of using pure DMF, reduction of the flow rate to 0.2 mL/h was not only unable to improve the stability of the electrospun jet, but made

Figure 4. The PSU electrospun mat from 80% DMF-20% acetone solvent when the applied voltage was 14 kV, flow rate was 1.5 mL/h and  $d=15\text{cm}$ .

it less stable. This generated more unspun droplets and more beads appeared in the microstructures (Fig. 3-b).

Surprisingly, the higher flow rate (1.5mL/h) remarkably improved the stability of the jet. To achieve a fully stable jet and completely avoid the formation of unspun droplets, the applied voltage was increased to 14 kV. Only under this condition we were able to fully suppress the formation of unspun droplets and avoid the formation of dotted pattern of (Fig. 4). Fig. 5 illustrates the microstructures of the electrospun mats when the needle tip collector distance ( $d$ ) was varied from 10 to 20 cm and the mentioned adjustment on the flow rate and the voltage were applied. The microstructures of the electrospun mats for  $d = 15\text{ cm}$  or  $20\text{cm}$  were almost the same, although very few beads can be spotted for  $d = 20\text{ cm}$ . The beads were diminished when  $d = 15\text{ cm}$ . However, by reduction of  $d$  to  $10\text{ cm}$ , the surface of the fibers became rough and some particles like structure were formed, which had different structure from the electrospun fibers (Fig. 5-c and Fig. 6).

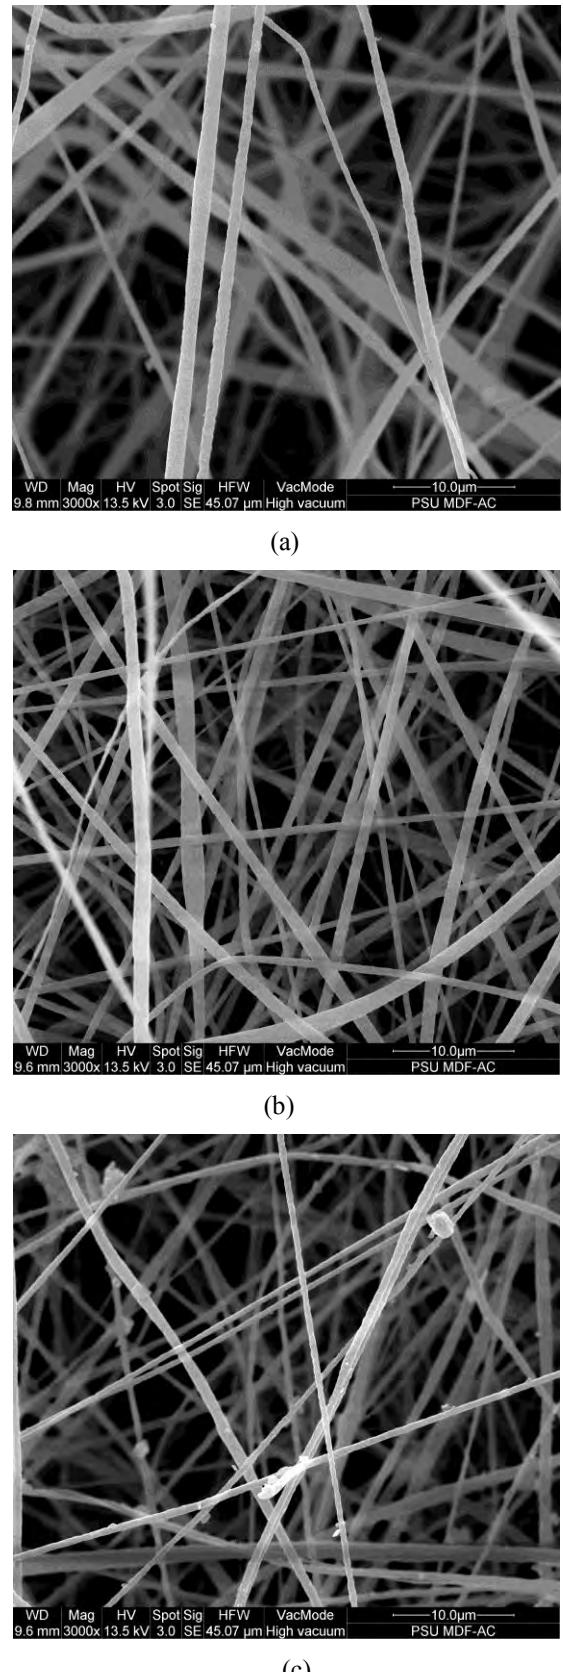

Figure 5. The SEM micrograph of the PSU electrospun fibers when 80% DMF-20% acetone solvent when the applied voltage was 14 kV, flow rate was 1.5 mL/h: (a)  $d=20\text{ cm}$ , (b)  $d=15\text{ cm}$ , (c)  $d=10\text{ cm}$ .

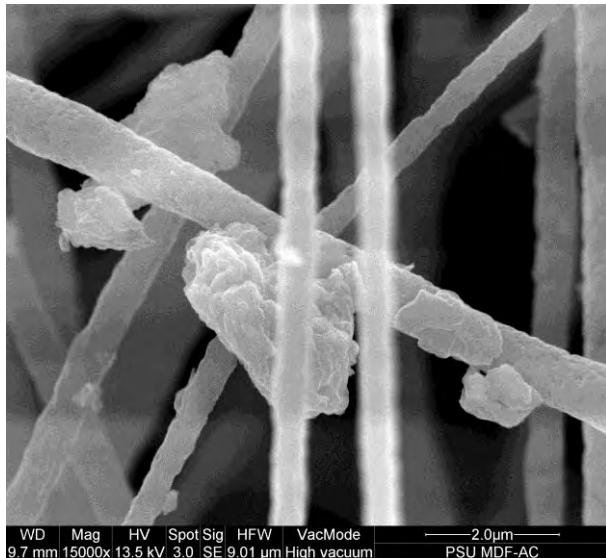

Figure 6 The SEM image of particle-like defect when 80% DMF-20% acetone solvent when the applied voltage was 14 kV, flow rate was 1.5 mL/h and d=10 cm.

## SUMMARY

We were not successful in the optimization of electrospinning parameters to generate defect-free mats with PSU solutions in DMF. This was mainly caused by an unstable jet that resulted in the formation of unspun droplets and a dotted pattern on the collector. Another manifestation of unsuitable spinning parameters was the formation of large numbers of beads in the mats. A stable jet and defect free electrospun mats were obtained with a solvent mixture of DMF/acetone 4:1 that has a drastically reduced surface tension. The collector distance, applied voltage, and flow rate were optimized to 15 cm, 1.5 mL/h, and 14 kV, respectively.

**Abstract**— The mold costs for low volume production molds can be expensive due to the mold material, the process planning time, and the fabrication costs. The focus of this research is to develop a methodology to fabricate molds for low volume production, where the production quantities vary between 1 – 200 components. For this application, the cycle time is not an issue. Employing an additive manufacturing solution could reduce the required amount of materials and the processing planning costs, but there are cost, or technology feasibility issues related to constructing a mold directly from a CAD file. Consequently, a hybrid manufacturing approach is taken where an AM process (material extrusion based) is used to create a sacrificial pattern for specialty, low cost, interchangeable inserts manufactured using an epoxy (Aremco 805). An over molding case study is carried out using a high temperature molding material - Technomelt-PA 7846 black. The pattern, insert, coating, and mold fabrication is discussed, as well as the initial results. The initial material cost estimates to fabricate this over molding solution is approximately \$140 US. The durability of the RTV coating and the inserts needs to be determined to yield the final solution costs.

**Keywords-mold fabrication; low volume; high temperature plastic materials; additive manufacturing**

## I. INTRODUCTION

The competitive landscape in the manufacturing domain is increasing in our global economy. The plastic mold making industry, which is a multi-million industry consisting of mainly small and medium size enterprises (502 establishments with 5,300 employees and \$926 million in shipments [1]), is actively pursuing opportunities to reduce tooling costs and processing time. The design solutions depend on the production volumes and planning horizons, and different mold materials and fabrication strategies are required for low volume, medium volume, and high-volume production. The focus of this research is on low volume production, where the production quantities vary between 1 – 200 components, the cycle time is not an issue, and the target application is ‘over molding’ for specialty applications, or prototype low volume production.

Low volume production molds are utilized in many industrial sectors, and can be used to test product functionality, or employed to create sample components for assembly automation ‘test and tune’ applications for automotive high production systems. ‘Soft’ tooling or temporary molds are fabricated to produce a limited number of products. If the design is not optimal, another mold can be fabricated for the updated design. The over molding process involves the use of two separate materials to form one cohesive component. The most common type of over molding is insert molding. Insert over molding is an injection molding process where one material is molded “over” a secondary “substrate” material.

Low volume molds are less costly than medium or high volume molds, but the material, process planning, and fabrication costs may still be thousands of dollars. Additive Manufacturing (AM) approaches have the potential to reduce process planning time, and to reduce the both the time and manpower associated with the mold fabrication process.

There are several AM processes that have been developed: vat photopolymerization, binder jetting, material extrusion, powder bed fusion, directed energy deposition, material jetting, and sheet lamination. The AM process family is capable of producing complex geometries without any in-depth process planning, and are used in the automotive, aerospace domains, as well as in the medical and dental domains [2]. The common element to all these processes is that a three-dimensional (3D) part is developed from layering two dimensional cross sections successively to create the final solid. Undercuts, free form geometry, and blind features are manufactured “easily”, especially compared to traditional machining processes. Presently, there are limited choices of material available for AM processes and anisotropic properties are exhibited due to the material bonding [3], [4]. There are compatibility issues with respect to the AM build process material with the molding material, and also limitations with respect to their cost effectiveness for ‘lower’ to intermediate production volume quantities as the product fabrication times may be long. Therefore, a rapid tooling design and fabrication strategy needs to be developed [5], which is the focus of this research. There are two solution paths being proposed: (i) employing an AM process to fabricate a mold (with the addition of a coating if

there are material compatibility issues), and (ii) employing hybrid mold fabrication strategies.

The goal of this research is to develop solutions to fabricate a 200 mm x 150 mm x 50 mm core and cavity mold set that can produce up to 200 parts for  $\leq \$1000$ . In this study, the molding material is Technomelt-PA 7846 black which is a polyamide plastic. Its mechanical properties are shown in Table I. Technomelt is a high melting temperature polyamide (application temperature: 200 to 240 °C [6]), which limits the usable mold materials.

TABLE I. PROPERTIES OF TECHNOMELT-PA 7846 BLACK

Mechanical property	Value
Density, g/cm <sup>3</sup>	0.98
Melting Viscosity at 230 °C, mPas	3,000
Glass Transition, °C	-30
Working Temperature, °C	-40 to 130
Softening point, °C	170 to 180

## II. LITERATURE REVIEW

Rodet et al. used the Stereolithography (SLA) [7] process to fabricate molds using the DSM Somos 7110 resin and SL 7510 materials, and SLA-250 and SLA-3500 machines. Variable layer thicknesses were explored and correlated to a surface roughness. The SLA tools had limitations due to their low thermal and mechanical properties (60-70°C - little strength left). Hopkinson et al. utilized an epoxy resin SL-5170 with a SLA-500 machine. The operating conditions were at a higher temperature (185°C). It was necessary to use different processing parameters for the molding compared to an aluminum mold solution, and there was difficulty ejecting the components (polypropylene material). Kovács et al. analyzed the warpage issues related to mold thermal conductivity, and explored using an epoxy resin filled with metal powder to increase stiffness and heat conductivity [8]. The SLA process family was not feasible for directly fabricating a mold set for components to be molded with the Technomelt-PA 7846 black material at this time.

The binder jetting process is an additive manufacturing process that fabricates components and assemblies by layering powdered material and applying a binder where a ‘solid interior’ should be. The binder jetting family of technologies is capable of printing variety of powder materials, which includes polymers, metals, ceramics, sand, and plasters. However, the raw material costs for metals [9] are high compared to the raw stock costs used for machining; consequently, this process may be more suited to a medium volume production application. This is also true for the powder bed fusion processes.

The material extrusion family for AM processes consists of placing individual beads side by side to build up a layer. A contour boundary curve is extruded, and a raster fill strategy is used to fill the appropriate interior regions. The material is extruded through a nozzle. Typically, the build material is a thermoplastic such as Acrylonitrile Butadiene Styrene (ABS) or Polylactic Acid (PLA), although a polycarbonate can be employed. Both this process and the readily available material selections are problematic. Fabrication issues exist with the surface finish, anisotropic mechanical properties, and voids

within the tool paths [10], but these issues are secondary. The glass transition temperature for ABS is approximately 105 °C, and the melting point for PLA 150 to 160 °C. Polycarbonate has a glass transition temperature at approximately 147 °C. The softening point for the Technomelt-PA 7846 black is 170 to 180°. Thus, the material extrusion processes do not lend themselves to a high temperature mold fabrication application.

Consequently, directly printing a mold set from a Computer Aided Design (CAD) model is not feasible due to cost issues (binder jetting and powder bed fusion), or due to the available build materials (SLA and material extrusion). Therefore, a ‘rapid tooling’ hybrid mold manufacturing approach is to be explored.

S. Ma et al. investigated the feasibility of making reinforced epoxy molds. The metal, ceramic and mineral powders were mixed with epoxy to increase its mechanical properties. Different ratios of the powders were studied to find the best mixture to optimize mechanical and thermal properties. 20% of alumina powder found to be the most suitable additive [11]. T. Tabi et al compared thermal, mechanical and thermomechanical properties of injection molding of PLA material into epoxy-based PolyJet and conventional steel (P20) mold. They found that it is possible to mimic the thermomechanical properties of nucleated PLA which is injected into hot steel mold by injecting it into an epoxy-based PolyJet mold [12]. Therefore, using a metallic-resin mix for controlling the heat transfer and providing structural integrity is a valid solution approach for a mold, and is a focus of the solution presented here.

## III. METHODOLOGY

For the hybrid manufacturing strategy, a disposable pattern for the core and cavity mold components will be manufactured using an AM process (rapid tooling), and the balance of the components are machined or cast to create permanent and interchangeable components. Two hybrid options are explored: (i) create a shell of each core and cavity mold surfaces, and back fill the shell with a filler material, and (ii) create a pattern, and use the pattern to create an interchangeable insert with a suitable resin material. For this paper, option 2 is explained. The process flow is presented in Fig. 1.

### A. Mold Design

The mold base consists of two aluminum blocks sized to accommodate a variety of inserts. There is a 35 mm border around the machined rectangular cavities that are to be used for the mold inserts. Fig. 2 shows the mold base blocks and its sections, where: the A features (2 per side) are entrance holes specifically designed for the epoxy filling operation; the B features (4 per side) are to allow the users to quickly interchange epoxy inserts for new production runs; the C feature is the insert cavity, which includes a 30° draft angle and 15 mm corner fillet radii for ease of interchangeability; and the D features (2 per side) are used to align the core and cavity blocks. These D features are also used to align the match plates to the mold set. The ejector features are threaded to fix the insert into position, and work as an ejector mechanism that pushes the used insert out of mold base cavities. The epoxy

insert contains nuts for stable location. To reduce bonding of the epoxy material to the aluminum block, an RTV silicone material (Mold Star® 30 [13]) is applied to the cavity surface before pouring the epoxy.

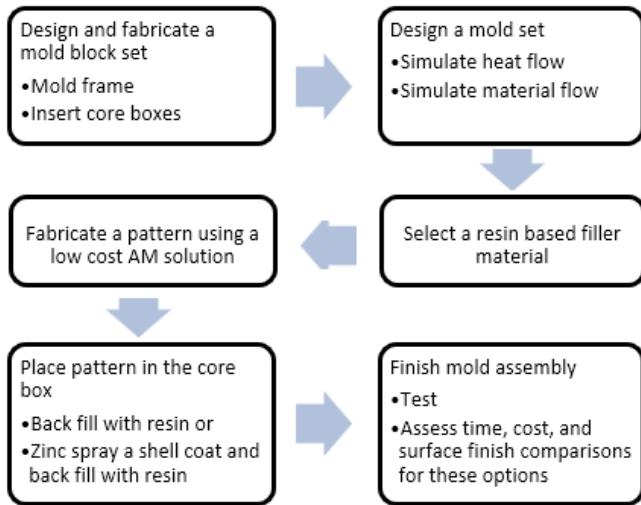

Figure 1. Hybrid mold design process flow.

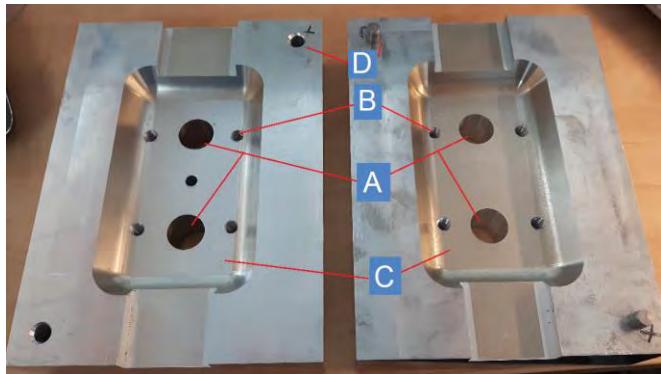

Figure 2. The mold bases- (A) the holes that epoxy is poured into the epoxy cavities (B) the ejector bolt of the epoxy block (C) epoxy filled cavities (D) hole-pin locators.

### B. Mold Making Process

To fabricate the molding cavities, a pattern is needed. As the pattern may have shape complexity, but does not need to have strength, low cost additive manufacturing processes and materials are ideal for this ‘rapid tooling’ application. Pattern design characteristics will vary depending on the final product requirements. The parting line and features will be unique for a general product as compared to an over molding solution. Once the sample is divided from the parting line, each segment is attached to each side of a match plate. The locating pins (feature D) of the mold base align pattern, the match plate, and the mold bases. Due to space constraints, the analyses for the various epoxy materials are not included. However, from the experimental activities, it was found that the Aremco 805 (Table II) had the low shrinkage, viscosity, mechanical properties at room temperature and 200°C, the temperature resistance, and the desired heat transfer characteristics.

TABLE II. PROPERTIES OF AREMCO 805 EPOXY [14]

Mechanical property	Value
Thermal Conductivity (W/m2.K)	70.98
Tensile shear (Pa)	1.2e+7
Flexural strengths (Pa)	1.06e+8
Linear shrinkage (m/m)	0.003
Shore D Hardness	87

In Fig. 3 (a) the build layers for the pattern are shown as visualized in the Insight® processing planning software (used for fused deposition modelling machines [15], in Fig. 3 (b) the original built pattern and an RTV coated pattern show the different surface textures, and in Fig. 3 (c), an over molding pattern is displayed, where the pattern includes representative over molding elements, the over molded region, and the match plate. RTV silicone rubber is used to coat the pattern to smooth the surface and to provide an easy part release. Surface roughness is an issue with the AM process family and researchers engaged in applying AM solutions for mold manufacturing have had ejection issues connected with the build surface finish. Post processing operations are typically required if a smooth surface is desired. Here, a material extrusion process and ABS material is employed to create the pattern, and in lieu of chemical smoothing or finish sanding, the RTV is employed to smooth the surface and be a releasant.

The patterns were easily removed from the epoxy. The final inserts are placed in the mold halves, as shown in Fig. 4. The over molded components have pockets for their placement in the insert. Additional end seals are also fabricated from the AM pattern for flash control.

The interior cavity surfaces are smooth. The process planning for the pattern was less than 1 minute, the assembly time for the pattern and match plate was approximately ½ hour, and the cure time for the epoxy and the silicone was approximately 26 hrs. The time where an employee directly interacts with the fabrication process is short, and the required skill level for this insert solution is very low.

### C. Injection molding analysis

The injection parameters need to be determined for the injection molding operation. Here, Autodesk Mold Flow Advisor 2017 is applied to determine the fill time, and the injection pressure using the input data provided in Table III.

TABLE III. MOLD FLOW SIMULATION INPUT DATA

Injection property	Value
Injection Temperature (°C)	225
Mold Temperature (°C)	40
Gate Diameter (mm)	3
Maximum machine injection pressure (MPa)	1

As shown in Fig. 4, the material injection gate is centrally located; consequently, the maximum fill time is 0.8 seconds along the longitudinal axis, but there are variants in the fill time, as shown in Fig. 5a. The temperature contours and cooling times are dependent on the system configuration, and are not presented here. The maximum injection pressure is at

the gateway, and 0.11 MPa. The average injection pressure is very low and is almost homogenized (Fig. 5b).

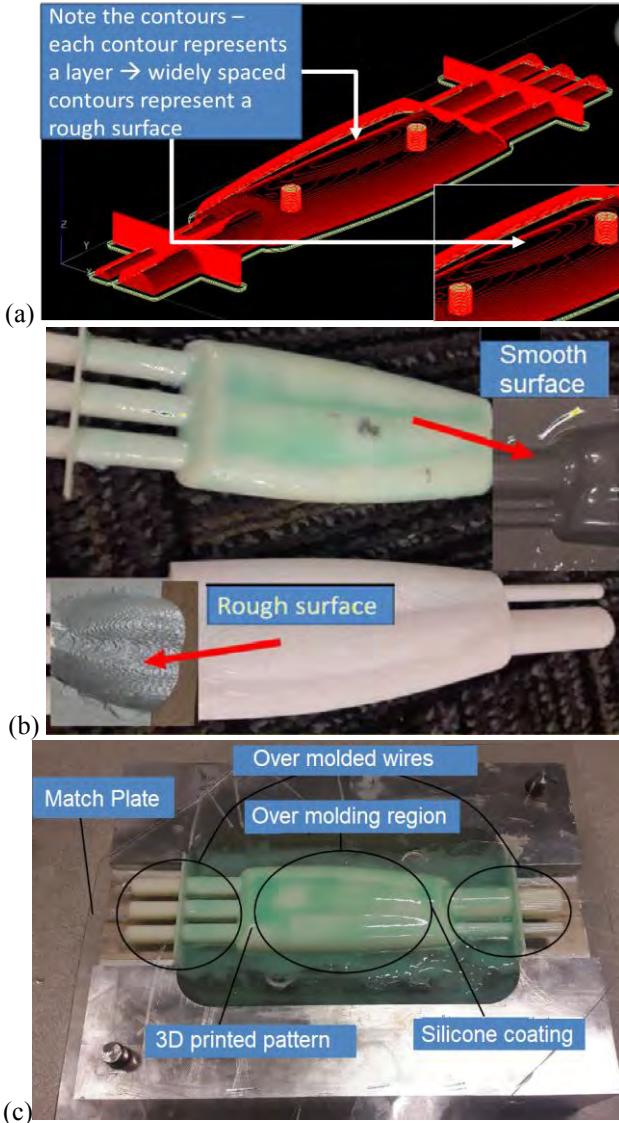

Figure 3. (a) The build layers as represented by the Insight® process planning software, (b) the built and coated patterns, and (c) The parts of the epoxy mold making process

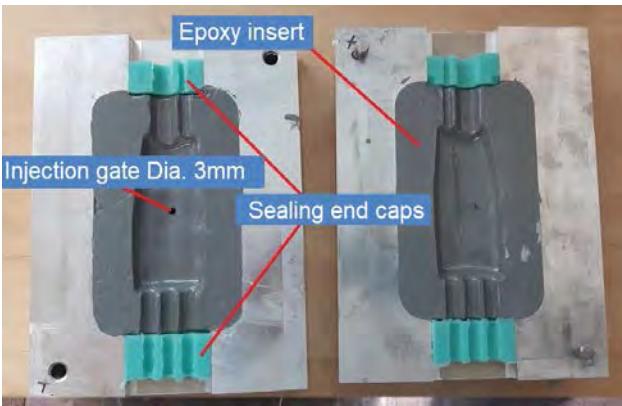

Figure 4. Epoxy inserts, and sealing end caps for the mold set.

#### IV. EXPERIMENTAL RESULTS

In order to test the mold, the test part (Fig. 6) was placed inside the mold. The over molding region is encircled in the picture. The wires fit into the sealing end caps. The injected Technomelt-PA 7846 black covered the wire splice completely, and as shown in Fig. 7, the over molded product has a very smooth surface. The resulting product did not adhere to the mold cavity surface, and was removed easily. The material costs for this solution are divided into 2 categories: capital costs and consumable cost. (Table IV). The overall cost is approximately \$140 US, which is much less than the cost of making a permanent aluminum mold using conventional machining processes (estimated to be \$840 US, using a 3 axis mill, and a final polishing operation, Table V).

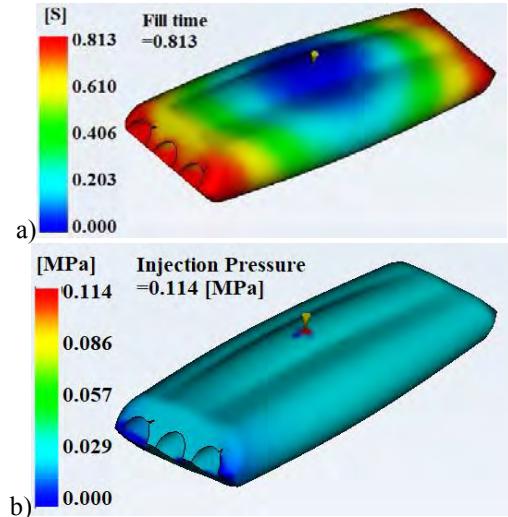

Figure 5. a)Fill time contours. B) Injection pressure contours.

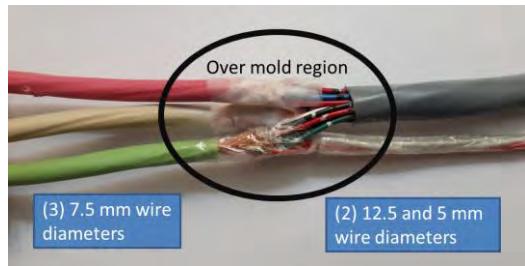

Figure 6. Over molding test application.

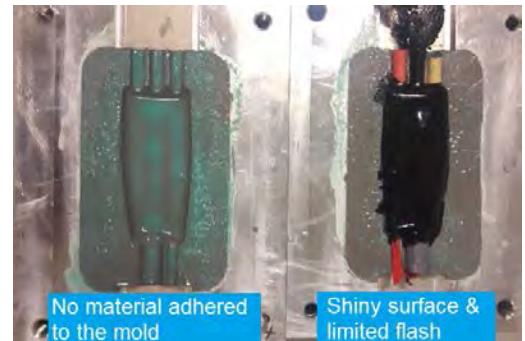

Figure 7. The over molded product in the mold. Note that there is no residual material in the left cavity and minimal flash in the right cavity.

For machining a permanent aluminum mold, the Mastercam verification analysis indicates that 4 hours machining is required to fabricate the two mold blocks (Fig. 8). The machining process includes a face milling, two rough machining operations, followed by a finishing pass with a large step over. In Table V, a detailed cost breakdown is presented.

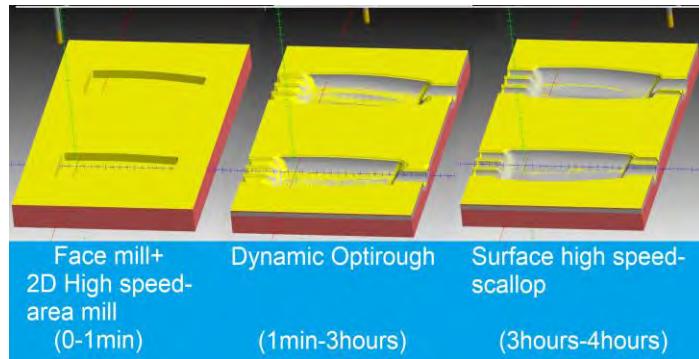

Figure 8. Permanent mold machining strategies and verification model.

TABLE IV. MATERIAL COSTS FOR FABRICATING THE EPOXY MOLD

<b>Capital costs</b>	Aluminum blocks	\$70
	Match plate material	\$5
	AM pattern printing	\$16
<b>Consumables</b>	Aremco 805	\$44
	RTV Silicone	\$6
<b>Total (US Dollar)</b>		<b>\$141</b>

TABLE V. COSTS FOR MACHINING A PERMANENT MOLD (NOTE: THIS DOES NOT INCLUDE MATERIAL COSTS)

Process	Time	Cost
Process planning	6 hours	\$300
Set up time	1 hour	\$80
Machine run	4 hours	\$400
Polishing	16.2 inch <sup>2</sup> - 2 μm Rough	\$60 [16]
<b>Total (US Dollar)</b>		<b>\$840</b>

The final product is shown in Fig. 9. There is some flash; consequently, the sealing end cap solution will be redesigned.

Figure 9. Final over molded product. The production quantity limitation for this mold solution will be caused by the wear of epoxy insert edges, the durability of the epoxy material from thermal shocks, and the durability of RTV silicone coating. Future experiments will be performed to determine the mold tool life.

Although the durability is important, epoxy insert replicates for a specific product will not increase the overall cost significantly. Therefore, if there are tool life issues, the RTV silicone coating can be applied as needed, and several epoxy inserts can be produced with the AM pattern.

## V. SUMMARY AND CONCLUSIONS

A lower cost mold fabrication solution is presented for low volume, high temperature molding materials. AM processes cannot directly be used to fabrication a low-cost solution, but AM processes can be utilized to manufacture a sacrificial intermediary pattern. This pattern is employed to create an insert (or inserts – as required) made from an epoxy. Further experiments need to be performed to determine the tool life. Once this is completed, a comprehensive cost analysis can be developed to determine the overall costs of this build strategy.

# Influence of Flow Velocity on Erosion-corrosion Performance of 90° Carbon Steel Elbows in Potash Brine

Raheem Elemuren, Richard Evitts, Ikechukwuka Oguocha, Glyn Kennell, Akindele Odeshi, Regan Gerspacher  
Mechanical Engineering, Chemical and Biological Engineering  
University of Saskatchewan  
Saskatoon, Canada

**Abstract**— In this study, the effects of flow velocity and solid concentration on erosion-corrosion behavior of AISI 1018 long-radius steel elbows (Schedule 40) in saturated potash brine were investigated. Potash brine containing 10 and 30 wt% of silica sands flowing at 2.5, 3.0, 3.5 and 4.0 m/s through a continuous loop with pipe internal diameter of 2.54 cm was used as the slurry. All experiments were conducted at 30 °C. The surface damage on elbows was evaluated using scanning electron microscopy (SEM). It was found that material loss per unit area was greater at high slurry velocity and solid concentration. Corrosion pits were visible on the elbow surfaces at low slurry velocities, but pits were not formed at higher velocities. Mechanical damage was concluded to be the dominant degradation mechanism at high flow velocities.

**Keywords-** *wear; erosion-corrosion; potash brine; pit; carbon steel*

## I. INTRODUCTION

The common occurrence of pipeline damage in the mineral processing industry is often attributed to erosion-corrosion. It is a process that occurs when abrasive solids suspended in a flowing corrosive liquid interact with the pipe internal wall resulting in significant material loss that may cause the pipe to leak or fail catastrophically. Pipe locations that experience abrupt changes in the flow direction, such as elbows, are subjected to severe hydrodynamic intensities occasioned by high angle impact by the particles in the moving fluid as well as change in flow regime at varying positions in the elbow [1].

It is widely acknowledged that the flow velocity and solid concentration are some of the key parameters that influence the wear behavior of pipeline materials subjected to erosion-corrosion [2]–[9]. Liu *et al.* [10] studied the effect of fluid flow velocity on the erosion-corrosion behavior of carbon steel elbows in 3.5wt % sodium chloride solution containing quartz sand particles as erodent. They discovered that the erosion-corrosion rate of elbow samples increased with increasing flow velocity. Zeng, Zhang and Guo [11] investigated the erosion-corrosion performance at different locations in a stainless steel elbow using a flow loop and reported that the maximum erosion-corrosion rate occurred at the outer wall of

the tested elbow outlet. Khayatan, Ghasemi and Abedini [12] compared the erosion-corrosion performance of pure titanium at different impingement angles. Their data showed that maximum degradation rates occurred at an impingement angle of 40°.

It is well known that the minimum material loss rate during erosion-corrosion of elbow occurs at the inlet section [10], [11]. The aim of this study was to investigate the effect of slurry flow velocity on the exit section of AISI 1018 steel elbow during erosion-corrosion in a slurry consisting of saturated potash brine and silica sand.

## II. EXPERIMENTAL PROCEDURE

In this study, long radius 90° 1018 steel elbows (schedule 40) were used. The chemical composition range (in wt%) of the steel is presented in Table 1. A typical optical image of the microstructure of the as-received elbows is shown in Fig. 1. The specimen for microstructure observation was prepared using standard metallographic methods. It was cut from one of the procured elbows and ground using SiC papers of 320, 400, 600, 800 and 1200 grit sizes. This was followed by polishing with 3 µm MD-Dac and 1 µm MD-Nap polishing clothes and finally etched for 30 s using Nital solution consisting of 2% nitric acid and 98% ethanol. A Nikon eclipse MA-100 inverted optical microscope was used to examine the microstructure which consists of a mixture of 82% ferrite and 18% pearlite.

Erosion-corrosion tests were conducted at 30 °C for 120 h in a flow loop (diameter of 2.54 cm) using ASTM G119-09 [13]. Solid concentrations of 10 and 30 wt% and slurry flow velocities ranging from 2.5 m/s to 4 m/s were used. Fig. 3 shows a diagram of the flow loop used in this study. The operating temperature was controlled with the aid of a heat exchanger placed within the slurry tank.

TABLE I. CHEMICAL COMPOSITION OF 1018 STEEL

Fe	C	Mn	Mo	P	S
Balance	0.19-0.21	0.42-0.45	0.001	0.012-0.018	0.005-0.01

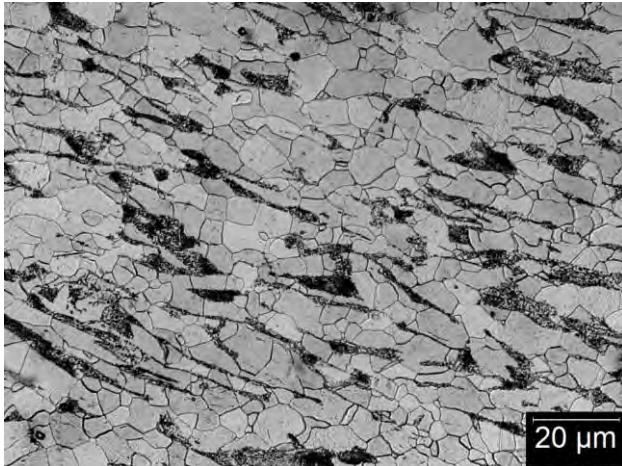

Fig. 1. Optical micrograph of 1018 steel elbow

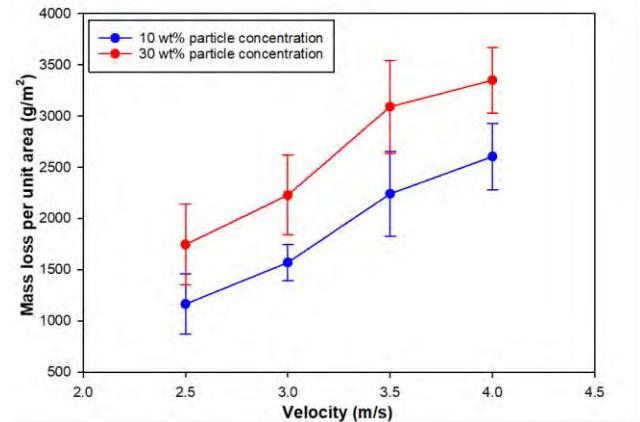

Fig. 2. Mass loss per unit area of elbows at different flow velocities after 120 h.

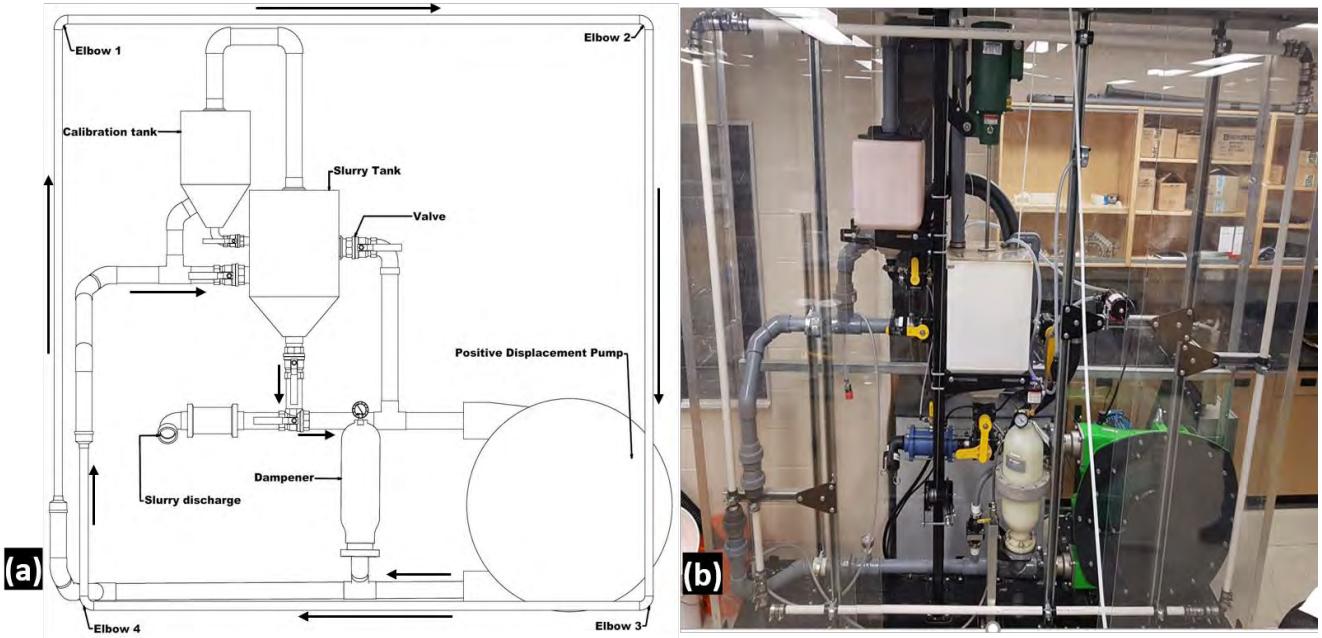

Fig. 3. Diagram of the experimental erosion-corrosion flow loop: (a) schematic (b) pictogram

The average weight loss of four 1018 steel elbows placed strategically at different locations in the loop was determined. The wear surfaces of tested elbows were evaluated using JEOL JSM-6010LA scanning electron microscope (SEM) to understand the dominant damage mechanisms.

### III. RESULTS AND DISCUSSION

#### A. Weight Loss Measurement

The mass loss per unit area obtained for the tested elbows under different velocities and solid concentrations is presented

in Fig. 2. Mass loss per unit area was affected by changes in both flow velocity and solid concentration. It increased with increasing slurry flow velocity and solid concentration. This is probably due to increase in mechanical interaction between the elbow surface and sand particles as slurry flow velocity and sand concentration increased.

#### B. Surface Characterization

Fig. 4 shows typical SEM micrographs obtained for the exit sections of tested elbows after 120 h in the loop. Fig. 4(a) shows the presence of corrosion pit and erosion-corrosion wear

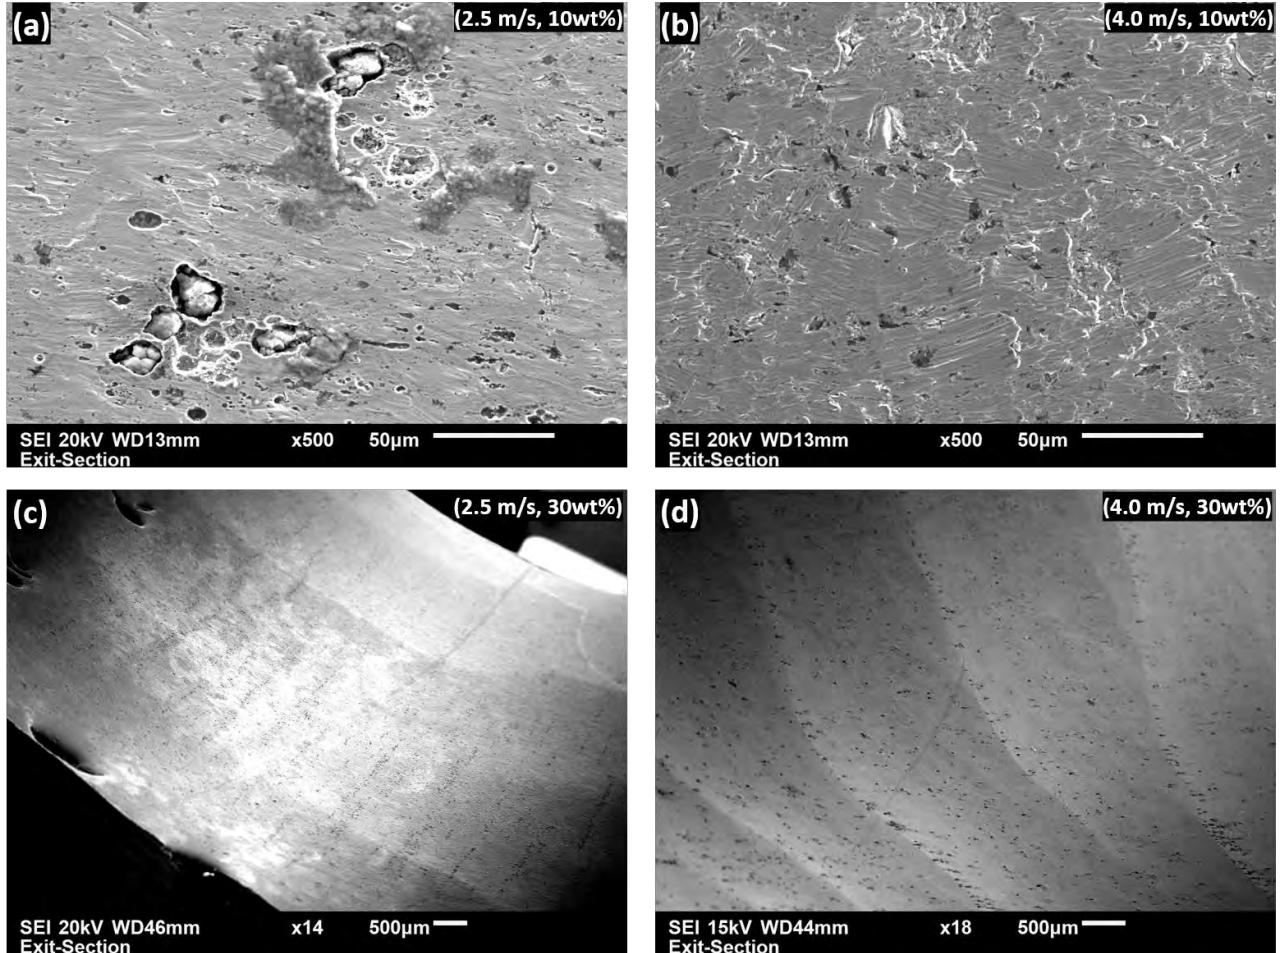

Fig. 4. Typical SEM micrographs of the elbows subjected to erosion-corrosion after 120 h: (a) and (c) exit section at 2.5 m/s; (b) and (d) exit section at 4.0 m/s.

scars (grooves) for elbows tested in a potash slurry containing 10 wt% flowing at 2.5 m/s. However, corrosion pits are not observed in the elbow subjected to a slurry flow velocity of 4.0 m/s shown in Fig. 4(b). The presence of grooves is an indication that mechanical erosion contributed to the material degradation process, while the formation of corrosion pits indicates that corrosion played a role during erosion-corrosion of elbows at low velocities. At high slurry velocities, mechanical damage appears to have played a more prominent role in material degradation than corrosion. This can be due to the fact that more particles strike the elbow surface and subsequently increase the depth of particle impingement into the surface. Fig 4(c) and 4(d) shows the surface morphologies of elbow tested at 2.5 m/s and 4.0 m/s using a particle concentration of 30 wt%. It can be observed that ridges formed on the elbow surface due to interactions with the sand particles over the test period. Few corrosion pits were observed on the surface of elbows tested at a slurry flow velocity of 2.5 m/s, which is consistent with what was observed for elbows tested with a slurry containing 10 wt% solid concentration.

#### IV. CONCLUSIONS

The mass loss per unit area of 90° steel elbows due to erosion-corrosion in saturated potash brine solutions containing silica sand were determined and the wear surface of the inner section of the elbows was investigated using a scanning electron microscope. The conclusions below are drawn from the experimental results.

1. Degradation of the tested elbows at low velocities was dominated by corrosion attack as evidenced by the presence of corrosion pits on the elbow surface. On the other hand, erosive wear due to particle impingement was the dominant damage mechanism at high slurry velocities.
2. Material loss per unit area increased with increasing flow velocity and solid concentration.

**Abstract**— Graphene oxide (GO)-based materials have been studied for applications in adsorption and water treatment. Experimental results revealed that GO is a promising adsorbent due to its low-cost production, large surface area, and strong interaction with a wide range of dyes in an aqueous phase. GO chemical structure has the potential to be tuned using chemical methods such as cross-linking to produce a framework material. Therefore, in this study, cross-linking of GO structure using chitosan biopolymer as a cross-linker agent was investigated. Cross-linked GO composites were prepared through a green solution-based chemistry approach. Chemical structural, morphological and thermal changes in the cross-linked GO composites were investigated using Fourier transform infrared (FTIR) spectroscopy, scanning electron microscopy (SEM), and thermal gravimetric analysis (TGA). Also, adsorption properties of samples were obtained using methylene blue (MB) as a cationic probe, in solution phase. According to the spectroscopy results, cross-linked composites suggested interaction between the GO sheets with chitosan through the formation of amide linkages. SEM results showed irregular layer shapes connected to each other with higher surface roughness and porosity in cross-linked samples. Changes in the thermal stability of cross-linked samples can be ascribed to the cross-linking effect. Kinetic adsorption studies indicated higher sorption capacity of cross-linked samples toward MB in aqueous phase compare to pure GO and chitosan.

**Keywords** ; graphene oxide, chitosan, cross-link, composite.

## I. INTRODUCTION

Removal of dyes and organic contaminants originating from printing, food and pharmaceutical industries throughout the world has greatly impacted materials engineering and chemistry. Many of the dye molecules are known to be carcinogenic and can affect air and water quality resulting in various undesirable human and ecosystem health issues [1]. Among the processes used for removal of dyes and contaminants, using the method of adsorption by solid adsorbents is considered as an efficient remediation technique

due to its simplicity, low-cost and possibility of recycling of the adsorbent in the adsorption process [2].

Recently, graphene and graphene oxide (GO)-based materials have been investigated as potential adsorbents for applications in wastewater treatment [3]. Graphene comprises of  $sp^2$ -hybridized carbon atoms arranged in a two-dimensional honeycomb lattice. Compared to graphene, which has a low aqueous solubility, GO is highly dispersible in organic solvents due to the presence of different oxygenated functional groups on its structure. The highly negative charge density of GO in aqueous solutions serves as an effective adsorption site for cationic dyes [3]. Thus, this material could be valuable for adsorption applications targeting cationic species in aqueous phases (such as methylene blue (MB) cation) and gas (such as  $N_2$ ) capturing applications [4]. Furthermore, the chemical structure and properties of GO can be further tuned using chemical methods [5]. Fabrication of framework structures from individual GO sheets was studied using chemical interactions to fabricate GO self-assembled structures [6]. Therefore, developing a stable framework from interconnected GO layers is attractive for the successful and practical use of these materials which remains the main challenge. It was found that a GO framework structure can be achieved by cross-linking GO sheets through covalent or non-covalent bond using bio-polymers such as chitosan as a cross-linker [7]. Due to the presence of amino groups, chitosan is considered as a positively charged polysaccharide, which can strongly attract GO sheets with a negative charge through electrostatic interactions. In addition, chitosan amino groups can covalently bond to the carboxyl groups of GO to form a homogenous and well-dispersed GO composite [7]. Therefore, chitosan is an efficient cross-linker which promotes the formation of the GO composite.

This study investigates the use of chitosan as a bio-polymer to produce green GO-chitosan cross-linked composite materials. The aim of this work was to develop a GO framework material with enhanced structural and thermal stability and to evaluate the chemical structure, morphology, thermal stability, and MB adsorption properties of GO cross-linked composites with chitosan for wastewater treatment and adsorption applications.

## II. EXPERIMENTAL

### A. Materials

Medium molecular weight chitosan (Mw=95,0000-310,000~95% deacetylation), sodium nitride ( $\text{NaNO}_3$ ), potassium permanganate ( $\text{KMnO}_4$ ), sulfuric acid (98%, ACS grade), methylene blue (high purity, biological stain), hydrogen peroxide (30% v/v) were obtained from Sigma-Aldrich Canada Ltd. Graphite flake, natural, -325 mesh, 99.8% (metals basis) were obtained from Alfa Aesar Thermo Fisher Scientific.

### B. Synthesis of Graphene Oxide

GO was synthesized from graphite flakes using the modified Hummer's method [8]. Briefly, 100 mL of concentrated  $\text{H}_2\text{SO}_4$  was added into a 500 mL flask filled with 4 g of graphite in an ice bath, followed by the addition of 2 g of  $\text{NaNO}_3$  and stirred for 4 h. Then, 12 g of  $\text{KMnO}_4$  was gradually added while the mixture was stirred for 2 h. The ice-bath was then removed, and the system was heated at 35°C for another 30 minutes. Subsequently, 240 mL distilled water was slowly added to the system and continued to stir for another 30 minutes. Then 160 mL of water and 30% v/v  $\text{H}_2\text{O}_2$  were added to terminate the reaction. The solution was stirred overnight and purified using multiple washing with millipore water, HCl (30 %) and ethanol until it reached pH~7. After multiple washings, the solid GO was vacuum-dried at 40°C to obtain completely dried GO powder.

### C. GO-Chitosan Cross-Linked Composite Preparation

Preparing of the GO-chitosan composite materials was carried out by preparing the GO solution with a concentration of 1 mg/mL. Also, 1% w/v chitosan solution was prepared by dissolving 5 g of chitosan in 500 mL of 1% v/v glacial acetic acid. The resulting chitosan solution was added dropwise to the GO solution with continuous stirring for about 4 h. The mixture was neutralized to pH~ 7 followed by stirring for 12 h. The precipitate was separated from the supernatant via medium-speed centrifuge (5000 rpm) followed by washing with millipore water and drying at ambient temperature for 48 h. Separately, pure GO solution with concentration of 3 mg/mL was also prepared for comparison purposes. The resulting composites were ground in a mortar and pestle followed by sieving through a 40-mesh sieve. An outline of the experimental procedure is illustrated in Fig. 1.

Figure 1. Synthetic procedure for GO-based composite materials.

### D. Measurements and Characterization

Fourier transform infrared (FTIR) spectra were obtained to confirm successful oxidation of graphite by observing the appearance of different functional groups and to monitor changes in these functional groups upon cross-linking. A Bio-

RAD FTS-40 IR spectrophotometer was used to obtain the IR spectra of the composite materials. The sample powder was mixed with pure spectroscopic grade KBr (weight ratio: 1:10). The FTIR spectra was obtained in reflectance mode with a resolution of 4  $\text{cm}^{-1}$  over the spectral range of 500–4000  $\text{cm}^{-1}$  using 71 kHz SPINAL-64 decoupling during acquisition with external reference to adamantane at  $\delta=38.48$  ppm. The surface morphology and surface topography of non-cross-linked and cross-linked composite materials were studied using scanning electron microscopy (SEM) (Hitachi Model SU8010). Images from samples were collected under accelerating voltage (3 kV). Thermal stability and decomposition temperature of the obtained composite materials were measured using a TA Instruments Q50000IR thermal gravimetric analysis (TGA) system which was operated from room temperature to 500°C at a heating rate of 5°C  $\text{min}^{-1}$  under nitrogen atmosphere.

### E. Kinetic Sorption Studies of Methylene Blue

Study of the kinetics of sorption of cross-linked material with chitosan toward MB was carried out by means of the one-pot method [9], where ~100 mg of a powdered sample was added to a folded filter paper with both ends sealed before adding to the sorbate solution. The sealed filter paper was immersed in a fixed volume (250 mL) of a 5  $\mu\text{M}$  MB solution. The MB solution aliquots were pipetted (3 mL) at selected time intervals and the residual supernatant MB concentration estimated by UV-vis absorbance of MB ( $\lambda_{\text{max}}=664$  nm). The kinetic uptake of pure GO, chitosan and its cross-linked composite at each sampling time interval ( $t$ ) was determined using (1), where  $C_0$  (mM) refers to the initial dye concentration at  $t=0$ ,  $C_t$  (mM) is the residual amount of MB at variable time ( $t$ ),  $V$  (L) is the volume of the MB solution, and  $m$  (g) is the weight of the adsorbent.  $C_0$  and  $C_t$  refer to the dye concentration at  $t = 0$  and variable times.

$$Q_t = \frac{(C_0 - C_t)}{m} V \quad (1)$$

To show and compare sorption characteristics of GO and its cross-linked form with chitosan the pseudo-second-order (PSO) model was used to obtain sorption parameters (such as  $Q_e$  which is the adsorbate quantity in the solid phase (mg/g)) and kinetic parameters (such as  $K$  which represents the sorption affinity constant). Kinetic isotherm profiles were obtained by plotting  $Q_t$  vs  $t$ . The PSO kinetic models (2) was used to evaluate parameters of the isotherm, where  $Q_e$  is the amount of solute adsorbed at a pseudo-equilibrium (mg/g) condition,  $Q_t$  is the amount of solute adsorbed at time  $t$  (mg/g) and  $K_2$  is the rate constant of PSO adsorption model.

$$Q_t = \frac{Q_e^2 K_2 t}{1 + K_2 t Q_e} \quad (2)$$

## III. RESULTS AND DISCUSSION

Various GO samples were cross-linked with chitosan, where GO was obtained from graphite powder as shown in Fig. 2.

Figure 2. Image of the produced GO-based cross-linked composite materials

#### A. Fourier Transform Infrared (FTIR) Spectroscopy

Fig. 3 shows the FTIR spectra of the cross-linked composite materials versus pure GO and chitosan as precursors. Firstly, the successful GO preparation (oxidation of graphite) was validated using FTIR by the characteristic peaks located at  $\sim 3200\text{--}3700\text{ cm}^{-1}$  ascribed to the stretching of the hydroxyl groups ( $\text{O-H}$ ),  $\sim 1680\text{--}1730\text{ cm}^{-1}$  and  $1550\text{--}1650\text{ cm}^{-1}$  as characteristics of the carbonyl groups ( $\text{C=O}$ ) and  $\text{sp}^2$ -hybridized  $\text{C=C}$ , and the bands at  $\sim 1230\text{--}1350\text{ cm}^{-1}$  corresponds to epoxy groups. Also, in the spectrum of chitosan, the main characteristic peaks are centred at  $1650\text{ cm}^{-1}$  and  $1590\text{ cm}^{-1}$ ; these correspond to the  $\text{C=O}$  stretching vibration of  $\text{NHCO}$  and the  $\text{N-H}$  bending of  $\text{NH}_2$ , respectively. The presence of the peak of both precursors (GO and chitosan) are supported by similar spectral features of cross-linked composite materials. However, some bands for the cross-linked GO composites are absent or their intensity increase when compared to similar bands for the non-cross-linked GO. Formation of covalent bonds between GO and chitosan can be demonstrated by elimination of some of the original GO bands and rise of new ones. The absence of a peak at  $1730\text{ cm}^{-1}$ , is attributed to  $\text{C=O}$  in carboxylic acid moieties in GO, and the greater intensity of the peak at  $1595\text{ cm}^{-1}$  corresponds to the formation of covalent bond in cross-linked GO composites. This information provides support for the formation of amide linkages between GO and chitosan as the linker and is in agreement with a previous report [10].

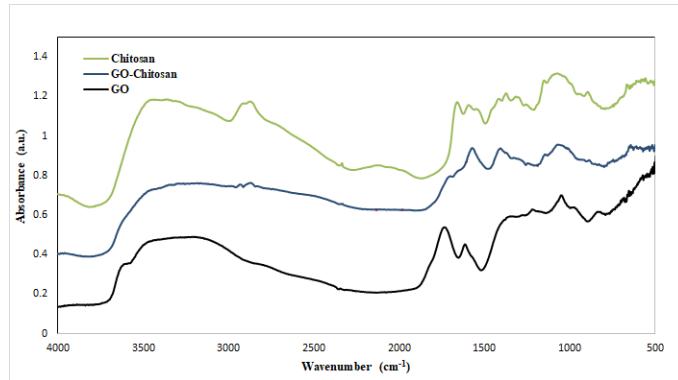

Figure 3. FTIR spectra of the precursors and GO-based cross-linked composite.

#### B. Scanning Electron Microscopy

Fig. 4 shows SEM micrographs of non-cross-linked and cross-linked GO composite materials. Fig. 4 (a) depicts graphite as a starting material, while Fig. 4 (b) is GO both made up of multiple layers stacked on top of each other. By comparison, the cross-linked GO composites Fig. 4 (c) and (d) indicate wrinkled ledges with irregular shape of layers

connected to each other. The micrographs revealed that cross-linking of the GO alters its morphology and surface roughness according to the cross-linker type and content. The obtained results herein indicate the composites possess higher surface roughness and porosity when compared with pristine graphite or GO. These variations in morphological and textural changes provide support for the self-assembly cross-linking between GO and chitosan.

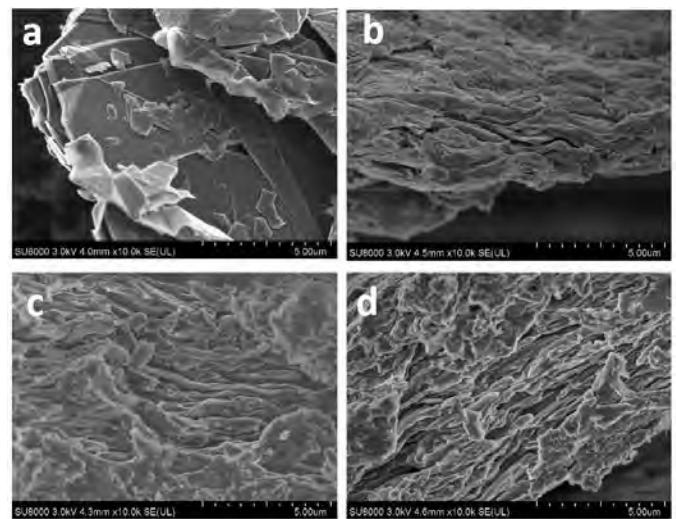

Figure 4. SEM micrographs of graphite (a), GO (b), GO-based cross-linked composite materials (c) and (d).

#### C. Thermal Gravimetric Analysis

The TGA results for the cross-linked GO composite materials are shown in Fig. 5. A rapid thermal decomposition occurred at  $\sim 200^\circ\text{C}$  for GO, while the cross-linked GO displayed two thermal events at approximately  $250^\circ\text{C}$ , and  $\sim 455^\circ\text{C}$ . These thermal events for the GO composites correlate to decomposition of GO oxygen functionalities and its framework structure, respectively. The change in the thermal stability of the cross-linked GO is due to framework effects arising from formation of covalent (amide) linkage and cross-linking with chitosan in agreement with earlier FTIR band result (Fig. 3).

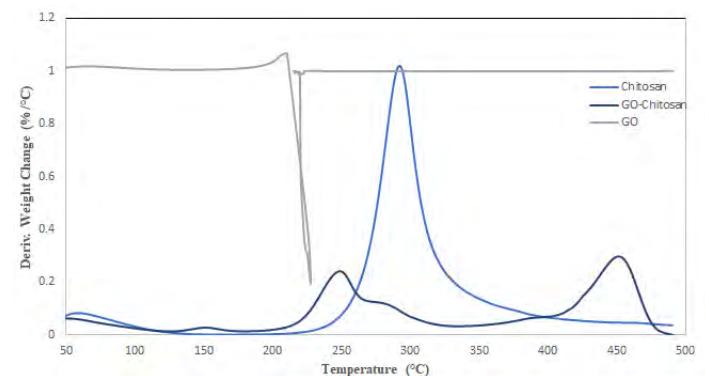

Figure 5. TGA curves of GO and GO-based cross-linked composite.

#### D. Kinetic Uptake Studies of Methylene Blue

Kinetic uptake studies of GO cross-linked chitosan systems can provide valuable insights on the reflection of cross-linking effect on adsorption properties GO composites. The surface functionality and sorption properties are affected by structural changes in the GO cross-linked material [11]. Fig. 6 presents the kinetic adsorption profiles with MB over a 240 minute interval, in which the PSO kinetic model provided reasonable fitting results. According to the obtained kinetic parameters ( $k$  and  $q$ ) as listed in table 1, the GO cross-linked composite displays enhanced uptake capacity for MB which is related to the cross-linking effect. The  $Q_e$  and the PSO rate constant values ( $k$  and  $q$ ) for the three sorbent materials increased upon cross-linking: chitosan (4.175) < GO (5.059) < GO-chitosan (5.107) and, chitosan (0.003) < GO (0.006) < GO-chitosan (0.019), respectively. It was shown that the intra-particle diffusion and external diffusion play an important role in the adsorption kinetics [12]. The greater kinetic uptake of the composite material recommends there are more active adsorption sites according to the increasing  $Q_e$  values as the GO becomes cross-linked. The decreasing kinetic trend of all sorbent materials suggests diffusion of MB through the pore network of the sorbent materials decreased with increasing contact time between sorbent and MB. This may be related to the decreasing number of available adsorption sites as time increases.

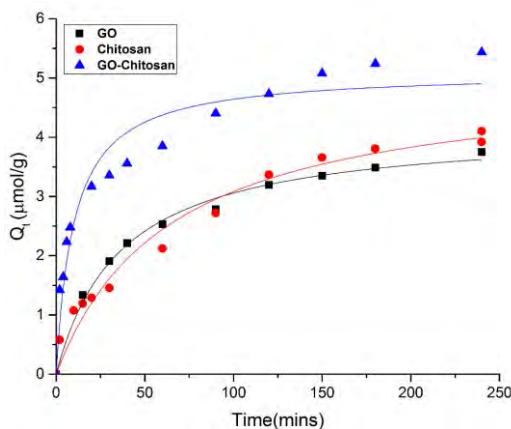

Figure 6. Uptake kinetic profile of MB by GO and GO-based cross-linked composite material, where the fitted lines are associated to the second-PSO model (see (2)).

TABLE 1. PSO KINETIC MODEL VALUES FOR, GO, CHITOSAN AND ITS CROSS-LINKED COMPOSITE

model	pseudo-second order		
equation	$Q_t = \frac{Q_e^2 K_2 t}{1 + K_2 t Q_e}$	value	standard error
adj. R-Square	0.99779	0.981663	0.96183
GO	q (mg/g) k (g mg/min)	4.17552 0.00655	0.07646 5.21701E-4
chitosan	q (mg/g) k (g mg/min)	5.05941 0.00308	0.28235 6. 54771E-4
GO-chitosan	q (mg/g) k (g mg/min)	5.10796 0.01948	0.19656 6.64771E-4

#### CONCLUSIONS AND FUTURE WORK

In this study, GO-based cross-linked composite materials were synthesized with various surface properties and morphologies that arise from cross-linking with chitosan at various compositions. FTIR was conducted on the cross-linked composites and compared to pure GO to support the formation of amide linkages. The greater surface roughness of the GO cross-linked composite materials parallel the variable morphology revealed by SEM. TGA results revealed evidence of cross-linking between GO and chitosan according to changes in the thermal stability of the composite materials. In conclusion, GO-based composites could be used as stable framework structures for potential applications in the removal of dyes and pesticides in wastewater environments.

Future testing to support this study will involve BET nitrogen adsorption to obtain information on gas sorption capacity and estimate the average pore size and surface area of samples using a Micromeritics ASAP 2020 (Norcross, GA) instrument. Also, mechanical properties of GO composite thin films will be measured by Dynamic Mechanical Analyzer (DMA) 2890.

**Abstract**— In this study, a laser additive manufacturing method, known as selective laser melting (SLM), was applied to produce cube blocks of 316L stainless steel. The microstructure and corrosion properties of the produced samples were analyzed using scanning electron microscopy, cyclic potentiodynamic polarization testing, and electrochemical impedance spectroscopy. The results were also compared with the properties of a conventional wrought 316L stainless steel sample. The microstructural studies showed that the SLM-manufactured samples have a regular network of melt pools containing austenite grains along with elongated or equiaxed cellular sub-grains. The potentiodynamic polarization results depicted that the SLM fabricated samples had higher positive pitting potential and a wider passivation range than those of the wrought sample, corresponding to their better corrosion resistance. However, the SLM fabricated samples showed a weaker re-passivation property, which possibly is attributed to the presence of pre-existing porosities in the structure of the SLM sample formed during the fabrication process. The EIS data also confirmed a larger capacitive arc for the SLM fabricated samples than its wrought counterpart, indicating a higher charge transfer impedance and a better corrosion resistance.

**Keywords:** *Selective laser melting, Additive manufacturing, 316L Stainless steel, Microstructure, Corrosion properties*

## I. INTRODUCTION

Nowadays, innovative and advanced 3-dimentional printing, also named additive manufacturing (AM), as a bottom-up method, is rapidly growing and has drawn many attentions from both academia and industry due to its capabilities in the production of near-net shaped components. Comparing with conventional manufacturing processes, such as casting or forming, this technology provides many advantages including fabrication of metallic parts with more complex shapes, less time from design stage to manufacturing, no need to post processing, and lower wastage precursors. In this technology, without the usage of specialized molds or tools, in a single step process, 3D components are fabricated through layer-wise addition of melted/sintered precursors powder on the substrate or previous layers, based on their

digitally defined Computer Aided Design (CAD) data [1-6]. In recent years, various laser-based additive manufacturing methods for fabrication of metallic components have been developed, such as laser engineered net shaping (Lenz), direct metal deposition (DMD), laser solid forming (LSF), direct laser fabrication (DLF), laser metal deposition shaping (LMDS), direct metal laser sintering (DMLS), and selective laser melting (SLM) [1,5,7].

316L austenite stainless steel (316L SS) with excellent corrosion resistivity, decent mechanical properties, and good weldability is widely used for various applications in many industries, such as oil and gas, marine, and biomedical sectors. Currently, 316L components are mainly produced using conventional manufacturing methods, which do not allow for the production of complex shapes and therefore, final parts need to be welded or machined, consequently both fabrication time and cost increase. Additive manufacturing has emerged as an appropriate solution to resolve this issue. Nevertheless, the components built through these techniques have different microstructures and properties than those fabricated through conventional methods, which makes it crucial to study and research their as-printed properties [5,6,8]. In spite of existing comprehensive works on investigating various properties of SLM fabricated parts, there is very limited literature on corrosion related characteristics and electrochemical properties of AM components [9]. In the present study, the microstructure and corrosion performance of a 316L stainless steel (SS) produced through SLM technique were studied and the results were compared with a conventional wrought 316L SS.

## II. MATERIALS AND METHODS

Several cube blocks of 316L SS with the edge length of 15 mm were printed through SLM technique using a Renishaw AM 250 3D printer machine. The SLM processing parameters included powder layer thickness of 40  $\mu\text{m}$ , laser power of 180 Watt, hatch distance of 0.08 mm, hatch offset of 0.18 mm, exposure time of 65  $\mu\text{s}$ , and the bed temperature of 80°C. The precursor powder particle size for SLM was maximum 63  $\mu\text{m}$  in diameter.

Table 1. Nominal chemical composition of the used wrought and SLM-316L SS (wt. %)

Material	C	P	Si	Ni	Mn	S	Cr	Mo	Fe
Wrought 316L SS	0.017	0.032	0.540	10.090	1.570	0.025	16.890	2.040	Bal.
SLM-316L SS	0.030	0.025	0.750	14.000	2.000	0.010	18.000	2.620	Bal.

The chemical composition of SLM-316L SS and its wrought counterpart are presented in Table 1. To investigate the impact of the building direction, the SLM produced samples were cross sectioned both perpendicular and parallel to the building direction, provided the top and the side views, respectively. To study corrosion resistivity of the samples, Cyclic Potentiodynamic Polarization (CPP) and Electrochemical Impedance Spectroscopy (EIS) tests were carried out. Before the electrochemical testing, all samples were cold mounted into an epoxy resin to limit the exposed area of the sample to only one face, while a wire was connected to the back side of the sample through the resin, providing the electrical connection during the electrochemical tests. This was followed by standard grinding and polishing of the surface to a mirror-like surface finish. All the tests were performed using an IVIUM Potentiostat/Galvanostat instrument in a three electrodes cell system containing the sample as the working electrode, a platinum plate as the auxiliary electrode, and Ag/AgCl as the reference electrode. In all experiments, aerated 3.5 wt. % NaCl solution at room temperature ( $25\pm1$  °C) was used as the electrolyte. Before every test, open circuit potential (OCP) was measured for 3600 s to ensure the samples reached to the stability. The CPP test was conducted at scan rate of 1 mV/s, starting from -0.2 V versus the OCP up to the vertex current of 10 mA, in which the scanning direction was then reversed. The EIS test was performed in an AC current with the amplitude perturbation of  $\pm 10$  mV with respect to the OCP in a frequency range from  $10^5$  Hz to  $10^2$  Hz in the 3.5 wt. % NaCl solution at 25 °C. For microstructural study, the polished samples were electro-etched in 20% Nitric acid solution at the voltage of 1.7 V for 15 s.

### III. RESULTS AND DISCUSSION

Fig. 1 shows the microstructures of electro-etched wrought and SLM-316L samples. It can be seen that the SLM sample possesses a woven network of well-defined melt pools (Fig. 1a-d). This special structure has been resulted from the scanning action of the laser beam, where the long axis of the elliptical shaped melt pools corresponds to the direction of the laser scan in the SLM process (Fig. 1a-top view). Fig. 1d shows the cross-section of the printed sample across the plane parallel to the building direction (side view), revealing overlapped melt pools with semi-circular shapes. Clearly, the side view (Fig. 1d) contains higher density of the melt pool boundaries than the top view (Fig. 1a). At higher magnification, the austenite grains were appeared inside each melt pool and in each of the grains, elongated or equiaxed cellular sub-grains structure were revealed (Fig. 1a, c). The size of the sub-grains is around 1  $\mu\text{m}$  in diameter. These microstructural features are ascribed to extremely rapid solidification rate of the process, which in

turn induces the elemental segregation and enrichment of sub-grain boundaries [7]. Trelewicz *et al.* [7] have shown that because of Mo and Cr segregation along the cell boundaries of SLM-316L, the corrosion characteristics of the intercellular regions are different, associated with rapid solidification and non-equilibrium nature of the process. Consequently, when the surface was electro-etched, the cell boundaries were not corroded as severe as the interior of the cells, resulting in unveiling the sub-grain structure. As expected, the microstructure of the wrought sample (Fig. 1e) contains annealed equiaxed grains along with recrystallized regions formed during annealing.

The cyclic potentiodynamic polarization curves of the SLM (both top and side views) and wrought samples obtained in aerated 3.5 wt. % NaCl solution at room temperature are presented in Fig. 2. Electrochemical corrosion parameters including corrosion potential ( $E_{\text{corr}}$ ), corrosion current ( $i_{\text{corr}}$ ), pitting potential ( $E_{\text{pit}}$ ), defined as the inflection point in the anodic polarization curve, where the current density rapidly increases, and re-passivation potential ( $E_{\text{rep}}$ ), where the reverse scan intersects the forward scan, extracted from the CPP curves, are shown in Table 2. A combination of higher  $E_{\text{corr}}$  and lower  $i_{\text{corr}}$  corresponds to a better corrosion performance. Comparing the corrosion data reveals that the top side of the SLM-sample has the highest corrosion resistance. All samples exhibited a clear passive region. Similarly, the top surface of the SLM sample possessed the widest passive range with the highest  $E_{\text{pit}}$  contributing to a better corrosion properties of the sample. Using Tafel equation and tangent lines slopes on the cathodic and anodic regions of the curves, corrosion rates of the samples were derived that were found to be consistent with the above-mentioned results. In all samples, sharp fluctuations in current density can be seen in passive region showing the pitting initiation, so called metastable pitting. In fact, metastable pitting represents the start, growth and re-passivation of a micro-pit on the surface of the samples. However, when the critical value of the potential is reached, the micro-pit can be transformed to a stable pit and then the passive layer on the surface is permanently ruined [10]. Comparing the  $E_{\text{rep}}$  of the samples, it is evidenced that SLM sample has weaker re-passivation property.

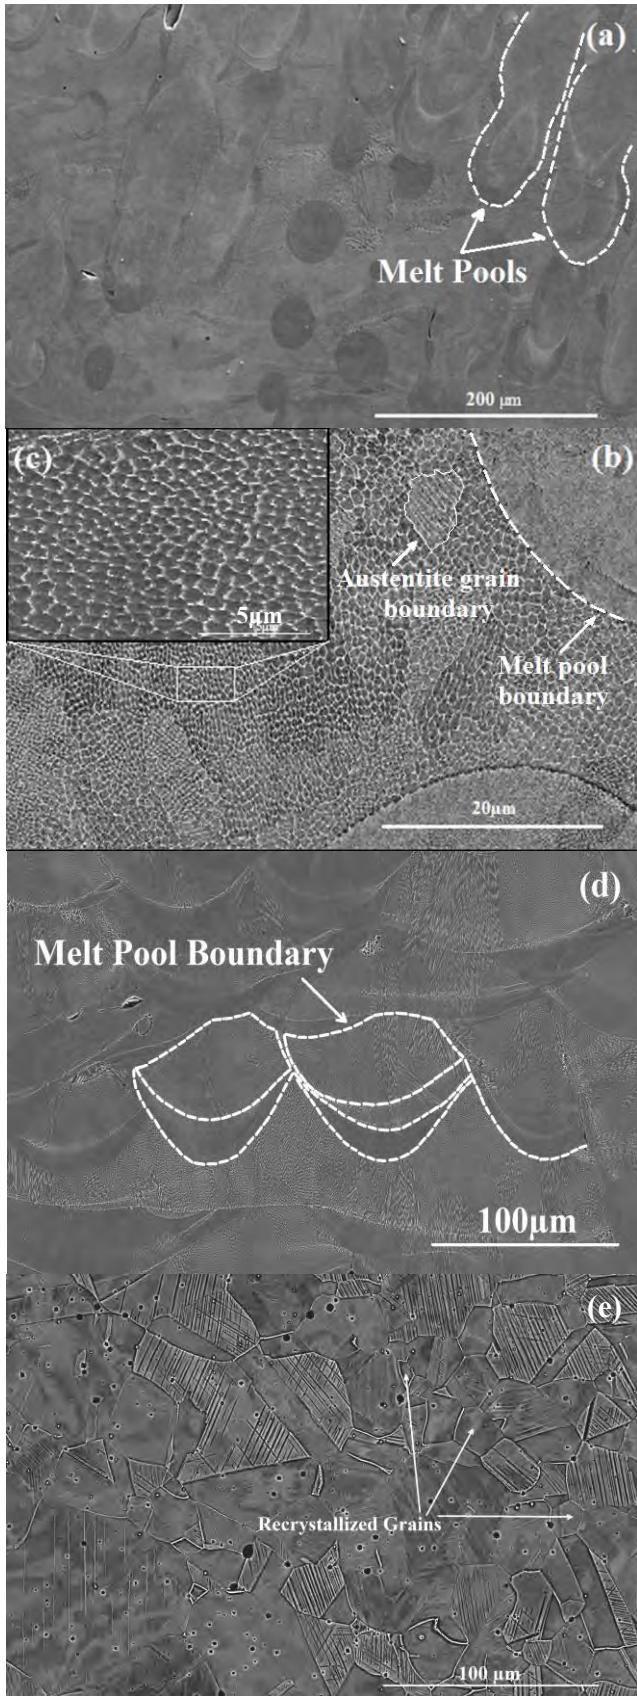

Figure 1. The microstructure of 316L SS: top view of the AM fabricated sample (a-c), side view of the AM fabricated sample (d), wrought sample (e).

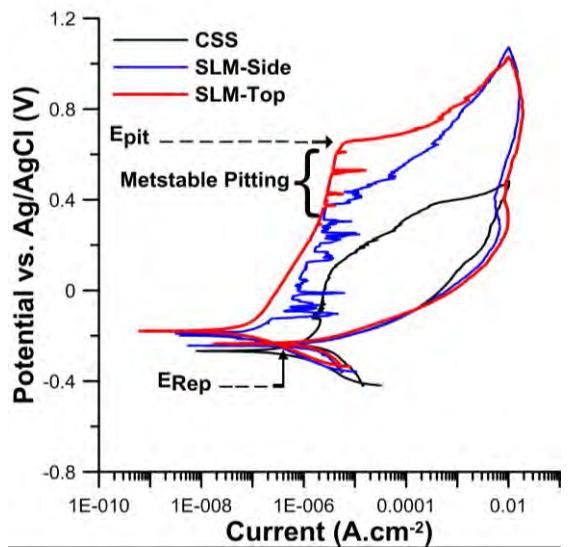

Figure 2. Cyclic potentiodynamic polarization curves of the studied samples.

No clear dependency so far has been reported between  $E_{\text{Corr}}$ ,  $i_{\text{Corr}}$ , and  $E_{\text{pit}}$  of additively manufactured products with porosity level of the sample [11]. However, it has been shown that the amount of  $E_{\text{rep}}$  in additively manufactured products is dependent on their porosity level [11]. Therefore, the improved re-passivation behavior of the wrought sample can be justified if the porosity level of the sample is considered zero relative to the SLM sample containing numerous pre-existing porosities in its structure (see Fig. 1d). The SEM micrographs of the SLM samples after the CPP test are depicted in Fig. 3. It can be seen that there is no preferred position for pit formation on the surface and the specimen exhibits isolated corrosion pits.

Additional experiment on the corrosion behavior of the samples were done by EIS tests to investigate the protective nature of the formed passive film on the 316L SS surface. The Nyquist plots in Fig. 4 depict a single semi-circle capacitive arc trend that corresponds to double layer and passive film formation on the samples' surfaces. This indicates that the corrosion mechanism of all three samples were identical and typical of stainless steel material. The EIS data showed a larger capacitive arc, an indication of improved corrosion resistance, for the SLM samples (both top and side views) than that of the wrought 316L SS. It confirms the aforementioned CPP results of the corrosion properties. Comparing the results of the top and side views of the SLM sample reveals that the top view is covered by a more protective passive layer that can be correlated to the lower density of the melt pool boundaries on this face than that on the side view.

#### IV. Conclusion

In the present work, the corrosion properties of the selective laser melted 316L stainless steel and its wrought counterpart were studied. Microstructural analysis of the samples

revealed that the SLM processed stainless steel contained very fine cellular sub-grain structure resulted from scanning action of the laser beam combined with rapid solidification of the melt pools, contributing to elemental segregation along the intercellular boundaries. Through electrochemical tests, it was found that SLM-316L SS has higher pitting

resistance, lower corrosion rate, and more noble corrosion potential than those of the wrought sample. However, its repassivation potential was degraded, which was primarily attributed to the pre-existing porosities in its structure formed during the fabrication process.

**Abstract**— Mechanoluminescence (ML) is the emission of light from a solid material in response to mechanical stimuli [1]. Mechanoluminescent materials are classified based on the types of stress activation required for luminescence behaviour. In this paper, we propose the study of light emission characteristics of an elastico-mechanoluminescent (EML) material dispersed in a soft polymer matrix, under high-strain compressive loading for a qualitative and quantitative testing of onsite strain. We developed a strain sensor by creating a composite material through the combination of a polydimethylsiloxane (PDMS) matrix structure and strontium aluminate, europium, and dysprosium doped (SAOED) crystals. SAOED crystals possess a strong luminescence behavior, which has led to their proliferation as a viable optical sensor. Composite materials were tested using a modified Kolsky bar and high-speed camera. The light-emitting characteristics of the SAOED crystals in response to mechanical stimuli allows for the quantification of stress-strain experienced by the composite material. The light intensity, which is measured by a complementary metal–oxide–semiconductor (CMOS) sensor in a high-speed digital camera, provides a quantitative measure of the strain-rate. Light-emitting characteristics of the EML material and the strain behavior of the material were studied.

**Keywords:** mechanoluminescent crystals, high strain-rate, elastico-mechanoluminescence, strain sensor, SAOED

## I. INTRODUCTION

Measurement of stress and strain can be carried out via non-contact or contact methods such as digital image correlation (DIC) [2] and piezoresistive sensing [3]. In recent years, there has been concerted effort to develop noncontact strain-sensing technology for real-time monitoring of structures such as electronic speckle pattern interferometry (EPSI). However, this process requires tedious data processing techniques for stress and strain characterization of a material [4]. Non-contact strain sensing for structural health monitoring (SHM) of mechanical, civil, and aerospace structures has garnered interest in recent years [5-6]. High-impact forces, which are currently detected by SHM, have posed a great threat to the reliability of aerospace structures for over 50 years [7]. This problem has led to

advancement in sensor technologies that allow for the monitoring and immediate measurement of stress-strain on these structures. These advanced sensors pose a significant challenge, as only trained professionals can fully interpret the data acquired from these measurements. Therefore, there is a need for an easy-to-use qualitative and quantitative stress-strain sensor for SHM.

Material that possesses the unique characteristic of mechanoluminescence (ML) makes it suitable for qualitative and quantitative stress-strain measurements. ML material emits light in response to mechanical stimuli such as tension, pressure, bending, compression, etc. ML material can be grouped into three categories: elastico-ML (EML), plasto-ML (PML), and fracto-ML (FML). These categories correspond to luminescence induced by elastic deformation, plastic deformation, and fracture, respectively [1]. The stress-induced luminescence behavior of fracto-ML and plasto-ML materials pose a severe challenge, as light is emitted post yielding. Hence, EML has been widely adopted for strain-sensing purposes, as it allows for non-destructive testing. This mechanical behavior of EML has led to its widespread use in sensing applications, such as a uniaxial tensile test for full-field strain measurement [8]. The mechanical and luminescent properties of EML materials provide both qualitative and quantitative measurements of strain.

Recently, Ryu et al. [9] proposed an ML composite based on polydimethylsiloxane (PDMS) for the measurement of high strain rate. They reported the light characteristics of the PDMS–ML composite europium tetrakis (dibenzoylmethide)-triethylammonium (EuD<sub>4</sub>TEA) crystals under high-strain compressive loading using a Kolsky bar and an image processing technique. EuD<sub>4</sub>TEA crystals are reportedly one of the brightest ML materials [10], and hence are used as a viable optical sensor. However, EuD<sub>4</sub>TEA crystals exhibit FML properties, which limit their application for non-destructive testing.

In this paper, we characterize the light-emitting properties of a PDMS-based EML composite for the direct visualization of stress and strain under high-strain compressive loading using a

Kolsky bar. The EML crystal used is strontium aluminate, europium, and dysprosium doped (SAOED), which possesses a green phosphor. The SAOED crystal is uniformly dispersed in a PDMS matrix. A Split-Hopkinson pressure bar or Kolsky bar is widely used to measure the stress-strain relation of material under high-impact load. Strain and strain rate of the sample are derived from the pulse data generated by strain gauges on the input and output bar, assuming homogeneous deformation of the sample. A complementary metal–oxide–semiconductor (CMOS) sensor in a high-speed digital camera is used to measure the light emitted from the composite material. Image processing of the acquired 24-bit RGB images from the high-speed camera is used to quantify the light emission characteristics of SAOED crystals in the polymer matrix.

We began this study by creating a composite material made of SAOED crystals uniformly dispersed in a PDMS matrix. The composite material was then subjected to high-strain compressive loading. The strain data acquired from the Kolsky bar and images produced by the high-speed camera were then processed to obtain a quantitative relationship between strain and light intensity.

## II. EXPERIMENTAL METHODOLOGY

### A. Materials

PDMS (Sylgard 184 kit) was acquired from Dow Corning Corp., and SAOED crystals were purchased from Sigma-Aldrich and used as received.

### B. Composite Fabrication

The PDMS mixture was first made by mixing a 10:1 weight ratio of PDMS base to curing agent. Then a 1:1 weight ratio of PDMS mixture to SAOED crystals was mixed and stirred. The combined mixture of PDMS and SAOED crystals was then heated in a polyethylene terephthalate (PETE) container for ~40 min on a heated bed at 52 °C (Fig. 1). The initial heating of the combined mixture increases the viscosity of the PDMS mixture and prevents the sedimentation of the SAOED crystals. Dispersion of the EML crystal was verified using an inverted microscope (Fig. 2A). The mixture was then degassed in a desiccator to remove air bubbles and poured into a circular aluminum mold with an inner circular diameter of 15 mm and a height of 4 mm. The combined mixture of SAOED crystals and PDMS mixture was then cured over a heated bed at 100 °C (Fig. 1). Six composite samples were made for each test.

### C. Experimental Setup

A high-speed CMOS sensor camera (Phantom V1611) was used to photograph the ML emission during loading, and a Split-Hopkinson pressure bar or Kolsky bar, supplied high-strain compressive loading. The high-speed camera, set with consistent exposure time, was positioned perpendicular to the Kolsky bar ~30 cm from the sample. The Kolsky bar consists of a striker, input bar, and output bar, with strain gauges attached on the input and output bars. Two strain gauges were placed on the input bar and output bar, which were located close to the centre of the bar. The strain gauges were positioned 180° from each other to negate bending waves when connected to a half-bridge circuit. Compressed nitrogen gas was used to drive the striker of the Kolsky bar. The pressure of the gas released is controlled by a valve on the compressed gas tank (Fig. 3). A hollow output bar

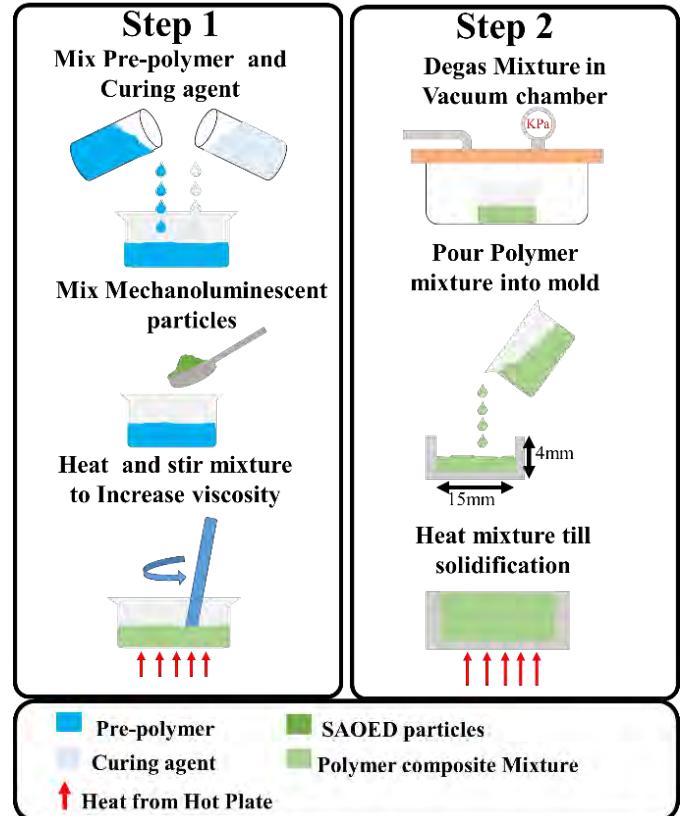

Figure 1. Fabrication process of strontium aluminate, europium, and dysprosium doped composite.

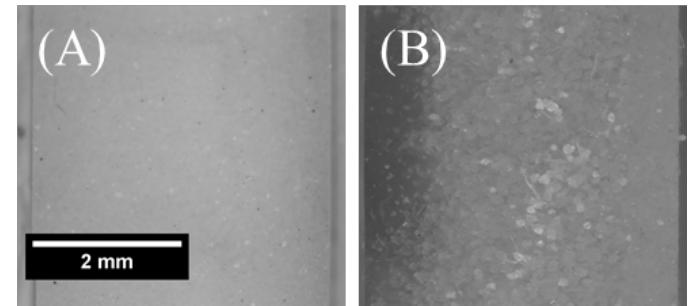

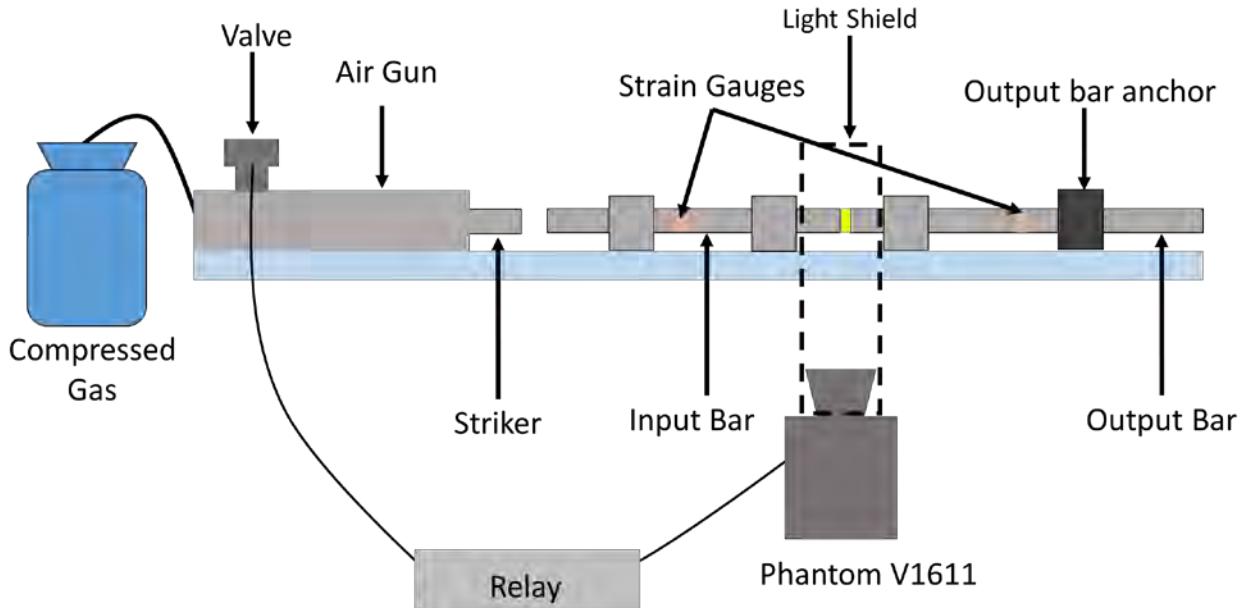

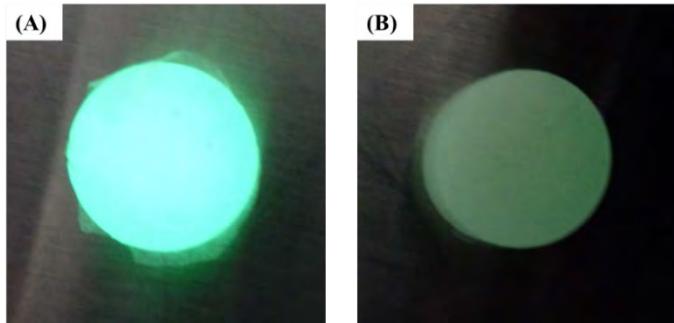

Figure 2. Mechanoluminescent crystals in polymer matrix. (A) Crystals suspended in the polymer matrix. (B) Initial result showing sedimentation of strontium aluminate, europium, and dysprosium doped (SAOED) crystals.

was used to increase load sensitivity [11]. National instrument USB-6341 was used for data acquisition from the strain gauges, and data acquisition occurred at 100 kHz. A relay was used to accurately synchronize the start time of the high-speed camera and the Kolsky bar (Fig. 3).

To begin testing, the PDMS-EML composite was consistently photo-excited by an 80 W LED lamp with a wavelength of 400–700 nm (white light) for ~2 min. This step ensured that the sample was fully saturated with the same photo-excitation power. An aging time of ~2 min immediately

**Figure 3.** Experimental setup consisting of a Kolsky pressure bar and high-speed camera.

**Figure 4.** Photo-excitation of PDMS–EML composite. (A) Photo-excitation of PDMS–EML composite before aging. (B) Photo-luminescent stress-free decay of PDMS–EML composite.

followed this step, to minimize the effects of stress-free photo-luminescent decay to maximize ML sensitivity [8]. The PDMS–EML composite was aged in a dark environment before the loading was applied (Fig. 4).

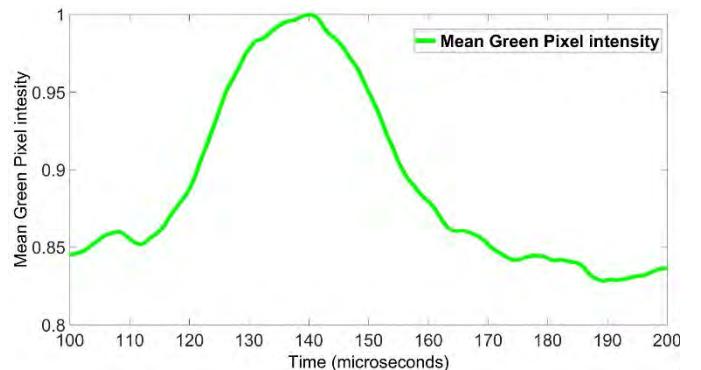

### III. RESULTS AND DISCUSSION

The light emission characteristics of the PDMS–EML composite were studied first, followed by derivation of strain from the pulse generated in the Kolsky bar. After aging the composite, the material was subjected to a high-impact compressive load from the Kolsky bar. The initial test was performed by controlling the shot pressure (520 kPa) from the air gun (Fig. 3). Image data acquired from the high-speed camera at a frame rate of 50,000 frames/s and data from the strain gauges which were acquired at higher frequency were synchronized with timestamps. Image processing techniques were then used to characterize the light emission characteristics of the PDMS–EML composite.

Image processing involved exporting the video file from the camera in 24-bit AVI (Audio Video Interleave) format, with a custom image resolution of  $64 \times 200$ . From the RGB data

collected green pixel values were chosen, as SAOED crystals possess a green phosphor. The green pixel values of the images were extracted, and an arithmetic mean of the values was used to quantify the intensity of light emitted. Green pixels could attain a mean value of 255 for very bright green and 0 for dark green. A second-order, low-pass filter and normalization were applied to the mean green pixel data to understand the emitting characteristics of the PDMS–EML composite (Fig. 4). The filtered and normalized mean green pixel data (hereinafter mean green pixel intensity, MGPI) were then plotted with respect to time (Fig. 5).

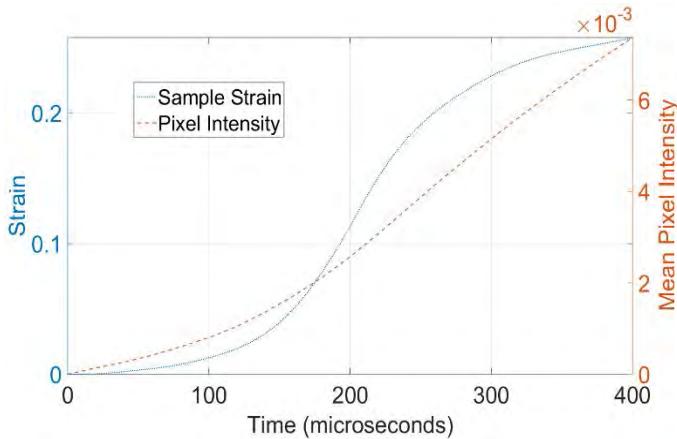

Fig. 5 shows the luminescence behavior of the PDMS–EML

**Figure 5.** Quantification of light-emitting characteristics of SAOED crystals under compressive load.

composite during high-impact loading. The luminescence behavior displayed by the composite was similar to the pulse generated by the Kolsky bar.

The strain data were then correlated with the MGPI data with the aid of timestamps (Fig. 6). The luminescence behavior of the PDMS–EML composite does not provide a 1:1 correlation with the strain. However, has an instantaneous response to the applied strain.

**Figure 6.** Strain and MGPI of PDMS–EML composite at a shot pressure of 520 kPa.

#### IV. CONCLUSION

In this paper, we studied the behavior of an EML material dispersed in a PDMS matrix under high-strain compressive loading. For this purpose, a PDMS–EML composite was created using a clear silicone elastomer and SAOED EML crystals. The crystal dispersion in the polymer matrix was also studied to verify its uniform distribution within the matrix. To carry out mechanical testing, a Split-Hopkinson pressure bar or Kolsky bar was used to produce a high-strain compressive load on the composite material. A CMOS sensor high-speed camera was used to collect images of the light-emitting characteristics of the PDMS–EML composite. Image and data processing techniques were used to quantify the light-emitting characteristics of SAOED crystals in a soft polymer matrix as well as the mechanical behavior under a high strain rate.

Preliminary results of the PDMS–EML composite show great promise. However, the transmittance of the load to the crystals is limited in a soft polymer matrix, as the strain transmittance is low. Hence, the magnitude of light intensity observed was limited.

#### ACKNOWLEDGMENT

This research was partially supported by the Natural Sciences and Engineering Research Council Undergraduate Student Research Award and the Lassonde School of Engineering, York University. The authors are grateful for their financial support. We also thank Chaudhry Salman for his work and inputs on the Kolsky bar.

Email: krishna.challagulla@laurentian.ca

**Abstract**—The unit-cell composition of three-dimensional finite element models for 3-0 and 3-1 type polymer (PVDF) - ceramic ( $\text{BaTiO}_3$ ) and ceramic (PZT-7A) - ceramic ( $\text{BaTiO}_3$ ) structures are compared to determine the effects of fiber interaction at the surface of the unit-cell on the effective elastic, piezoelectric and dielectric properties of the multifunctional composite systems. The first unit-cell type examined has enclosed fibers that are completely contained within its boundaries, the second type has fibers that are contained within the sides of the unit-cell but can be cut at the top and bottom surfaces, and the third type has fibers that can be cut on the top, bottom and side surfaces of the unit-cell. All cut fibers are matched on opposing surfaces for continuity. Randomly distributed and aligned circular fibers, randomly distributed and randomly oriented circular fibers, and one central enclosed fiber with varying volume fractions and aspect ratios are compared with these three unit-cell structures. Results show that fiber models display greater or equal values of  $C_{22}$  when compared to aligned or randomly oriented fibers for all cases except aspect ratio 1 polymer-ceramic structures. The third type of unit-cell shows the highest  $e_{22}$  values for single, aligned and randomly oriented fiber structures, except for the aspect ratio 10 polymer-ceramic case where the second type of unit-cell has greater results for aligned and single fibers. Finally, it can generally be seen that randomly oriented fibers have smaller values than similar aligned and single fiber structures with the exception being  $C_{22}$  of the ceramic-ceramic structures.

## I. INTRODUCTION

Piezoelectric materials are being used more commonly for commercial and industrial applications due to their electromechanical properties. In products such as sensors, actuators and hydrophones their unique behavior makes them useful even as monolithic materials. Their properties, however, can be enhanced by combining multiple of these materials in a multifunctional composite structure. These composite systems can include many different types of materials, though the ones being examined in this study will be of the polymer-ceramic and ceramic-ceramic type.

Structured piezoelectric multifunctional composites have been studied fairly extensively from an analytical, numerical and experimental perspective. Kar-Gupta and Venkatesh determined the effects of geometry and grain-size on 3-0, 3-1 and 3-3 fibrous structures in [1]. Wu et al. examine the actuation performance of barium titanate nanoparticles in an epoxy resin in [2]. Yavarow and Erturk [3] develop a nonlinear elastodynamic model for fibrous piezoelectric composites, validating their mathematical model against experimental results.

This being said, randomly distributed and randomly oriented multifunctional composite structures have not been nearly as established. There has been some research done such as Berger et al. in [4], however a complete understanding of the effects of different structures on the effective electromechanical properties of random fiber multifunctional composites is not currently available. This study will try and determine how the interaction between fibers and the surface of a unit-cell will affect the overall properties. Thus, the objectives are:

- (i) To develop a unit-cell based finite element model that will predict the elastic, dielectric and piezoelectric properties of several 3-0 and 3-1 type multifunctional composites with different boundary types at varying aspect ratios, volume fractions and cross-sectional shapes for aligned and randomly oriented fibers.
- (ii) To systematically characterize the effects of unit-cell boundary structure on the effective electromechanical properties of multifunctional composites.

## II. PIEZOELECTRIC MATERIALS

A total of three piezoelectric materials are used in this study: barium titanate ( $\text{BaTiO}_3$ ), polyvinylidene fluoride (PVDF) and lead-zirconate titanate (PZT-7A). Their properties are outlined in table 1 on the next page. PVDF is used as the matrix polymer in the polymer-ceramic models, while PZT-7A is the matrix ceramic in the ceramic-ceramic case.  $\text{BaTiO}_3$  acts as the fiber in all composite structures. For this study, the matrix was poled in the 2-direction while the fibers were poled along their longitudinal axis for maximum effect, this is recognized as being an ideal case.

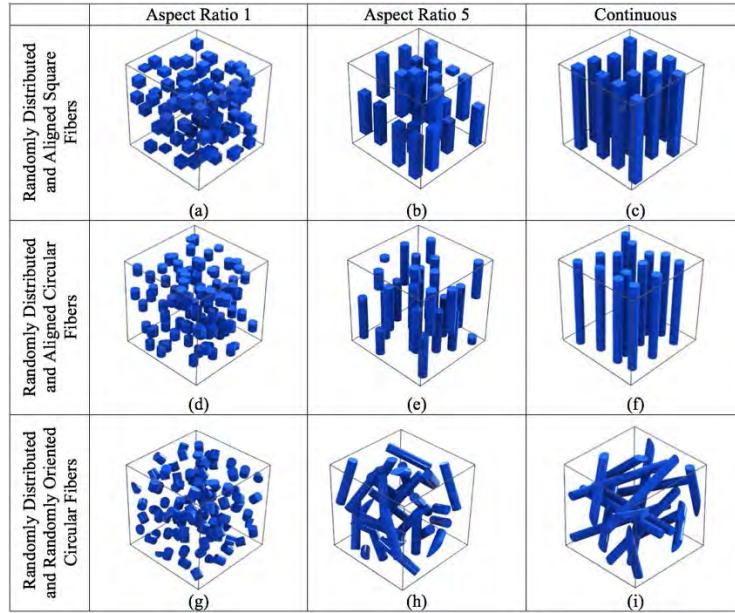

Figure 1: Schematic illustrating nine multifunctional composite structures based on fiber aspect ratio, cross-sectional shape, distribution and orientation.

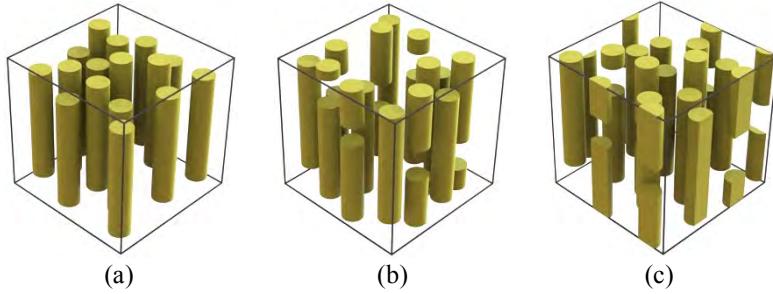

Figure 2: Unit-cell boundary types: (a) type 1 – fibers completely enclosed; (b) type 2 – fibers enclosed within the sides and not the top; (c) type 3 – fibers not enclosed within the surfaces.

TABLE I. MATERIAL PROPERTIES OF BaTiO<sub>3</sub>, PZT-7A AND PVDF

Material Properties	BaTiO <sub>3</sub>	PZT-7A	PVDF
$C_{11}^E = C_{33}^E$ [GPa]	150.40	148.00	4.840
$C_{12}^E = C_{23}^E$ [GPa]	65.94	74.20	2.220
$C_{33}^E$ [GPa]	65.63	76.20	2.720
$C_{22}^E$ [GPa]	145.50	131.00	4.630
$C_{44}^E = C_{66}^E$ [GPa]	43.86	25.40	0.052
$C_{55}^E$ [GPa]	42.37	35.90	1.060
$\kappa_{11} = \kappa_{33}$ [nC/Vm]	12.8	3.984	0.0664
$\kappa_{22}$ [nC/Vm]	15.1	2.081	0.0708
$e_{16} = e_{34}$ [C/m <sup>2</sup> ]	11.40	9.31	-0.001999
$e_{21} = e_{23}$ [C/m <sup>2</sup> ]	-4.32	-2.324	0.004344
$e_{22}$ [C/m <sup>2</sup> ]	17.36	10.9	0.1099

Piezoelectric materials are governed and fully defined by 21 elastic, 18 piezoelectric and 6 permittivity constants [5]. In the first equation,  $\sigma$  represents a second order stress tensor,  $C^E$  a fourth order elasticity tensor (at zero electric field),  $\varepsilon$  a second order strain tensor,  $E$  an electric field vector,  $D$  an electric displacement vector,  $e$  a third order coupling tensor and  $\kappa^\varepsilon$  a second order permittivity tensor (at zero strain). The indices i, j, k and l are remapped in the following way: 11 → 1, 22 → 2, 33 → 3, 23 → 4, 13 → 5 and 12 → 6.

$$\begin{aligned}\sigma_{ij} &= C_{ijkl}^E \varepsilon_{kl} - e_{ijk} E_k \\ D_i &= e_{ikl} \varepsilon_{kl} + \kappa_{ij}^\varepsilon E_j\end{aligned}\quad (1)$$

### III. COMPOSITE UNIT-CELL STRUCTURE

The multifunctional composite structures analyzed in this study were generated using python scripts which were then run using the commercially available finite element software, ABAQUS. The code developed created fibers with specified cross-sectional shapes and aspect ratios, then placed them randomly in a non-intersecting fashion within a unit-cell until a desired volume fraction was reached. Fibers were also constrained in relation to the boundary of the unit-cell in three ways, as shown in figure 2:

- Type 1: fibers are completely enclosed within the boundary of the unit-cell. No fiber gets cut at or even touches any surface of the unit-cell.
- Type 2: fibers are enclosed within the four sides of the unit cell but can be cut on the top and bottom surfaces.
- Type 3: fibers can be cut on any surface of the unit-cell.

All fibers cut on one surface have a complementary fiber on the opposing surface to have continuity if multiple unit-cells were to be attached, shown below in figure 3.

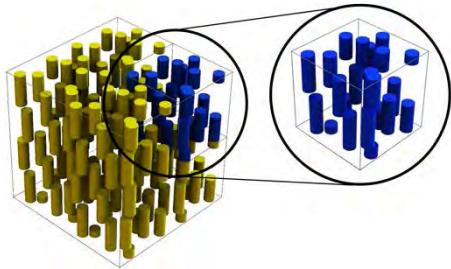

Figure 3: Continuity at unit-cell boundaries using complementary fibers.

The finite element models were run using three-dimensional four-node linear piezoelectric tetrahedron elements (C3D4E). Nodes were given four degrees of freedom, each of the three directions and one electric potential (1, 2, 3 and 9, respectively). Fiber diameter and length was also kept constant in order to maintain aspect ratio. The number of fibers within a unit-cell could have been increased by keeping aspect ratio constant and reducing the diameter, however this was not done in this study to keep fibers consistent, which limited the volume fraction to approximately 25% [6].

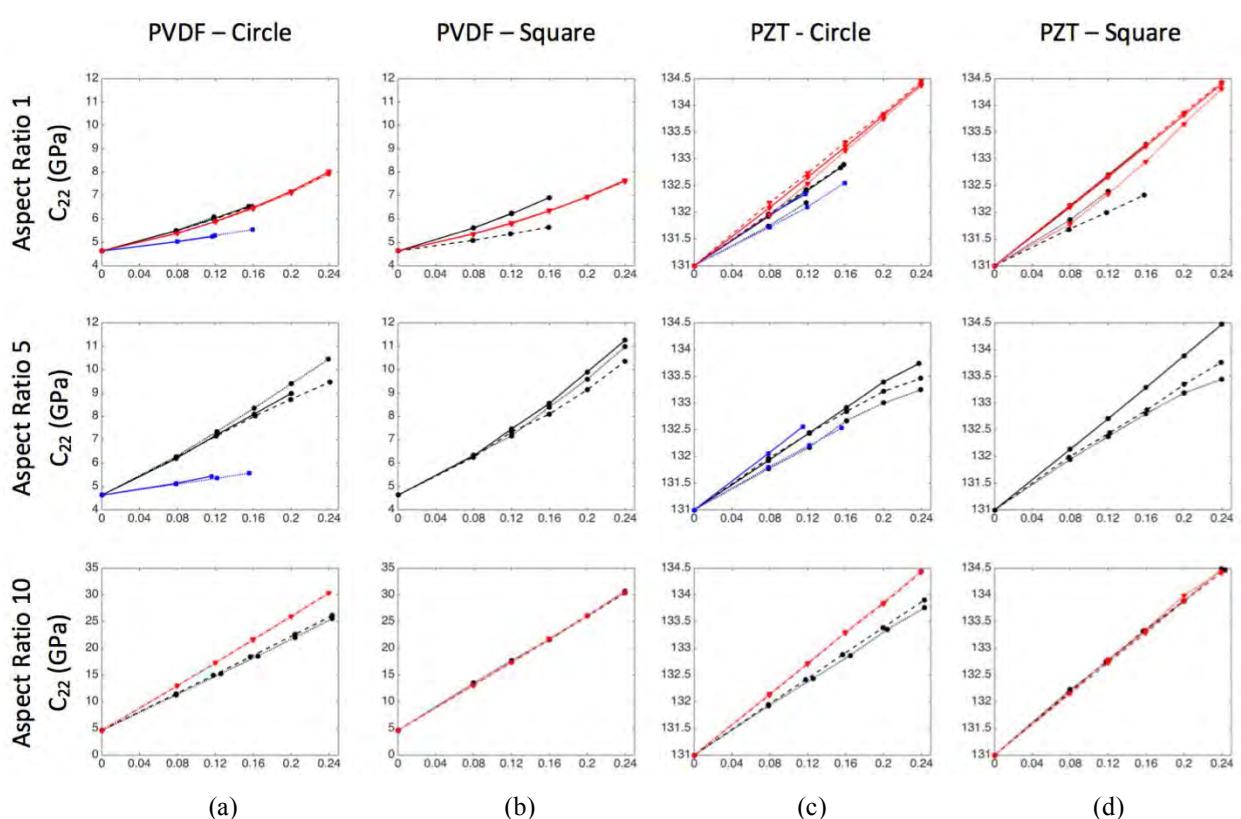

#### IV. RESULTS

Finite element methods were used to analyze the various composite structures described in section 3 in order to determine effective elastic, dielectric and piezoelectric

properties. The results plotted in the graphs of figure 4 show these effective properties for each structure at a given aspect ratio, volume fraction, cross-sectional shape, material and boundary type. Results displayed for any randomly distributed fiber structures are averages calculated from multiple iterations of the model. The cross-sectional fiber shapes examined are circular and square, while the material compositions studied are polymer-ceramic and ceramic-ceramic. Aspect ratio 1, 5 and 10 (short, medium and long fibers, respectively) are also compared with the three types of boundary structures.

The random fiber results from this study are initially compared to single fiber results with comparable structures to determine their accuracy. The circular single fiber results were verified against Kar-Gupta and Venkatesh [1], as well as Bowen et al [7], and Brito-Santana [8]. Single fiber results with the first type of boundary structure are shown to have nearly identical values and trends as those in [1, 7 and 8], which is as expected since the structures are the same. There is some variance with different boundary structures and with randomly distributed fibers, however the models are overall in good agreement.

Square fibers were also compared with Kar Gupta and Venkatesh [9]. The aspect ratio 10 randomly distributed and single fiber structures were compared with those of [9] and showed similar trends. Though both studies examined polymer-ceramic and ceramic-ceramic structures with the same materials, the combinations of materials were different so an exact verification could not be made.

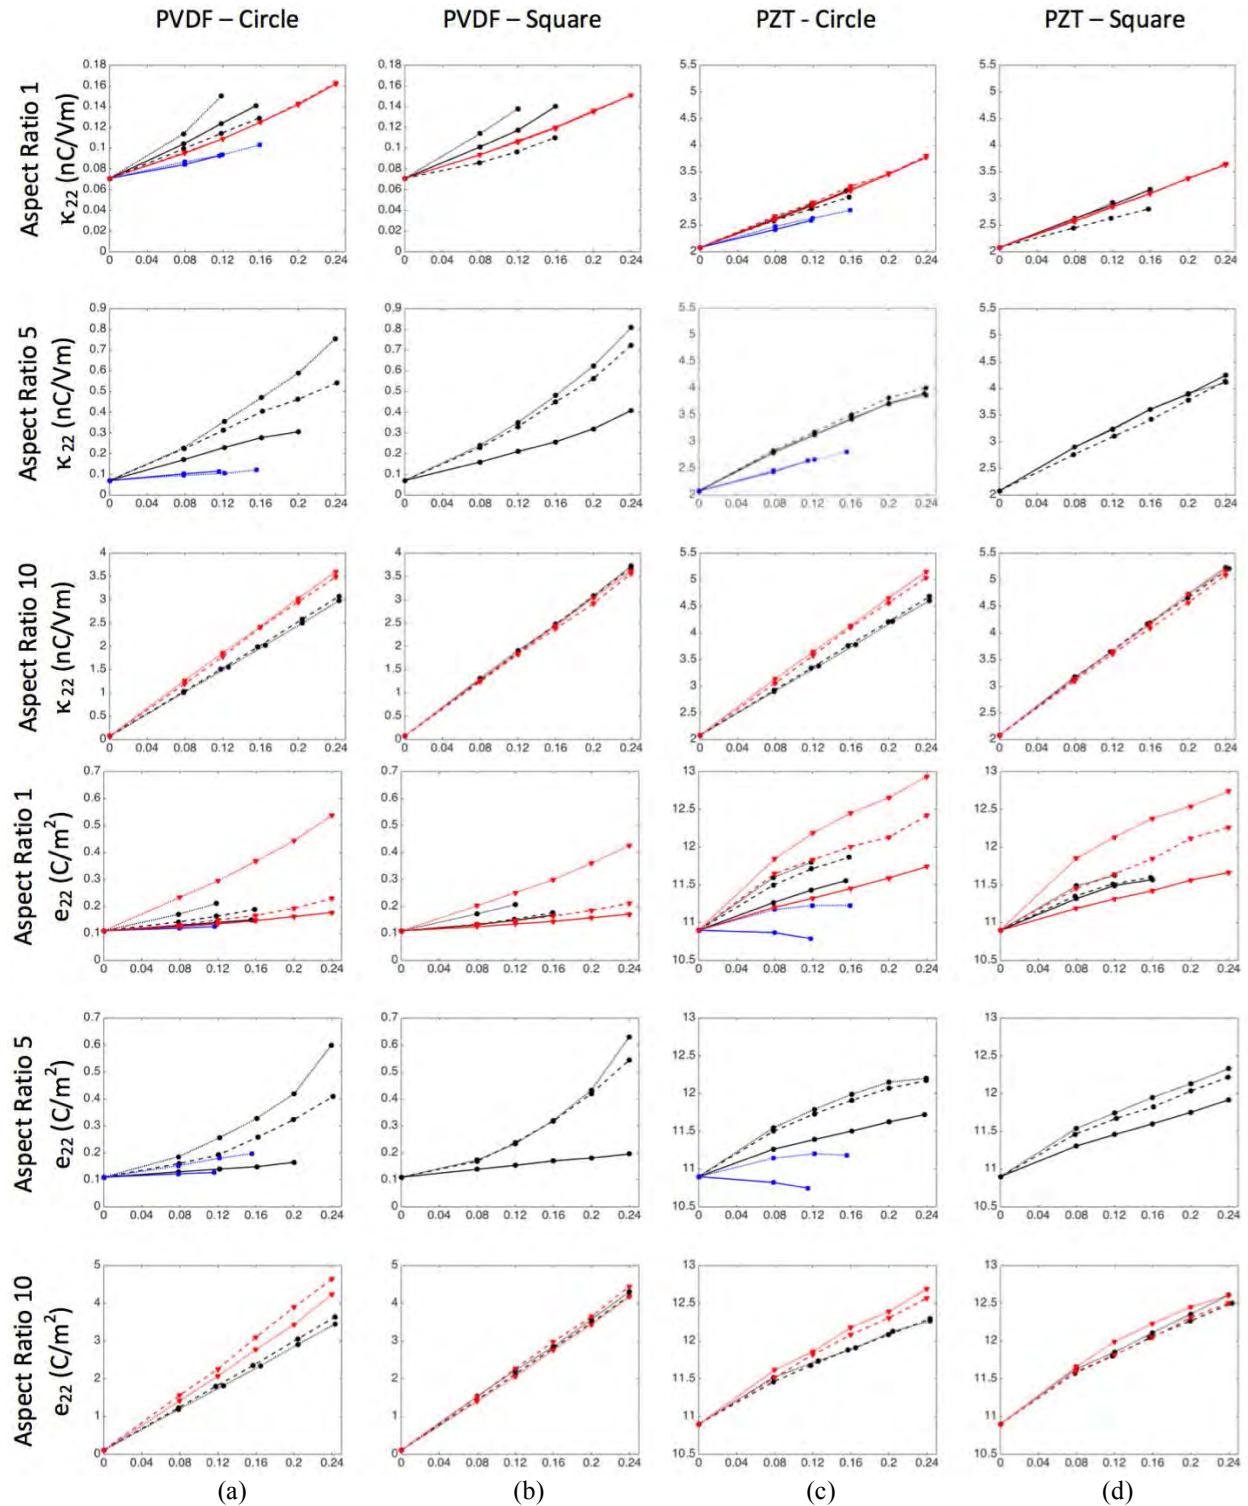

Figure 4: Variation of effective properties with respect to fiber volume fraction in (a) polymer (PVDF) - ceramic (BaTiO<sub>3</sub>) system with aligned and randomly distributed circular fibers, randomly oriented and randomly distributed circular fibers, and single aligned fibers (b) polymer-ceramic system with aligned, randomly distributed and single square fibers, (c) ceramic (PZT-7A) - ceramic (BaTiO<sub>3</sub>) system with aligned and randomly distributed circular fibers, randomly oriented and randomly distributed, and single aligned circular fibers, and (d) ceramic-ceramic system with aligned, randomly distributed and single square fibers - multifunctional composite structures.

For  $C_{22}$ , single fiber models display greater or equal values compared to aligned and randomly oriented fibers in all cases but aspect ratio 1 polymer-ceramic structures. In the longitudinal direction, it appears that the length and continuity of the fiber plays a more significant role in increasing mechanical properties than boundary type. It can, however, also be seen that the first type of boundary structure has the highest  $C_{22}$  value for a given structure when compared to the second and third boundary types with the exception of aspect ratio 1 ceramic-ceramic circular structures and aspect ratio 5 polymer-ceramic circular structures.

Randomly oriented fibers are generally seen to have the lowest values for  $C_{22}$ ,  $e_{22}$  and  $\kappa_{22}$  when compared to aligned and single fibers with the exception being  $C_{22}$  of the ceramic-ceramic structures. Aligned fiber multifunctional composite systems have several distinct advantages when compared to these randomly oriented structures. They can be placed more efficiently in the unit-cell, leading to higher packing factors as well as providing generally flexible structures [10] with low acoustic impedance values [11]. Randomly oriented fiber structures, however, can provide higher values in transverse directions compared to aligned structures and can be easier to manufacture [12-15].

## V. CONCLUSION

Random fiber multifunctional composites have a wide variety of advantages compared to structured and single fiber structures. Their ease in manufacturing and higher values in transverse directions make them useful and often less expensive. However, as the applications for these composites becomes more pronounced, their complexity will increase and the numerical models used to predict their behaviour will need to be improved. The purpose of this study was specifically to determine how the effective electromechanical properties of multifunctional composites might be affected by changes in the interaction between fibers and the surface of the unit-cell. At given volume fractions of fibers, aspect ratios, materials and cross-sectional shapes, the effects of the boundary structure of a unit-cell were found to be the following:

- (i)  $C_{22}$  values were more commonly larger as a result of longer and continuous fibers rather than based on a unit-cell boundary type, however the first type of boundary displays generally higher values compared to the second and third type except for aspect ratio 1 ceramic-ceramic circular structures and aspect ratio 5 polymer-ceramic circular structures.
- (ii) The highest  $e_{22}$  values for single, aligned and randomly oriented fiber structures except for the aspect ratio 10 polymer-ceramic case was the third type of unit-cell.
- (iii) Randomly oriented fibers have the lowest values in general when compared to aligned and single fiber structures, with the exceptions of  $C_{22}$  of the ceramic-ceramic structures.

This study presents an overview of the effects different fiber-surface interactions can have on the overall properties of a unit-cell. When creating models to study the behaviour

of random fiber multifunctional composite structures, the conclusions drawn here can help identify discrepancies in electromechanical properties between models that appear to be the same. As is shown, the same structure with different surface-fiber interactions can have varying effective mechanical, piezoelectric and dielectric properties without having a different core structure. The large variety of structures being compared in this study with varying aspect ratios, volume fractions, materials and cross-sectional shapes provides a baseline for future numerical models with more complex structures and unit-cell surfaces.

## ABSTRACT

This paper experimentally investigates the wave transmission through partially immersed semicircular breakwater suspended on two rows of circular piles. Different wave and structure parameters have been investigated such as; incident wave height, wave length, wave period, breakwater draft and the clear gap between the supporting piles. Multiple Polynomial Regression (MPR) model is used to develop an empirical equation to calculate the transmission coefficient ( $k_t$ ) as a representative of the transmitted wave energy. In addition, a Flow-3D numerical study is carried out to simulate the transmitted wave hydrodynamics and verified against the experimental results. The numerical analysis shows good agreement with experimental results with an acceptable value of NRMSE. The results show that the transmission coefficient ( $k_t$ ) decreases by about 31% with increasing the relative wave length from 0.12 to 0.22 and wave steepness from 0.006 to 0.021. Also, the transmitted coefficient ( $k_t$ ) decreases by about 25% with increasing the relative immersion depths from 0.25m to 0.5m and increases by about 16% for increasing of pile porosity value from 0.5 to 0.83 respectively.

## 1 INTRODUCTION

Breakwaters are used for coastal protection from incident wave attack by reducing part of the wave energy before it reaches the shoreline to enhance safe vessel berthing and maneuvering. Different types of breakwater are widely used and developed around the world. The conventional types of these breakwater are such as Rubble mound and bottom seated concrete types. When water depth increases (>4.0 m), these structures become more expensive and difficult to build and need high seabed bearing capacity. In addition, these breakwater types interrupt alongshore sediment transport and cause erosion to beaches downcoast of the breakwater. These conventional types of breakwater stop the seawater exchange that is essential for fish migration and for maintaining the water quality. The increased wave reflection in front of breakwaters causes also navigation problems. On the other hand, floating breakwater have the drawbacks that; i-they are ineffective for long waves range of 4 to 6 seconds [1], ii-vulnerable to structural failure during storms, iii-require a high amount of maintenance, large roll and iv-sway motions may affect its performance to be used as a berth or a pier. In order to avoid these disadvantages, the floating breakwater are suspended on the pile system (Suspended breakwater) which give it advantages such as: a-Low construction cost and require less material; b-ease of construction, c-applicability in poor soil foundation and complex bathymetry, d-less interference to the ecosystem, e-allow flow exchange between water body and open sea, f-enabling fish migration and g-preservation of water quality and sediment transport activity. They can also be dismantled and relocated with minimum effort and without leaving permanent damage to the environment and reduce visual impact. They can also sustain and preserve the natural beauty of the beach and therefore they favorable to the beach users.

In recent years, research has been conducted to develop new configurations of a breakwater; the partial breakwater. This new concept consists of a solid body, completely or partially immersed, suspended on concrete piles or floating and fixed by cables. The total height of such caissons is far smaller than the water depth. So, this type of breakwater is partially permeable to the incoming ocean waves, especially for long waves which can be transmitted below the structure. Since most of the wave energy is concentrated close to the water surface in deep water, a structure located near the free surface or intersecting it can dissipate part of this energy or reflect it by diffraction. Several investigations were carried out on the rectangular caisson, the most classical shape, for example: (Drimer et al., 1992),(Tolba, 1998),(Koutandos et al., 2004) and (Koutandos et al., 2005). These studies showed that this structure can reflect the incident wave energy for small wave periods. More complex configuration, named BYBOP proposed by (Duclou et al., 2004), is more efficient in reducing transmitted wave. Table 1 summarizes the different shapes of semi immersed breakwater investigated by previous researchers.

**Table 1. Characteristics of different models of semi immersed breakwater studied by previous researchers.**

## 2 EXPERIMENTAL TESTING

### Experimental set-up

The tested breakwater model was installed in the middle of the wave flume and situated between the inclined wave absorber and the wave generator. The module consists of a half-pipe manufactured from poly-vinyl chloride (PVC), with an outer diameter of 0.2m and 0.01m thickness. Vertical wood plate with a thickness of 0.01 m was fixed with the upper edge of the half pipe and the plate height was sufficient to prevent the wave overtopping on the breakwater. Two rows of PVC pipes with 0.05m diameter ( $\phi$ ) and clear gap (G) of 0.25and 0.05 m were used as a supporter of the breakwater module as shown in Figure 1. The breakwater width (B) was kept constant at a value of 0.10 m and the tested breakwater drafts (d) were 0.20 and 0.1 m.

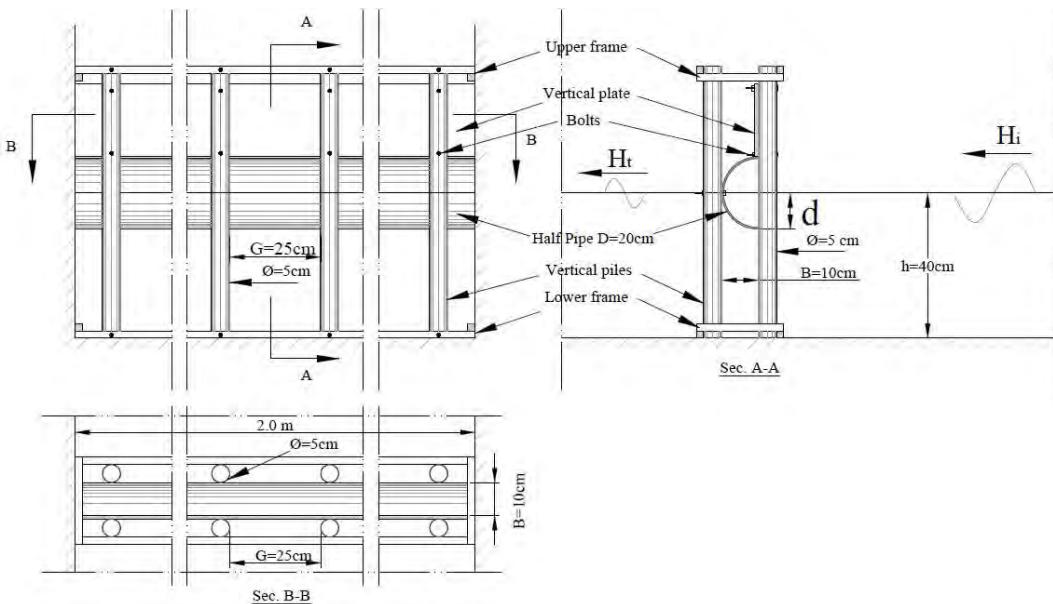

### Tests conditions

Table 2 summarizes the tested values for different wave and breakwater parameters. Eight wave values were conducted with two breakwater draft (d) of 10 and 20 cm and two piles gap (G) of 5 and 25 cm. The number of the experimental tests are 32runs.

### Wave gauge calibration

Standard conductivity-type wave probe was used to measure the variations of water level with time. The wave probe comprises of two thin parallel stainless steel electrodes (0.0015m diameter, space 0.0125m and length of 0.3m). The probe was connected to wave monitor module in the electronic console by a twin core flexible cable and delivered the output signals in the form of voltage data.Static calibration of the wave probe was carried out at the beginning of each set of experiments. Figure2 shows a linear relation between water level and output voltage resulting coefficient of determination ( $R^2=0.998$ ). The linear equation was used in the programming of data acquisition card.The collected data

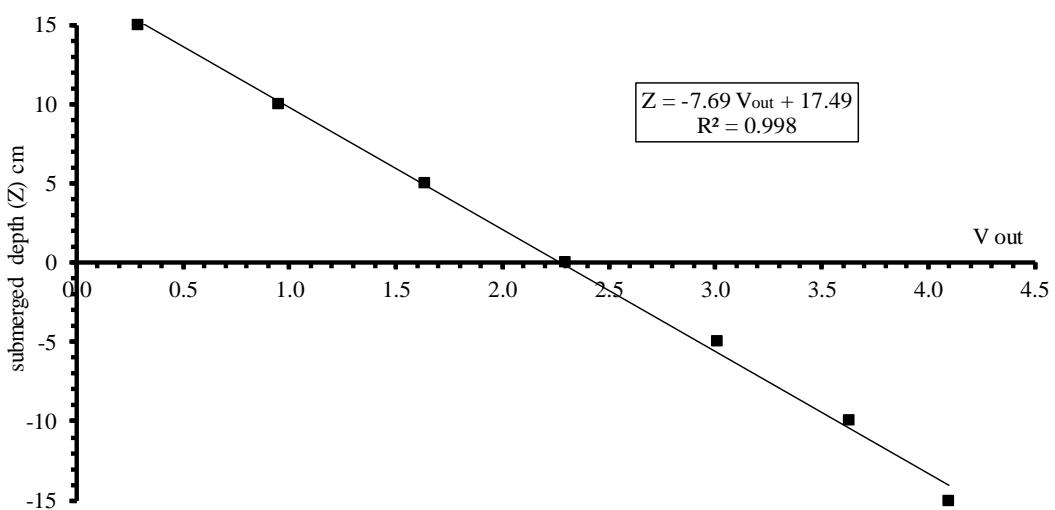

during recording period converted into the water level by a simple computer program, resulting in the variation of water surface with time.

**Figure 1. Different configuration of the tested breakwater.**

**Table 2. Experimental setup parameters of the breakwater model.**

Parameters	Unit	Ranges
Wave periods (T)	s	1.15 -1.8
Wave length (L)	m	1.81 - 3.35
Wave height (H <sub>i</sub> )	m	0.0207 - 0.038
Pile space (G)	m	0.05- 0.25
water depth (h)	m	0.40
breakwater width (B)	m	0.10
pile diameter ( $\phi$ )	m	0.05
outer pipe diameter (D)	m	0.2
Breakwater immersion depth (draft) (d)	m	0.1-0.2
Relative wave length (h/L)	-	0.12 - 0.22
Wave steepness (H <sub>i</sub> /L)	-	0.006 - 0.021
Relative immersion depth (d/h)	-	0.25-0.5
Porosity of the lower part of breakwater (P)	-	0.5-0.83

**Figure 2.Calibration of the wave gauge.**

### 3 METHODOLOGY

#### Dimensional analysis

The parameters affecting the transmission coefficient ( $k_t = H_t/H_i$ ) were investigated. These parameters are still water depth (h), the unit weight of water ( $\gamma_w$ ), the incident wave length (L), the incident wave height ( $H_i$ ), the transmitted wave height ( $H_t$ ), the reflected wave height ( $H_r$ ), the acceleration of gravity (g), the breakwater porosity (P), breakwater immersion depth -draft (d) and the breakwater width (B). The relationship between these variables for the studied models is expressed as follows:

$$f(H_i, H_t, h, \gamma_w, L, B, d, P, g) = 0 \quad (1)$$

As the ( $\gamma_w$ , (g) and (B) are constant, then the number of variables = 6, selecting  $H_i$  as repeating variable, number of dimensionless parameter = 6-1=5 as follows:

$$\pi_5 = f(\pi_1, \pi_2, \pi_3, \pi_4) \quad (2)$$

$$\text{Then, } k_t = f(h/L, H_i/L, P, d/h) \quad (3)$$

The effect of  $h/L$  and  $H_i/L$  on  $k_t$  is essentially need to investigate the hydrodynamic characteristics of the breakwater for coastal and deep-water regions and understand the performance of the breakwater for normal and extreme wave actions. Moreover, studying the effect of P and  $d/h$  on  $k_t$  is required to select the suitable structures configuration.

#### Incident and transmitted wave heights measurement

The dimensionless parameters were estimated from measuring the following variables in each individual experimental test. The incident wave heights ( $H_i$ ) was determined in the middle of the flume at the model location using the wave probe P<sub>1</sub> (without breakwater model). The wavelength (L) is calculated using the dispersion relationship based on the linear wave theory as follows:-

$$L = \frac{g}{2\pi} T^2 \tanh(kh) \quad (4)$$

Where k is the wave number ( $k=2\pi/L$ )

The transmitted wave heights ( $H_t$ ) from the breakwater was measured at the probe P<sub>2</sub> behind the breakwater model at a distance of 1.5m avoiding the effect of the turbulence caused by the wave breaking on the breakwater surface.(P1 and P2) locatins are shown in Figure 3 The transmission ( $k_t$ ) coefficient can be calculated as:

$$k_t = H_t / H_i \quad (5)$$

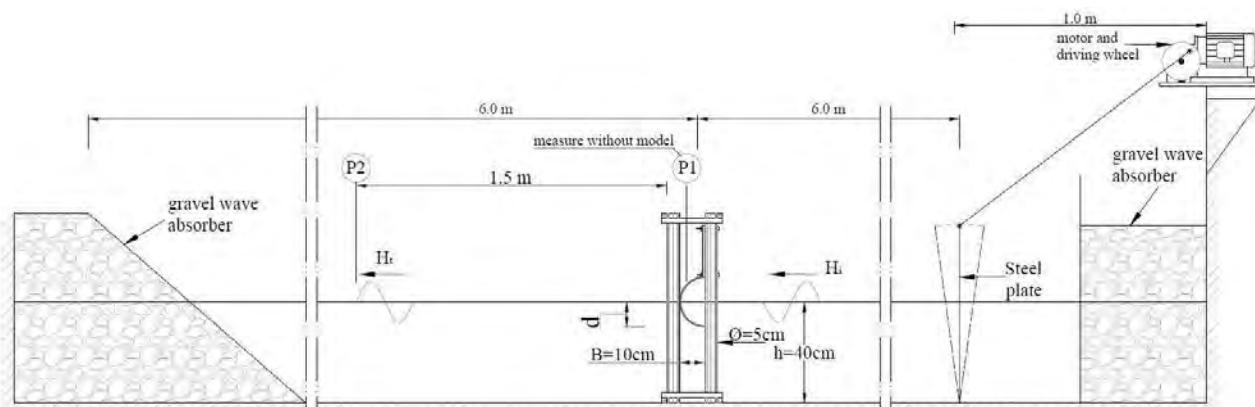

Figure 3. The wave flumes showing position of the breakwater model and the wave probes sites.

#### Multiple Polynomial Regression Model (MPR)

Using the above dimensionless parameters (See Equation 3), the regression analysis and the measured data, simple empirical equations for estimating the transmission coefficient for the different cases are developed. A Multiple Polynomial Regression (MPR) method was used to describe the behavior of a dependent variables ( $k_t$ ) that is related to the four independent variables  $h/L$ ,  $H_i/L$ , P,  $d/h$  ( $\pi_1, \pi_2, \pi_3, \pi_4$ ) (Teh and Venugopal, 2013). The statistical program (SPSS Statistics 24 by IBM) was used to develop the empirical equations. The MPR technique was adopted to account for the nonlinearity of the data set and is expressed as:

$$k_t = \begin{bmatrix} a + a_1\Pi_1 + a_2\Pi_2 + a_3\Pi_3 + a_4\Pi_4 \\ a_{11}\Pi_1^2 + a_{22}\Pi_2^2 + a_{33}\Pi_3^2 + a_{44}\Pi_4^2 + \\ a_{11}\Pi_1\Pi_2 + a_{13}\Pi_1\Pi_3 + a_{14}\Pi_1\Pi_4 + \\ a_{23}\Pi_2\Pi_3 + a_{24}\Pi_2\Pi_4 + \\ a_{34}\Pi_3\Pi_4 \end{bmatrix} \quad (6)$$

Linear Regression analysis was used and the predictors were selected by Enter method. The developed MPR model estimates the independent values ( $k_t$ ) by 14 predictors, shown in table 3.

### Flow-3D numerical model

Flow-3D is well known computational fluid dynamics(CFD) software, where the equations of motion are solved by the method of finite volume/finite differences in a Cartesian, staggered grid. The gravitational acceleration was set to 981 [cm/s<sup>2</sup>]. The viscosity and turbulence properties were set to be Newtonian Laminar flow which its result was more accurate and robust model available in the software.

#### Meshing and geometry

The semicircular model was exported in a stereo lithographic (stl) format to Flow-3D where the appropriate mesh could be generated. The accuracy of the results and the simulation time are effected by the cell size. So, it is important to minimize the amount of cells while including enough resolution to capture the important features of the geometry as well as sufficient flow details. For these reasons, multi-block mesh was used in the simulations, where bigger size cells were used at less geometric details domain, and the smaller size cells near more geometric complexity as shown in Figure4.

##### 3.1.1 Boundary and initial conditions

The upstream boundary condition in x direction was set to wave boundary and the downstream boundary was a wall boundary with wave absorbing block. All other open boundaries were specified as symmetric. The Stock wave theory of 5<sup>th</sup> order has been used in Flow-3D; the wave is characterized by the wave height ( $H_i$ ), wave length (L) and wave period (T). In addition, at initial ( $t=0$ ) a fluid region with height of 40 cm was simulated.

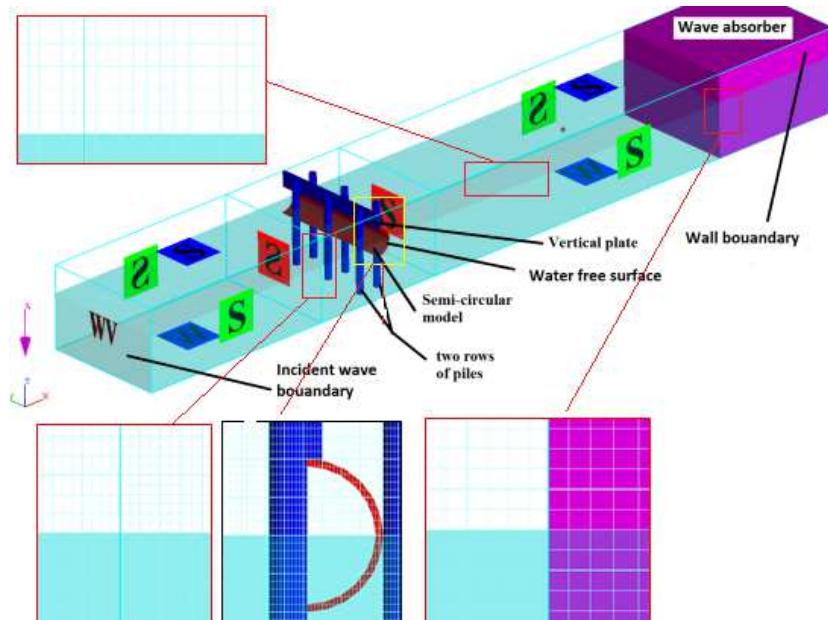

Figure4 simulating of breakwater model in Flow-3D.

## 4 RESULTS AND DISCUSSION

the hydrodynamic efficiency of the partially immersed breakwater is affected by the wave and structure characteristics. The wave parameters are; wave length and height (L and  $H_i$ ), and the structural parameters are; the breakwater draft (d) and the space between piles (G). The dimensional analysis presents the hydrodynamic performance of the breakwater in the form of relationships between transmission coefficient ( $k_t$ ) and dimensionless parameters representing the wave and structure characteristics as presented in Equation 3.

### Effect of Relative wave length ( $h/L$ ) and Relative immersion depth ( $d/h$ )

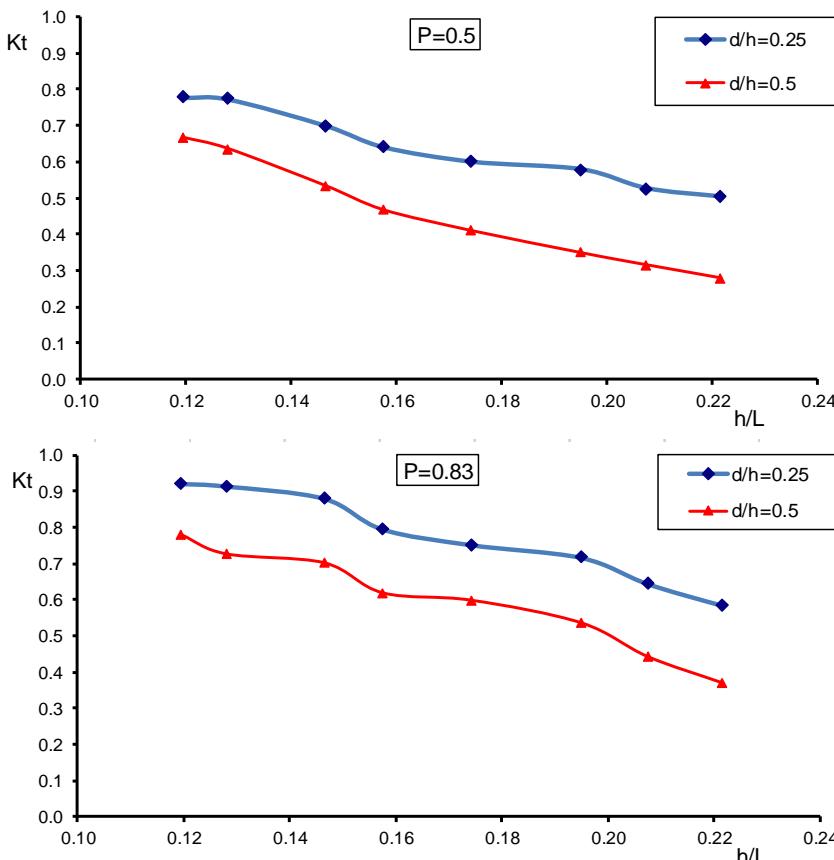

Wave length is one of the most dominant parameters in the wave interaction with breakwater. In present study, the relative wave length( $h/L$ ) represents more the effect of wave length since the still water depth ( $h$ ) was kept constant throughout the experiments. The variation of transmission coefficient ( $k_t$ ) as a function of ( $h/L$ ), is presented in **Figure5** for relative immersion depth ( $d/h$ ) ranges from 0.25 to 0.5 at piles porosity ( $P$ ) equal 0.5 and 0.83. **Figure5** shows that by increasing of ( $h/L$ ),  $k_t$  decreases for all values of ( $d/h$ ). For example, at  $d/h=0.25$  and  $P=0.5$ ,  $k_t$  decreases by 36% with ( $h/L$ ) increases from 0.12 to 0.22. This is presumably explained by considering the water particle motions. For shorter wave length,  $h/L$  increases, the water particles velocity and acceleration increase and after interaction with the breakwater. The water particles velocity and acceleration suddenly change then the resulted turbulence causes low wave transmission. While the breakwater width is not enough to effectively disturb the orbital cycle for longer wave length. Then, its hydrodynamic performance reduces for the lower value of  $h/L$ .

The variation of transmission coefficient,  $k_t$ , with respect to( $d/h$ ) is also shown in **Figure5** for relative wave length ( $h/L$ ) ranges from 0.12 to 0.22 at piles porosity ( $P$ ) equal 0.5 and 0.83. For all values of ( $h/L$ ), by increasing of ( $d/h$ ),  $k_t$  decreases. For example, at  $h/L=0.12$  and  $P=0.5$ ,  $k_t$  decreases by 14% with ( $d/h$ ) increases from 0.25 to 0.5. This may be attributed to the increase of ( $d/h$ ), the area that the water passes through decreases then the transmitted wave energydecreases.

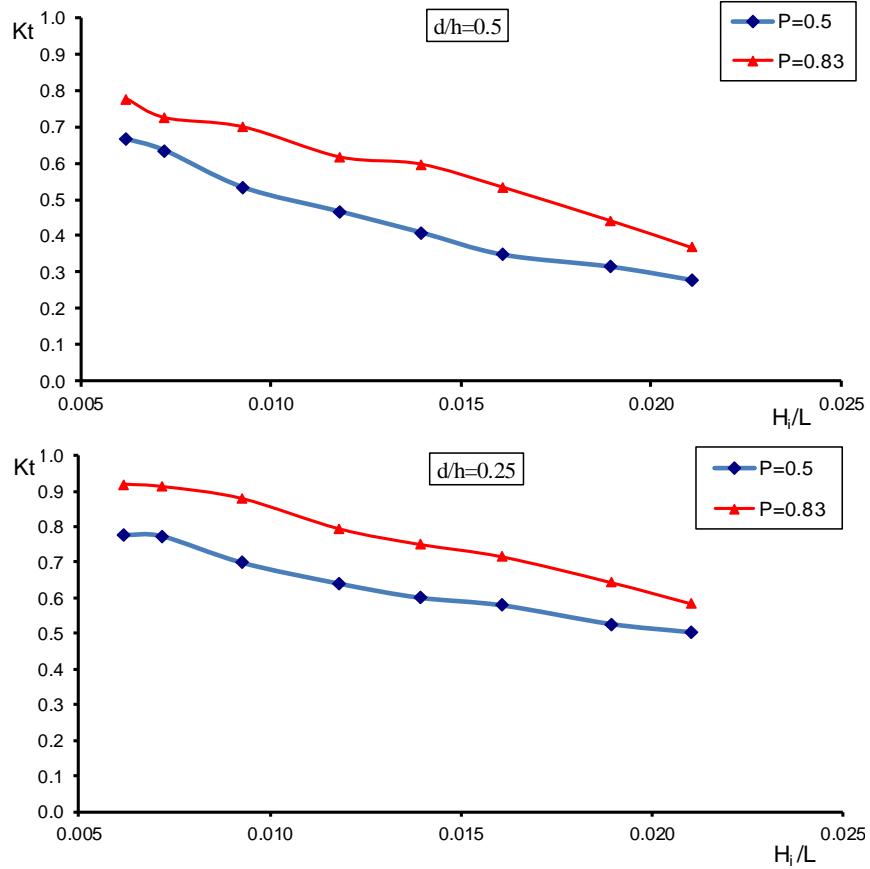

### Effect of piles porosity ( $P$ )and Wave steepness ( $H_i/L$ )

The variation of the transmission coefficient,  $k_t$ with respect to( $P$ ) is shown in **Figure6** for wave steepness ( $H_i/L$ ) ranges from 0.006 to 0.021 at ( $d/h$ ) equal 0.5 and 0.25. **Figure6** shows that by increasing of ( $P$ ),  $k_t$  increases for all values of ( $H_i/L$ ). For example, at  $H_i/L =0.006$  and with ( $P$ ) increases from 0.5 to 0.83,  $k_t$  increases by 18% for  $d/h=0.5$ . This may be attributed to the increase of ( $P$ ), the area that the water passes through increases then the transmitted wave energy increases.

The variation of the transmission coefficients,  $k_t$  a function of wave steepness ( $H_i/L$ ), is presented in **Figure6** for piles porosity ( $P$ ) ranges from 0.5 to 0.83 at relative immersion depth ( $d/h$ ) equal 0.5 and 0.25. **Figure6** shows that by increasing of ( $H_i/L$ ),  $k_t$  decreases for all values of ( $d/h$ ). For example, at  $d/h=0.5$  and with ( $H_i/L$ ) increases from 0.006 to 0.021,  $k_t$  decreases by 58% for  $P=0.5$ .

**Figure5.** Effect of Breakwater draft ratio ( $d/h$ ) on the transmission coefficients as a function of relative wave length ( $h/L$ ) when  $P=0.5$  and  $0.83$ .

**Figure 6. Effect of pile porosity (P) on the different hydrodynamic coefficients as a function of relative wave length ( $h/L$ ) for a)  $d/h=0.25$  and b)  $d/h=0.5$ .**

## 5 CALIBRATION OF MPR MODELS

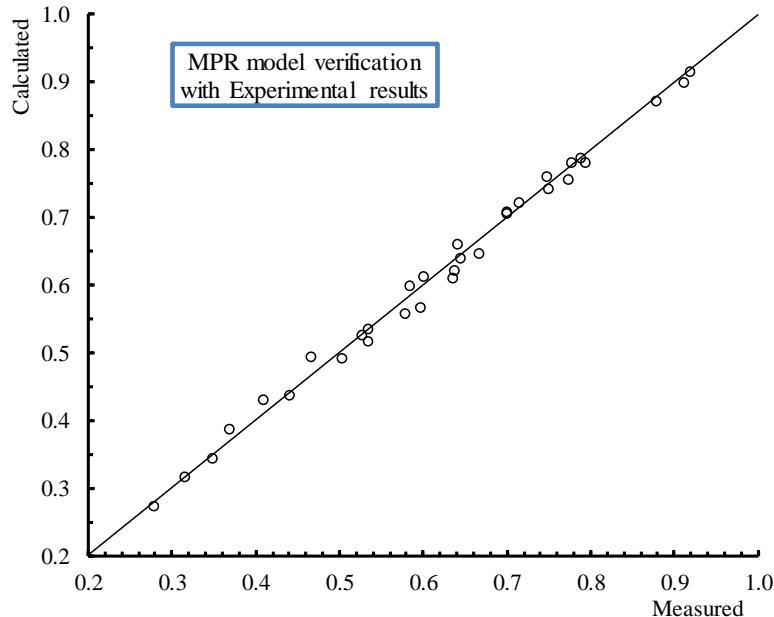

Table 3 presents the evaluation of coefficients values for *MPR* model using *Stepwise* method, while, Table 4 shows assessment of residuals analysis of transmission coefficient between calculated by *MPR* model and measured values. It can be observed that the equations over-predict and under-predict the transmission coefficient by values  $\leq \pm 0.03$ . Figure 7 shows the comparison between the measured and the calculated transmission coefficient ( $k_t$ ) of the breakwater using *MPR* model. A good agreement is obtained between the measured and the calculated transmission coefficient.

**Table 3. Evaluation of coefficients values of parameters for MPR model**

Coefficient	parameter	value
a	constant	1.39
a1	$h/L$	-6.19
a2	$H_i /L$	36.5
a3	$d/h$	-
a4	P	-1.04
a11	$(h/L)^2$	-0.27
a22	$(H_i /L)^2$	1329
a33	$(d/h)^2$	0.64
a44	$(P)^2$	-
a12	$(h/L)(H_i /L)$	-154
a13	$(h/L)(d/h)$	-12.07
a14	$(h/L)(P)$	18.95
a23	$(H_i /L)(d/h)$	60
a24	$(H_i /L)(P)$	-136
a34	$(d/h)(P)$	0.09

**Table 4. Residuals analysis of MPR model.**

NRMSE	0.04	0.045	0.03	0.046

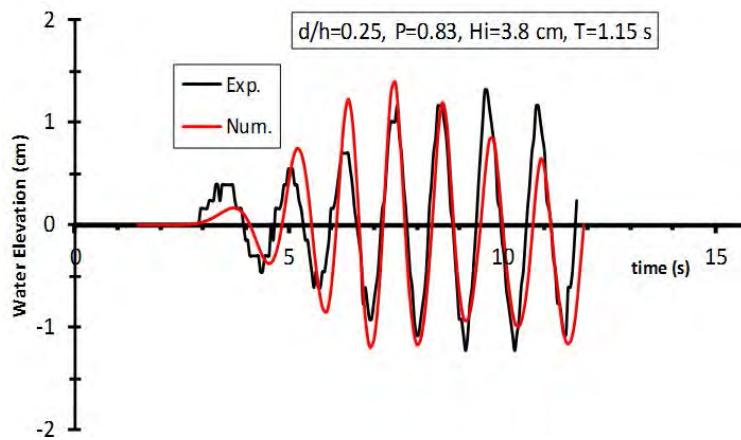

**Figure 7. Comparison between calculated and experimental transmission coefficients results for MPR model.**

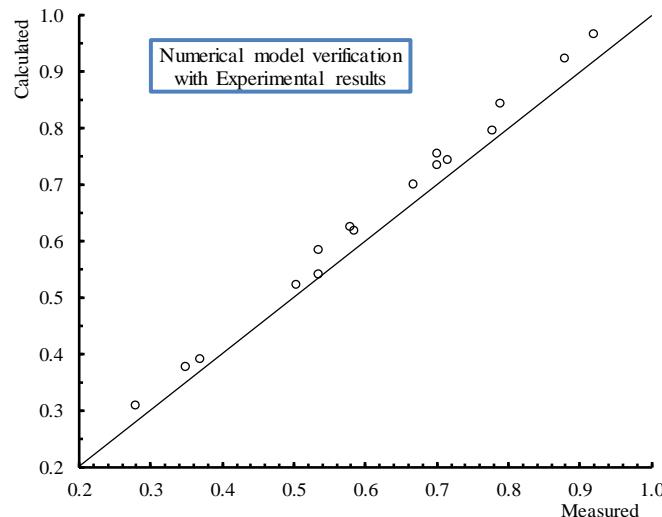

## 6 VALIDATION OF NUMERICAL RESULTS

Figure 8 shows data sample of the water elevation variation at location (P2) which represent the transmitted wave ( $H_t$ ). The figure presents the validation between experimental and numerical results for  $d/h=0.25$ ,  $P=0.83$ ,  $Hi=0.038m$  and  $T=1.15s$ . An acceptable agreement, between Flow-3D numerical and experimental results, can be observed.

Figure 9 presents a comparison between the measured and the calculated transmission coefficient ( $k_t$ ) of the breakwater using Flow-3D model. A good agreement is obtained between the measured and the calculated transmission coefficient.

**Figure 8. variation of water elevation with time @ P2 for experimental and numerical results.**

**Figure9.** comparison between numerical and experimental transmission coefficients results for Flow-3D model.

Table 5 shows assessment of residuals analysis of transmission coefficient between calculated Flow-3D and experimental values. It can be observed from the figure that Flow-3D model partially over-predict the transmission coefficient by values less than -0.06.

**Table 5.Residuals analysis of Flow-3D model.**

Residual= measured-calculated	d/h=0.5		d/h=0.25	
	P=0.83	P=0.5	P=0.83	P=0.5

Min Res.	-0.058	-0.051	-0.048	-0.055
Max Res.	-0.009	-0.030	-0.030	-0.019
NRMSE	0.087	0.097	0.122	0.143

## 7 COMPARISON WITH PREVIOUS STUDIES

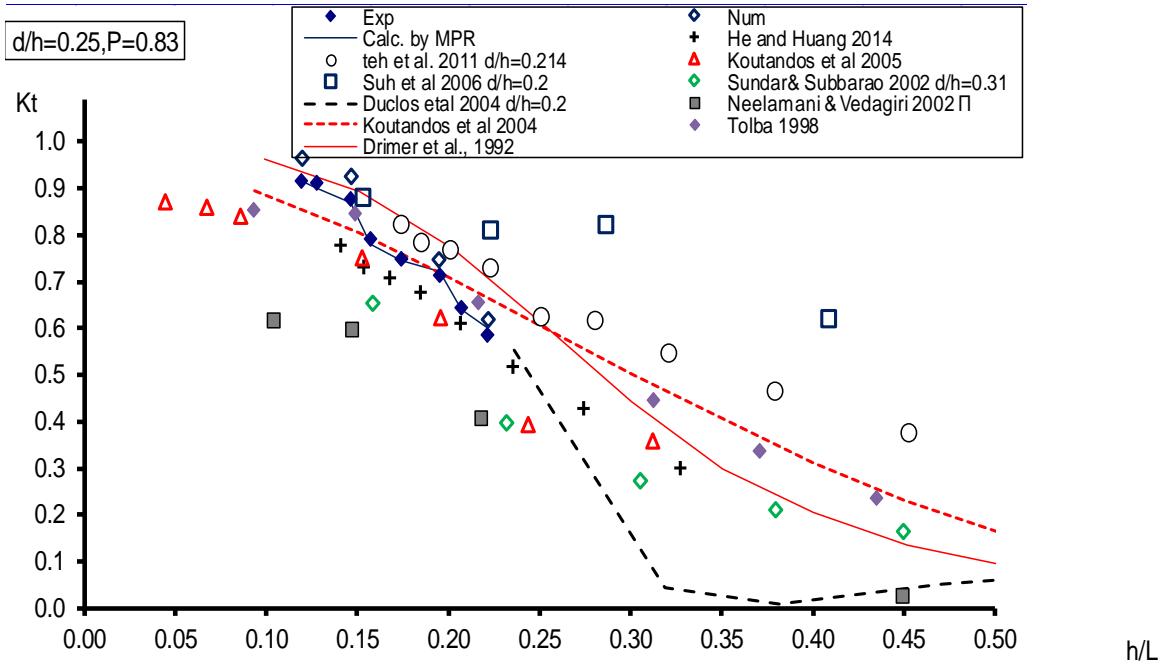

The experimental and numerical results of the present study as well as the empirical equation of transmission coefficient are compared with previous results for the studied semi-immersed breakwater.

Figures 10 presents the comparison between the results of the developed equation from MPR model, numerical and experimental results of the present study, and the different experimental and numerical results obtained by different published work presented in Table (1), as a function of h/L for the suspended breakwater with d/h=0.25. The figure shows that all calculated and measured  $k_t$  coefficient decrease with h/L increasing. Moreover, the MPR model and Flow-3D predicts the transmission coefficient with acceptable degree of accuracy. Figure 10 presents the hydrodynamic performance of the different semi-immersed models, investigated by other published work of (Teh et al., 2011), (Suh et al., 2006), (Sundar and Subba Rao, 2002), (Koutandos et al., 2005), (He and Huang, 2014), (Duclos et al., 2004) and (Neelamani and Rajendran, 2002). The performance of the different models ( $k_t$ ) is plotted as a function of h/L. The characteristics of these experimental studies are shown in Table (1). The figure shows that high scatter in the performance of the different compared models. This can be attributed to the difference in the geometry and cross sections shape used in each case. The results trend shows that all the  $k_t$  decrease with increasing h/L. Moreover, the present model gives smaller transmission values than (Suh et al., 2006) and (Teh et al., 2011) and larger values compared with others.

## 8 CONCLUSIONS

The wave transmission characteristic of a new shape of partially immersed breakwater is experimentally and numerically studied by using physical and Numerical models. The breakwater consists of a semicircular cross section suspended on two rows of circular piles, it was tested under different wave and structural parameters. In general, the proposed breakwater shows low transmission coefficients with increasing of the relative immersion depth (d/h) and decreasing of piles porosity (P). Furthermore, increasing of both relative wave length (h/L) and wave steepness ( $H_s/L$ ) cause lower transmission coefficients. Semicircular shape reduce the transmission slightly than rectangular shape especially for  $h/L > 0.16$ . The results are compared with experimental and theoretical published work and shows a reasonable agreement. In addition, an empirical equation is developed for estimating the transmission coefficient of proposed breakwater. The results of this equation shows reasonable agreement with the experimental results. More investigations with different partially immersed breakwater shapes, under irregular, and obliquely incident waves are

still required.

**Figure 10. Comparison between the results of the present suspended breakwater model and the different results obtained from previous works when  $d/h=0.25$  and  $P=0.83$ .**

## ACKNOWLEDGEMENT

The first researcher is supported by a scholarship from the Mission Department for the Government of Egypt which is gratefully acknowledged. Second appreciative acknowledge to Harbor Engineering Lab. In water and water Engineering Dpt.- Zagazig University for permitting the author to carry out the experimental work of this paper. Last, but not least I am thankful to Egypt-Japan University of Science and Technology (E-JUST) and Japan International Cooperation Agency (JICA) for offering the tools and equipment needed for the research work.

**Abstract**—The effect of upstream roughness on turbulent street canyon flow is presented. Horizontal measurements were conducted at near roof level of a street canyon using particle image velocimetry in a wind tunnel. Three upstream roughness arrays and two canyon width to height aspect ratios ( $W / h = 1$  and  $3$ ) were investigated. The arrays consisted of 3D cubes (plan area density,  $\lambda_p = 25\%$ ), 1h spaced 2D bars (skimming flow,  $\lambda_p = 50\%$ ) and 3h spaced 2D bars (wake interference flow,  $\lambda_p = 25\%$ ). Two-point correlations and integral length scales are computed over the different configurations. The results show a significant effect of upstream roughness on these quantities. It was found that a 3D upstream roughness has a significantly weaker correlation in the spanwise direction. A similar trend is observed in spanwise integral length scales. The shear layer boundary was found to be related to the strength of the correlations near roof level of the street canyon.

**Keywords:** Boundary layer · Street canyon · Particle Image Velocimetry · Wind tunnel

## I. INTRODUCTION

Air quality in urban environments is a critical issue in present times with the resulting socioeconomic implications being of great concern. Pollution in the earth's atmosphere leads to human death, disease and harm to our natural resources [1]. The simple street canyon model is a useful representation of most urban street configurations. The effects of canyon aspect ratio AR (streamwise width  $W$  / canyon height  $h$ ) and upstream roughness on street canyon flow is well studied. Grimmond and Oke [2] defined three regimes of flow in urban environments; skimming flow, wake interference flow and isolated roughness flow. They also found that the plan area packing density ( $\lambda_p$ ) of the upstream roughness and whether it was 2D or 3D had an impact on the flow within the canyon. Experimental wind tunnel studies on street canyons frequently use Particle Image Velocity (PIV) to measure the flow field, and mostly conduct measurements in a single vertical plane, such as Salizzoni Marro, Soulhac, Grosjean & Perkins [3], Savory, Perret & Rivet [4] and Blackman, Perret & Savory [5]. When studying this configuration in a wind tunnel, Savory, Perret & Rivet [4] noted

that it is crucial to match the roughness length scale ( $z_0$ ) and the integral length scale ( $L_{uu}$ ) within factors of 2-3 to ensure that full and model scale are matched properly. It was also noted that the geometry of the upstream roughness significantly effects the structure of the oncoming boundary layer, where 3D roughness is found to generate 3D turbulent structures which resembles a more realistic boundary layer found in nature. Suggestions by Savory, Perret & Rivet [4] have been employed in the present work.

Turbulence is a 3D phenomenon and thus to understand turbulent street canyon flow properly one must investigate how the flow behaves in both the spanwise ( $y$ ) direction and the vertical ( $z$ ) direction. Shaw, Brunet, Finnigan & Raupach [6] conducted a wind tunnel study of air flow over waving wheat. Two-point, space-time correlations of streamwise ( $x$ ) and vertical velocity components were computed from the wind tunnel simulation of an atmospheric boundary layer, with the wheat canopy model constructed of flexible nylon stalks. It was concluded that it was not appropriate to apply Taylor's hypothesis of frozen turbulence in the region of the canopy and, therefore, the integral length scales were computed directly from two-point statistics. It was also found that the lateral integral length scales were smaller than those computed in the streamwise direction by factors ranging from 1.9 to 4.2. Raupach, Finnigan & Brunet [7] stated that the approach of applying the Taylor's hypothesis is fraught with difficulty as high turbulence intensities ( $u' / \bar{U} > 1$ ) are present within the canopy. Inagaki, Kanda, Sato & Michioka [8] conducted multi-point measurements (3D velocities and temperatures) in a cubical array using multiple sonic anemometers aligned at equal heights in the streamwise and spanwise directions. Using two-point correlations, they reported that the correlation of the fluctuating streamwise velocity, the difference between instantaneous and mean velocities ( $u' = u - \bar{U}$ ) was higher along the streamwise direction than for an equal magnitude of spanwise separation. The result was attributed to the existence of coherent structures elongated along the streamwise direction. It was postulated that the coherent structure of  $u'$  is geometrically similar irrespective of the type of roughness.

Raupach, Finnigan & Brunet [7] conducted two-point correlations of various model and field canopies in the x-z and y-z planes. In the x-z plane the streamwise fluctuating velocity correlation produced nearly elliptical stretched correlation contours, with a tilt angle of approximately 18 degrees, an effect that was reported to diminish within the canopy. Shaw, Brunet, Finnigan & Raupach [6] suggest that this more rapid reduction of correlation within the canopy is due to the creation of small scale motion and the breakdown of large scale flow by canopy elements. In contrast, the correlation of the vertical fluctuating velocity revealed nearly circular correlation contours and was found to decay much more rapidly with spatial separation. The correlations in the y-z plane produced contours which were nearly circular for both streamwise and vertical fluctuating velocities. Raupach, Finnigan & Brunet [7] concluded that in a time-averaged sense, fluid motions near the top of the canopy are well correlated over length scales of the order of  $h$ . It is also suggested that zones where the sign of the correlation reverses could be a direct consequence of the formation of dominant flow structures [6]. The effect of the roughness and canyon geometry on the mean turbulent statistics near roof level in the horizontal plane is investigated in this work. The questions to be addressed in the present paper are:

- What is the impact of 2D versus 3D arrays and  $\lambda_p$  on two-point correlations and integral length scales in the streamwise and spanwise direction in a horizontal plane near roof-level of the canyon?
- What does this tell us about the mean structure of the flow at this location of the street canyon?

The objective of this present research is to establish how the oncoming boundary layer flow interacts with the street canyon over a range of configurations. The flow will be characterized in the spanwise direction to complement the work of Blackman, Perret & Savory [5], who characterized the vertical plane. The correlations and scales of turbulence will also be investigated to further understand the dynamics of the flow and structure of turbulence in the spanwise direction. The present results provide a clearer picture on the nature of 3D turbulent flow in street canyons.

## II. EXPERIMENTAL SETUP

The experiments were conducted in the low-speed, suck-down boundary layer wind tunnel in the LHEEA Laboratory (École Centrale Nantes, France). The dimensions of the working section were 2 m (width) x 2 m (height) x 24 m (length) and the wind tunnel had a 5:1 ratio inlet contraction. Boundary layer development was initiated by five 800 mm high vertical tapered spires located immediately downstream of the contraction and a 200 mm high solid fence across the working section positioned 750 mm downstream of the spires. The street canyon flow measurements were taken 5.5 m downstream of this initial development region. Two canyon aspect ratios were studied for three upstream roughness conditions. The street canyon was constructed using two square cross section rectangular bars with a height of 50 mm ( $h$ ) and a lateral length of 1500 mm. The upstream roughness conditions consisted of a

staggered cubical array ( $\lambda_p = 25\%$ ) or 2D square cross section rectangular bars with a spacing of 1 $h$  or 3 $h$  ( $\lambda_p = 25\%$  and  $\lambda_p = 50\%$ ). The height of the cubes and 2D bars was 50 mm. It should be noted that the experimental conditions in this present work are the same as in Blackman, Perret & Savory [5]. A schematic of the experimental setup can be found in figure 1.

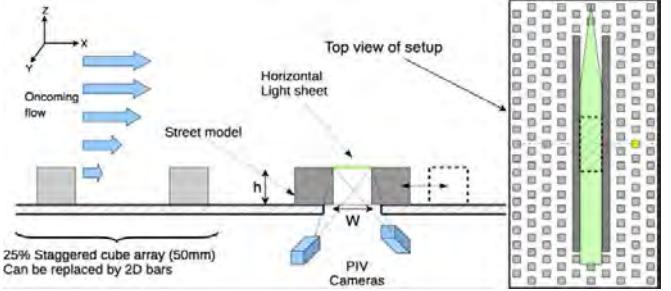

Figure 1. Experimental Setup

Stereoscopic PIV measurements were conducted in the horizontal plane located at a height of  $0.9 \pm 0.05h$  and aligned with the free stream flow. This height was verified by comparing turbulent statistics to those from Blackman, Perret & Savory [5] which consisted of measurements in the vertical plane. The PIV setup was located beneath the wind tunnel floor and images were taken through a glass floor. The final spatial resolution of the vector field was 1.6 mm (0.032 $h$ ) and a temporal sampling frequency of 7 Hz was used. The fields of view were  $1h \times 6h$  and  $3h \times 6h$  for the 1 $h$  and 3 $h$  canyons, respectively. A Litron double cavity 2x200 mJ Nd-Yag laser was used to illuminate the measurement region. The flow was seeded with glycol/water droplets (average diameter of 1  $\mu\text{m}$ ) via a fog generator. An iterative cross-correlation analysis was performed which consisted of an initial window size of 64 x 64 pixels with a final interrogation of 32 x 32 pixels and the overlap of the analysis window was 50%. A pulse interval of 500  $\mu\text{s}$  was used in the computation of the velocity vector fields. A pitot-static tube located at  $x = 15 \text{ m}$ ,  $y = 0 \text{ m}$ ,  $z = 1.5 \text{ m}$  was used to measure dynamic pressure from which the velocity was determined to be 5.9 m/s. This velocity was used for all of the experiments in this present work giving a Reynolds number of  $1.9 \times 10^4$ , based on this velocity,  $U_e$  and canyon height,  $h$ .

## III. RESULTS AND DISCUSSION

In this section, two-point statistics are discussed in part (a) and computed integral length scales are assessed in (b).

### a) Two-Point Statistics

Two-point space and time fluctuating velocity correlations offer important information regarding the nature of the flow field which single point measurements cannot provide. A two-point spatial correlation was conducted using the middle of the street canyon ( $x_{\text{ref}} = 0h$ ,  $y_{\text{ref}} = 0h$ ) as the reference point. The two-point correlation coefficient was computed using (1).

$$R_{uu}(x_{\text{ref}}, y_{\text{ref}}, x, y) = \frac{\overline{u'(x_{\text{ref}}, y_{\text{ref}}) u'(x, y)}}{\sqrt{\overline{u'^2(x_{\text{ref}}, y_{\text{ref}})}} \sqrt{\overline{u'^2(x, y)}}} . \quad (1)$$

Contours of the correlation fields are presented in figure 2 and figure 3 for 1h and 3h canyon widths, respectively. Plots of the correlations along the x and y centrelines for streamwise ( $u'$ ) and vertical ( $w'$ ) fluctuating velocities (with  $x_{ref} = 0h$ ,  $y_{ref} = 0h$  set as the reference point) can be found in figure 4 to figure 5. It can be observed that the correlation is symmetrical for all quantities in the spanwise direction. Symmetry in the y-z plane for correlations of streamwise and vertical velocity fluctuations was also observed by Shaw, Brunet, Finnigan & Raupach [6] and Raupach, Finnigan & Brunet [7]. Raupach, Finnigan & Brunet [7] noted that the correlation contours were roughly spherical with a radius of 0.8h. Within figure 2 and figure 3, the effect of roughness on the flow can be seen qualitatively. The effect of roughness is more prominent in C1h than C3h configurations. The structure of the correlation is more elongated in the streamwise direction and is narrower for C3h. The opposite is true for C1h, with the structure of the correlation elongated in the spanwise direction. For the AR = 1 canyons the largest spherical radius of the correlation (region of the correlation field which is circular) was 0.3h for the C1hR3h configuration, whilst for AR = 3 the largest radius was found to be approximately 0.3h for C3hR3h. This suggests that the size of the spherical radius of the correlations is independent of canyon geometry, and only dependent on roughness (other configurations had smaller spherical correlation radii, all within 0.1h-0.2h for both R1h and Rcu). Although the spherical correlation radii are smaller than those found by Raupach, Finnigan & Brunet [7], this could be attributed to the different flow regimes (flow over a model wheat field) and the measurement region being higher ( $z = 1h$  versus  $0.9h$  in the present work).

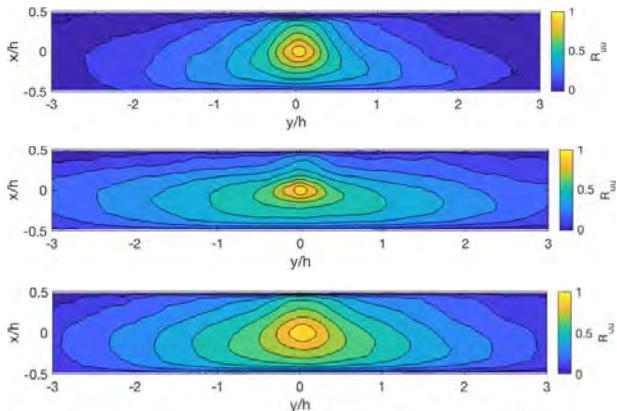

Figure 2. Two-point correlations: (top) C1hRcu (middle) C1hR1h and (bottom) C1hR3h

Raupach, Finnigan & Brunet [7] defined a significant correlation to be  $R_{uu} > 0.2$  at height h. Referring to figures 4 and 5 it can be found that for the C1hR1h and C1hR3h configurations there is a significant correlation for the entire spanwise width of the canyon (-3h to 3h). The C1hRcu configuration shows a significant spanwise correlation from -1.5h to 1.5h. It is also observed that  $\lambda_p$  does not seem to effect the spanwise correlation for the C1h configurations. For the C3h configurations the effect of roughness on the correlations

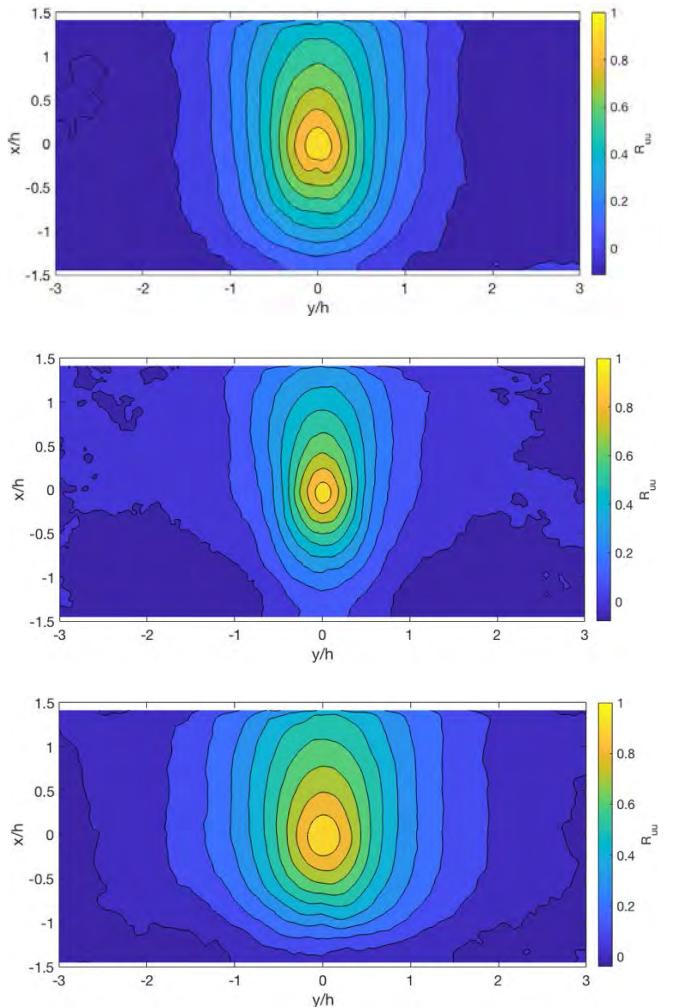

Figure 3. Two-point correlations: (top) C3hRcu (middle) C3hR1h and (bottom) C3hR3h

is less strong. The C3hR3h configuration has a significant spanwise correlation from -1.5h to 1.5h, C3hR1h and C3hRcu are -1h to 1h and -0.8h to 0.8h, respectively. It can be concluded that spanwise correlations decay much more rapidly when AR is increased. The smallest correlation for C1h was the largest for C3h. An opposite trend is observed for correlations in the streamwise direction, with C3h configurations having a significant correlation for most the canyon width (-1h to 1.5h) and the C1h configurations having significant correlations from approximately -0.4h to 0.4h. The correlation could decay more rapidly for C1h than C3h because of a larger circulation region expected in a larger AR canyon. It is also quite possible that the shear layer has an impact on the correlation decay. Blackman, Perret & Savory [5] computed the shear layer boundaries from vertical PIV data for the same configurations present in this work. The shear layer boundary was computed using turbulent kinetic energy in the shear layer [5]. They found that C3h had thicker shear layers than C1h. A thicker and larger shear layer would oscillate at a lower frequency, resulting in the flow in the canyon to have a lower frequency as well, this would result in a stronger correlation near roof level of the canyon with the AR

= 3. On the contrary, C1h was found to have a smaller shear layer [5]. The faster moving and thinner shear layer would cause the correlation near-roof level to decay more rapidly. In the present work, the streamwise correlation at near-roof level for C1h was symmetrical but asymmetrical for C3h (see figures 4 and 5). This, again, can be explained by the shear layer boundaries computed by Blackman, Perret & Savory [5]. Blackman, Perret & Savory [5] found shear layer boundaries to be less symmetrical in the streamwise direction for C3h than C1h. For C3h the thickness of the shear layer boundary was much thicker at the downstream wall than near the upstream wall (approximately 4x larger), this difference being significantly smaller for C1h (approximately 2x larger). There appears to be a relationship between streamwise correlation symmetry at roof level and the geometry of the shear layer. Finally, it was stated above that the effect of roughness is much more profound on the spanwise correlations near the roof level for canyons with an AR = 1 than 3. This trend is, again, present in the shear layer boundaries computed by Blackman, Perret & Savory [5], with the C1h configurations varying more with roughness. Correlation decay in the streamwise direction was found to be related to shear layer boundaries in that those configurations with the thickest shear layer had the strongest correlations at roof level.

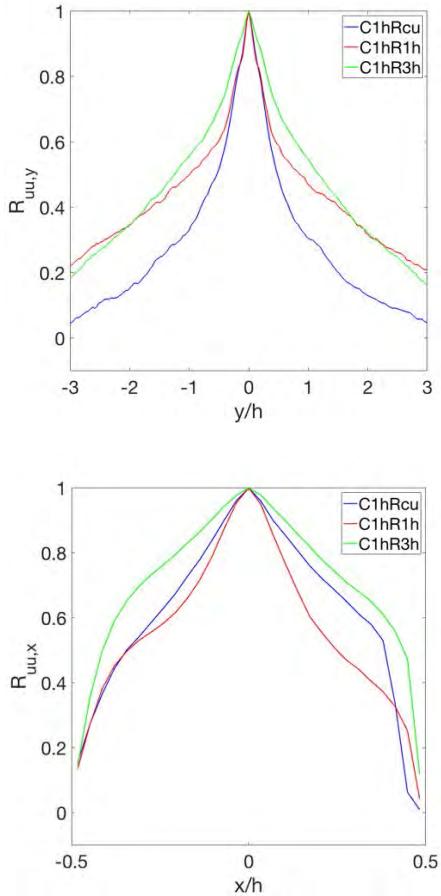

Figure 4.  $R_{uu}$  two-point correlations for C1h (top: y-direction, bottom: x-direction)

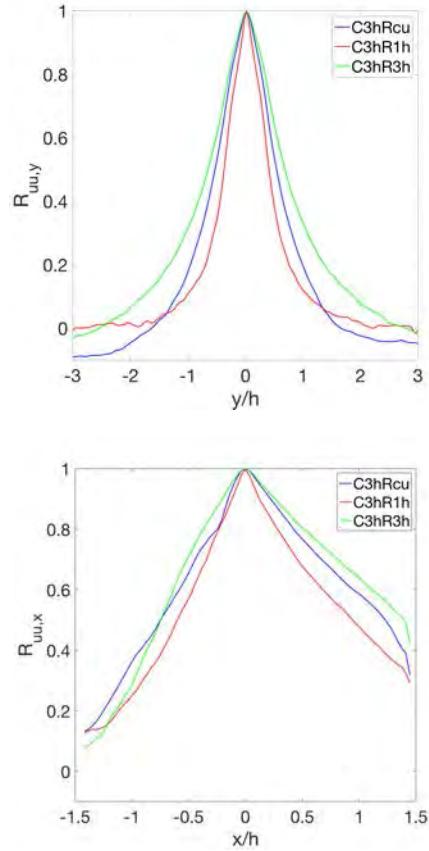

Figure 5.  $R_{uu}$  two-point correlations for C3h (top: y-direction, bottom: x-direction)

#### b) Integral Length Scale ( $L_{uu}$ )

The turbulence integral length scale can be defined as the size of the average-energy containing eddy. The turbulence integral length scales were calculated using (2) for the spanwise velocity fluctuations and (3) for the streamwise velocity fluctuations. The reference points used to compute  $R_{uu}$  used in (2) and (3) were  $x_{ref} = -0.5h$ ,  $y_{ref} = 0h$  for the streamwise  $L_{uu}$  and  $x_{ref} = 0h$ ,  $y_{ref} = -3h$  for the spanwise  $L_{uu}$ . The integral length scale was computed by integrating until the first zero crossing of a two-point spatial correlation.

$$L_{uu}(y) = \int (R_{uu}) dy \quad (2)$$

$$L_{uu}(x) = \int (R_{uu}) dx \quad (3)$$

The integral length scales for both the streamwise fluctuating velocity ( $u'$ ) and vertical fluctuating velocity ( $w'$ ) in the x and y directions are presented in figure 6. It may be seen that roughness and AR have a significant effect on the spanwise integral length scale.  $L_{uu,y}$  for C1hRcu was found to be almost 50% smaller than the  $L_{uu,y}$  for C1hR1h and C1hR3h. This suggests whether the flow is 2D or 3D influences the magnitude of  $L_{uu,y}$  not  $\lambda_p$ . Blackman, Perret & Savory [5] found that the

streamwise integral length scale was larger for the 2D case than the 3D case when packing density was equal. Volino, Schultz & Flack [9] also observed that integral length scales were significantly smaller for 3D than for 2D cases. The results from Takimoto, Ignaki, Kanda, Sando & Michioka [10] contradict this as they showed larger  $L_{uu}$  in the 3D configuration. However, as suggested by Blackman, Perret & Savory [5] this could be due the simulation method employed, as no spires were used in the experiment, resulting in a smaller boundary layer. Blackman, Perret & Savory [5] found that, at roof-level, the streamwise  $L_{uu}$  for Rcu was approximately 4h but it is lower in the present work because the measurements were taken at  $z/h = 0.9$ . The present results show that that  $L_{uu}$  is smaller for 3D than 2D flows in the spanwise direction, which was also found in previous work ([5] and [9]) for the streamwise direction. The integral length scales for vertical velocity fluctuations ( $L_{ww}$ ) were found to be approximately 3-4 times smaller than  $L_{uu}$ .

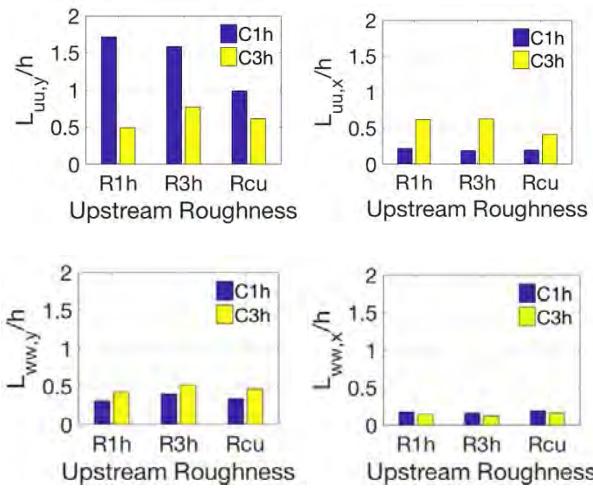

Figure 6. Impact of roughness on  $L_{uu,y}$ ,  $L_{uu,x}$  (top) and  $L_{ww,y}$ ,  $L_{ww,x}$  (bottom)

#### IV. CONCLUSION

Horizontal measurements were conducted at near roof-level in a street canyon using particle image velocimetry in a wind tunnel, for 6 configurations of upstream roughness and canyon aspect ratio. It was observed that the two-point correlations were symmetrical for all quantities in the spanwise direction. Stronger correlations were found for 2D roughness arrays than

in 3D arrays and the planform packing density was found to have no effect on spanwise correlations. It was found that the correlation decay in the streamwise direction was related to shear layer boundaries such that the configurations with the thickest shear layer had the strongest correlation. The  $L_{uu}$  was found to be smaller for 3D than 2D flows in the spanwise direction.

#### ACKNOWLEDGMENT

The authors would like to thank Mr Thibaut Piquet for his technical support during the experimental program and the LHEEA research group.

**Abstract**— An oil spill is a critical problem and appears to have increased in the number of incidence over the past decade. There are several methods for oil spill cleanups. One method is called sorption using either synthetic or natural sorbents. Synthetic sorbents are harmful to the environment as they create another form of waste for nature. This gives rise to evaluate a more environmentally friendly natural sorbent. This research represents the results of study carried out to evaluate the effect of chemical treatment (acetylation) on properties of flax straw as a natural fiber. Sorption capacity of untreated and chemically treated flax straw was examined. It was found that performing the acetylation treatment on flax straw, significantly increases oil sorption capacity in both light and heavy oil by 41% and 22% respectively and also decreases their water uptake by 5%. Moreover, by decreasing the particle size (to 0.6 mm) of the chopped flax straw, the oil sorption capacity increases. This research contributes to a greater understanding of flax straw properties for potential remediation and reclamation applications, representing the possibility of turning the available waste material into a valuable oil sorbent.

**Keywords** ; flax straw, treated straw, oil spill, cleanup, remediation.

## I. INTRODUCTION

Our planet has enormous resources of oil and gas deep under its surface which is economically important in all parts of our lives. Every day, a portion of this valuable material is drawn out of the earth using modern machinery by thousands of oil and gas companies. At the same time, the number of related oil spill incidents are rising and therefore more research is required in oil spill cleanup [1].

So far, various methods are used in different circumstances, including sorption methods. Sorbents are either synthetic or natural. Although manufactured sorbents are high in sorption rate, they create another form of waste after application [2]. This is the main reason why studying natural sorbents are important. Most of the plants consist of fibers which are found to be a reliable oil sorbent [3]. Among them, the flax plant

which is widely available across the province of Saskatchewan consists of a large number of fibers [4]. In Canada, flax is mainly cultivated because of its linseed oil and after the extraction of the oil seed the remaining plant is left to decompose in the field or burned. To develop an oil sorbent using this biomass, the first approach can be to extract the fibers from the plant's stem. Based on studies, flax fiber can adsorb up to 30 grams of oil per gram of the fibers which is considerable [4]. However, the process of removing fibers from the plant straw is time consuming and costly which would not be suitable for a low-cost oil sorbent.

The second proposal, which is the basis of the current study, is to develop an oil sorbent using the stem of flax plant commonly referred to as flax straw. To improve oil sorption and reduce water uptake, a chemical acetylation treatment was performed on the sample and the change in oil sorption characteristics was observed. Based on observed results, the acetylation method was found to increase the oil sorption capacity of flax straw while decreasing the water uptake.

## II. EXPERIMENTAL

### A. Materials

Flax straw from bales was supplied by Biolin Research Inc., a local company researching on development and application of value-added products from flax plant in Saskatoon, Canada. Flax received from the manufacture had a packing density of 220-310 g/L. Two types of oil were selected and purchased from Fisher Scientific based on ASTM F726 – 17, and ASTM F716 – 07. Light oil had a density range of 0.820 g/cm<sup>3</sup> to 0.870 g/cm<sup>3</sup>, while heavy oil had a density range of 0.930 g/cm<sup>3</sup> to 1.000 g/cm<sup>3</sup>. For acetylation, acetic acid and N-Bromosuccinimide (NBS) were provided by Fisher Scientific.

### B. Raw Flax Straw Oil Sorbent Preparation

A batch of flax straw was washed with distilled water, weighted and put in the oven at 60 °C for 24 h. After 24 h, the samples were reweighted to calculate the moisture content. After oven drying the batch of flax straw was chopped using the Retsch knife milling machine. The gap between the knife

and cutting bar was adjusted to 1 mm and the opening of the output screen was 8 mm (Fig. 1). An outline of the experimental procedure is illustrated in Fig. 2.

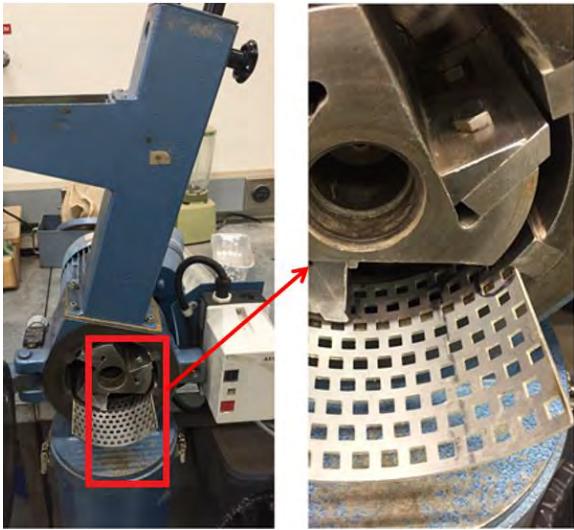

Figure 1. Chopping machine used for cutting the flax straw.

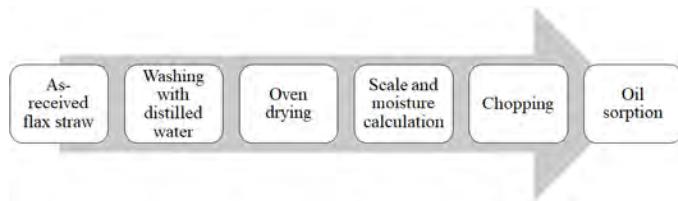

Figure 2. Experimental procedure for flax straw oil sorption test.

### C. Characterization of Flax Straw

Three-dimensional imaging and viewing of the surface morphology for the as received flax straw was conducted using scanning electron microscopy (SEM) model JEOL JSM-6010 LV (Tokyo, Japan). Images were taken at a low operating voltage of 5 kV to prevent samples from burning (Fig. 3).

At this stage, a dried batch of flax straw was sieved based on the ASABE Standard S424.1: method of determining and expressing particle size of chopped forage material by screening. The opening size of the series of sieves used in this study was 3.3, 2.3, 1.6, 1.1, 0.8 and 0.6 mm.

### D. Acetylated Flax Straw Oil Sorbent Preparation

For the acetylated samples, 15 grams of sieved material with a size less than 0.6 mm was chosen. The samples were placed in a flask containing 300 mL acetic anhydride and 1 % NBS. The container was then placed in an oil bath at 100 °C for 1 h as was proposed for a similar natural plant sugarcane bagasse [5]. After the reaction was completed the samples were removed from the container, washed with ethanol and acetone multiple times to remove any remaining by-products. The samples were then oven dried at 60 °C for 12 h.

### E. Oil Sorption Experiment

The sorption characteristics of raw and treated flax straw were evaluated with light and heavy oil. To understand the relation of particle size and sorption capacity, the experiments were performed on light and heavy oil for different particle sizes. Based on ASTM F726 – 17 the sorbent was considered of Type II (loose sorbent). Each sample had an approximate minimum weight of 4 grams. To begin the test, flax straw samples were put in a rectangular stainless-steel Mesh No.20 (0.841 mm opening) basket having dimensions of 4 x 9 x 7 cm<sup>3</sup> (length x width x depth). Since the sorbent is of the loose type, the basket should have enough space for sorbent to freely float within the test cell. The rectangular basket was then lowered into the 1000 mL beaker containing 200 mL light or heavy oil. After 15 minutes of soaking the basket was removed from the beaker and hung for 30 seconds allowing excessive oil to drain. The sample was then removed from the basket and the experiment weight was recorded. Standard deviation considered for this experiment was 15 % and each experiment was repeated three times. The weight of adsorbed oil was calculated by subtracting the weight of dry sorbent before the experiment from its weight after the experiment. Oil sorption capacity of samples were calculated using (1).

$$\text{oil sorption} = \frac{\text{weight of adsorbed oil}}{\text{weight of sorbent}} \quad (1)$$

### F. Water Uptake Experiment

The proposed experiment for water uptake calculations is as follows: each trial test utilized approximately 5 grams of raw or treated flax straw. Samples with different sizes were placed in a 200 mL beaker and distilled water was added until they were completely submerged for 10 minutes. The samples were removed from the water and placed into a basket to hang for 5 minutes in order to release excess water. Finally, the sample were weighed. The amount of water uptake was calculated by subtracting the dried sample weight from wet sample weight.

## III. RESULTS AND DISCUSSION

SEM was used to observe the morphology of the flax straw. As shown in Fig. 3 (c) there are several layers in a single flax straw structure. Each of them consists of a primary thin layer which contain both cellulose and hemicellulose [6]. The flax stem consists of two main parts; fiber and non-fiber part. The non-fibrous, soft spongy part is also called shives.

Figure 3. Images of purified and dried flax fiber or straw (a) macroscopic (b)

and (c) SEM with magnification of 50X and 200X, respectively.

In Fig. 4 the content of the sieved material with openings of 3.3 mm is compared to the sieve with 0.6 mm openings. The combination of shives and fiber is more homogenous in the smaller mesh size compared to the larger size.

Figure 4. Comparison between the content of two different mesh sizes.

Different sieves used in this experiment are shown in Fig 5. The weight of particles trapped within each sieve is calculated as well as the mass ratio of each size category.

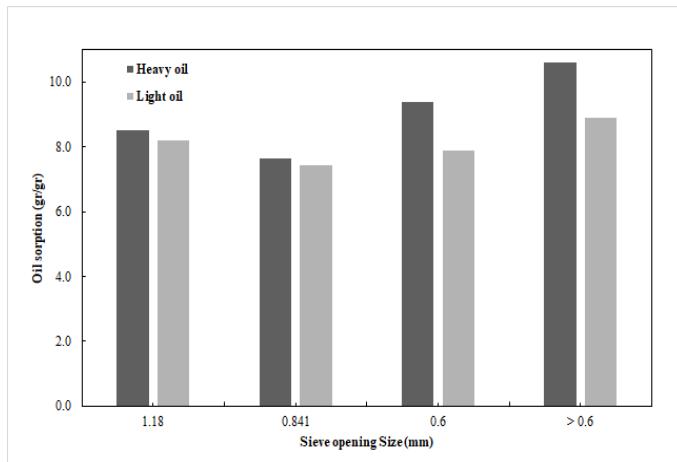

Figure 5. Comparison between oil sorption of the raw sample in light oil and heavy oil.

The result illustrates a steady increase in oil sorption capacity of raw flax from 7.6 g/g to 10 g/g while the particle size of the samples decreased from 0.841 mm to 0.6 mm, respectively. Although decreasing the particle size of the flax straw increases oil sorption capacity, it is expected that decreasing the size to 0.6 mm or smaller, will decrease the capacity due to lack of void spaces [7]. However, for sizes larger than 1.6 mm, the experiment did not successfully pass the test requirement of being in a range of 15 % deviation and the acquired results had many fluctuations. This can be explained by having less homogenous combination of fibers and shives in higher sieve sizes compared with smaller sizes which agrees with results shown in Fig. 4.

Fig. 6 compares the oil sorption capacity of raw and treated sample for sizes 0.6 mm. Acetylated samples show a slightly higher oil sorption capacity which is probably due to the higher capillary forces between plasticized cellulose fibers and oil. More importantly, acetylated samples revealed less water uptake compared to untreated samples. This is due to the chemical modifications where the hydroxyl groups on the surface of fiber are replaced with acetyl groups. Upon this modification the properties of the fiber changed, and they became hydrophobic.

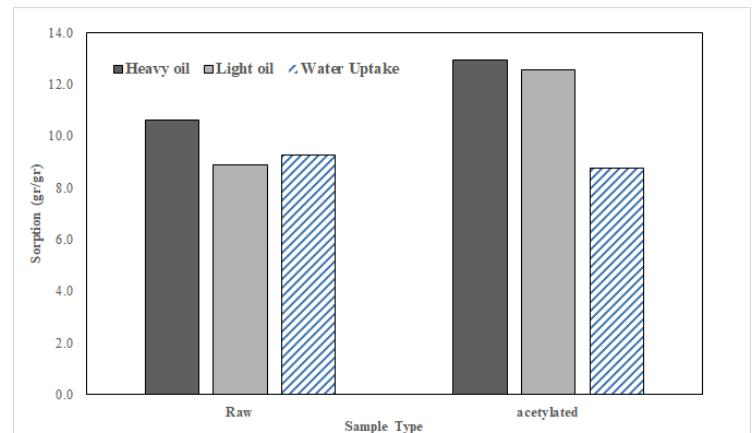

Figure 6. Comparison between the sorption capacity of the raw sample in light oil with heavy oil.

#### IV. CONCLUSIONS AND FUTURE WORK

A new method for water and oil sorption was developed using flax straw where different physical and chemical treatment was performed on this material and the oil and water uptake properties was shown to improve.

1. It was found that the combination of shives and fiber is more homogenous in the smaller mesh size compared to the larger size which is an important consideration prior to performing oil sorption experiment.
2. The oil sorption results revealed an increase in oil sorption capacity up to 11 g/g with decreasing particle size to 0.6 mm.
3. Chemical modification changed the sorption properties of flax straw where the chemically treated samples showed an increase in oil sorption capacity by 41% and 22% in light oil and heavy oil, respectively. Also, the water uptake was reduced by 5% in chemically modified samples which is related to changes in surface properties (such as functional groups) of flax straw.
4. In conclusion, to address the use of sustainable sorbents, this study showed that a natural sorbent material made of waste flax straw obtained from the oil seed industry in Saskatchewan could be used as an oil spill cleanup material.

Future testing to support this study will involve investigation of oil sorption properties of fibers in a media where both water and oil are presented at same time. Another important consideration would be investigation reusability and flammability of sorbent.

#### ACKNOWLEDGMENTS

The authors would like to acknowledge the support of the Department of Chemistry at University of Saskatchewan in assistant with performing acetylation setup. The authors express their gratitude to Alvin Ulrich for helpful discussions and the supply of the flax straw.

**Abstract**— Design projects have become common in engineering classrooms. Earlier exposure to and training in the design engineering process hold much value for an enriched experience and an in-depth understanding of engineering design. Simultaneously, students in their earlier years require more guidance and frequent feedback to inform their own expectations of learning objectives, as well as develop effective learning strategies. In this paper, we will examine the considerations required to design and conduct an undergraduate engineering design course, with reflections from several years' experience with a second-year mechanical engineering design course.

**Keywords-** *Design; Experiential Learning; Problem Based Learning; Collaborative Learning; Course Creation*

## I. INTRODUCTION

Design is the primary mode in which professional engineers operate, but until recently, there has not been a focus on teaching design and the associated soft skills. This has led to decades of engineering graduates that are excellent scientists, but lack design, analysis and professional skills [1-4]. Surveys of industry professionals and recent engineering graduates show that the attributes of design, teamwork, communication and problem solving are the most important in their daily work [3][5][6]. There have been efforts to improve these skills in undergraduate programs, beginning with the introduction of Capstone Design courses, and later, cornerstone design courses to give first year students an introduction to the design process.

This paper describes the process behind the development and coordination of a second-year mechanical engineering design project course with the goal of creating a bridge between the first year introduction to the engineering design process, and the more complex, open-ended Capstone Design projects.

Cornerstone Design courses have been introduced relatively recently and were created in response to the apparent disconnect that first and second year engineering students were feeling from engineering practice [4]. The outcomes from these Cornerstone Design courses can vary greatly depending

on the constraints placed upon the course, such as available time, resources and class size. Additionally, the prior knowledge and training of first year students can vary greatly, limiting the potential subject matter and scale of the projects. Despite these limitations, Cornerstone Design courses have had great success, and their introduction has helped to increase student satisfaction with their early education [4].

## II. BACKGROUND

### A. Experiential Learning

Kolb's experiential learning cycle [7] is the model that is most commonly associated with teaching engineering design and the engineering design process. Kolb's cycle is composed of experimentation, concrete experience, reflective observation and abstract conceptualization. The iterative nature of this learning theory matches well with the engineering design process as a whole, where a product is designed, built, tested and analyzed, and lastly reflected upon for possible future design improvement. The experiential learning cycle can also be applied at a smaller scale to the individual steps of the design process. For example, during the conceptual design phase, students will generate potential concepts, evaluate the concept against design goals and criteria, and use this knowledge to iterate their designs if they do not satisfactorily meet their requirements.

Kolb's experiential learning cycle has been implemented into several pedagogical methods. Of interest when discussing engineering design projects are Problem or Project-Based Learning (PBL) and Cooperative Learning (CL). PBL is a student focused approach aimed at improving the problem-solving skills of students. Students are encouraged to hypothesize solution methodologies and perform independent research to solve problems. Students then propose solutions, and test their appropriateness, followed by critical reflection on the process. Teachers act as facilitators to the process [8]. Cooperative Learning is a teaching methodology focused on improving how students work in teams, which is a very important part of design project experience. The most commonly implemented model of CL is that of Johnson et al. [9], which specifies 5 basic conditions under which students

must work; positive interdependence, individual accountability, face-to-face promotive interaction, appropriate use of collaborative skills and regular self-assessment of group functioning. Research has shown that students taught in this method tend to have higher individual academic achievement and improvements in design skills, communication skills and group skills [10].

### B. Design Project Selection

Choosing the correct subject for an engineering design project, particularly for first or second year students, can be difficult. The project should be challenging, pushing them to think beyond what they have seen in class. The project should be scoped in a way that is able to be completed within the timeline set by the course. The subject of the project should be well understood and documented and not include material from the fringes of scientific understanding. As these projects are part of an engineering education, they should emphasize the application of theory (mechanics, thermodynamics, etc). Finally, they should use the engineering design process as a framework.

Dutson et. al. [11] identified five potential sources for design projects for use in engineering curriculums. In hypothetical projects, course directors invent a project which can be tailored to meet the requirements of the class. Student selected projects, in which students, sometimes with guidance, choose the problem they wish to solve. Research related projects are recruited from professors and related to their research activities. Finally, industry sponsored projects are solicited from industry, ideally to solve real problems a company faces.

Each of these sources for design projects has their own advantages and disadvantages depending on the desired outcomes of the project, and each has been applied to Capstone projects. When working with Cornerstone design projects however, meeting the requirements of “understood subject matter” and “application of theory” is significantly more limiting. Searching for design projects from research, industry or student design competitions that can meet the scope requirements as well as contain only the theory and skills that first or second year students have been exposed to would be extremely difficult. Student selected projects are also difficult if the course developer would like to include the full design cycle (design, build and test) as students at that stage of their education have a poor understanding of the full scope of work required for projects. Hypothetical projects are the most convenient choice for project topics as all aspects of the scope, technical requirements and resources required can be tailored to meet the needs of the course. If properly contextualized, a hypothetical project can teach many of the same lessons as a “real” engineering problem.

### C. Teamwork

Teamwork is often cited as the most desired outcome from team projects [12]. Teamwork is the primary mode in which professional engineers operate and encouraging students to work well within a diverse team environment is of great interest for course developers. There are many models of

effective teams that have been introduced [13-15], and there are several key behaviors that each of them attempts to promote.

The first behavior encouraged is interdependence [12]. In order for an effective group to complete their task they must rely upon the work of the individual members of the team; if one member of the team does not complete their assigned task, it prevents the entire group from completing the project. There are varying levels of interdependence that teams can operate under from pooled interdependence to intensive interdependence. In pooled interdependence, students divide tasks, and complete them in parallel often with poor levels of communication. Intensive interdependence is considered the more desirable form, and each of the team members’ divided work relies upon input from other team members’ work, which encourages communication and coordination.

Trust is another important factor for effective teams. Trust itself can be defined in many ways, but the definitions most closely related to team effectiveness is the students’ confidence in the abilities and trustworthy intentions of their team members [12]. Trust can be encouraged in teams through team-building exercises that help to reveal the abilities and strengths of the team members, as well as share past teamwork experiences.

The most cited and common complaint from students when working in teams is the concept of social loafing [12]. Social loafing occurs when one or more member of the team refuses to complete their fair share of the team’s work. Self and peer evaluation has been found to be the most effective method of reducing social loafing in teams. When the individual contributions made by team members can be quantified and reported, social loafing can be largely eliminated. Another method of reducing social loafing is to encourage each team member to have a unique contribution to the team. Unique contributions are easiest to encourage in multidisciplinary environments such as Capstone projects but can be more difficult in Cornerstone design projects as the students all have similar pre-existing skills.

### D. Feedback and Mentorship

Compared to technical subjects, design can be much more ambiguous and subjective. Usually there can be multiple solutions to a problem, and the path taken to reach a solution can vary greatly. Coupled with the extensive amount of time required to complete one design project, students can become lost, lose motivation, or become stuck in non-productive modes of thinking. In industrial settings, projects will often follow a stage-gate process with milestones and checkpoints to ensure that projects remain on track. In a course context, student deliverables will match these milestones, and students will receive feedback in the form of marks and comments. Giving meaningful feedback can be difficult, particularly if students have difficulty articulating their thought process. Simply relying upon written feedback can lead to students continually making the same mistakes or failing to internalize corrections or suggestions. Often this is linked to “concept fixation” which is common for early designers [16].

### III. EXPERIENCES AND DISCUSSION

#### A. Course Context

The courses described in the remainder of this paper is the second and mechanical engineering design project courses at York University's Lassonde School of Engineering. This course has been run for 3 years and has been updated each year based upon feedback and reflections from previous iterations.

At this point in their academic career, students who participated in this course had taken the prerequisite physics and math courses, as well as two first-year introduction to engineering design courses. The introduction to design courses included exposure to the design process, design-for-x, various creative thinking and innovative design heuristics. These courses also included a team-based design project; however, this project was taken only to the conceptual design phase, emphasizing needs analysis and brainstorming techniques. Additionally, students have been introduced to CAD modelling in SolidWorks™ and were given the chance to 3D print their designs. Additional relevant courses include an introduction to Machine Element Design which was run concurrently with the design project course and Mechanics of Materials.

The goal of this course is to give students an opportunity to experience the complete design process as well as promote good teamwork practices. Integrating as many of the skills and theories to which students had been introduced up to this point was one of the primary driving factors in the choice of the projects. By incorporating the various elements of the undergraduate curriculum into the project, students will be able to see practical applications of their theory as well as observe how interrelated their seemingly distinct core courses can be.

#### B. Past Projects

For the reasons mentioned previously, we chose to proceed with hypothetical projects for this course. We had specific goals of incorporating elements of physics, mechanics of materials, machine element design computer aided design (CAD) and rapid manufacturing. All student teams were given the same design challenge. A portion of the grade was based upon the relative performance compared to the other teams to promote friendly rivalry and ensure students move beyond a design that "just works" and optimize their design.

Each year the project changed, but some elements remained common. First, some form of energy transformation was included in all projects. Second, low strength raw materials were supplied to make the structural design non-trivial and ensure that students considered the material properties as a design variable. The variety of materials available was limited to encourage creativity in a constrained environment. Electronic components were excluded or extremely limited to place emphasis on the core mechanical principles desired, and to ensure that all students had an equal understanding of the theory.

Teams assumed the role of a design team competing for a design contract. They are given a design brief with a set of requirements and constraints, as well as the performance metrics by which they will be evaluated.

In the first iteration of the course, students were tasked with designing a scale version of a car that would store energy for locomotion in a spring. Limitations were placed upon the size of the vehicle, and the loading force; the loading force was much lower than the force required to extend the available springs. Performance was based upon vehicle weight and distance travelled on a single charge. Students applied principles of gear design, force and mechanical advantage, friction and strength of materials.

The second project had students design a small generator that would be powered by a raised weight of fixed mass. The context given was that they were designing a device that could be used as a cell phone charger, or small light source in remote communities. Students were given a small dc motor, and limited materials (high density fiberboard, metal rods, machine screws and nuts, glue). All designs had to mount to a standard fixture. Teams were evaluated on the value of the materials their design used and the length of time that they were able to sustain a 4V output from the generator. Gear train design, strength of materials and motor characteristics were some of the knowledge emphasized.

The third iteration took inspiration from a news article that showed children making a dangerous river crossing suspended on a single rope. Students were tasked with designing a small, battery powered carriage that could carry a basket with a mass across a single rope. The rope was placed at various inclines, and the performance of the designs was evaluated on the speed of crossing the rope, and the total cost of the designs.

All of these design challenges appeared, to the students, to be simple, but as they began to apply their engineering knowledge to the analysis and design process, they found that even simple challenges can be complex.

#### C. Team Creation and Teambuilding

A team size of 4-5 was chosen for this course as the literature highlights that larger teams can be more susceptible to social loafing, and teams smaller than 3 may not have all of the skills required to complete the task [17]. Of the three possible group formation methods (self-selected, instructor-selected or random), instructor-selected was chosen as it is generally regarded as the most effective method [17-18]. Students were required to complete a questionnaire at the beginning of the term, and students were distributed based on a number of criteria.

In the first iteration, the primary criteria by which students were assigned groups was personality based. Students completed an online Myers-Briggs personality assessment with the goal of distributing different personalities. While teams created with similar personality types tend to have better communication and reduced conflicts, teams with diverse personalities can have enhanced problem-solving skills as the weaknesses of one member can be complemented by the strengths of others [19]. In subsequent iterations, personality or creativity style profiles were used more as a teambuilding exercise than the primary grouping criteria.

Other criteria which were taken into consideration at a lower weighting during team formation were overall GPA,

available free time, and previous skills. Subsequent iterations focused on distributing students primarily upon GPA and students comfort with hands-on activities as those were found to be better indicators of successful students.

The first two weeks of tutorials were dedicated to encouraging teams to work together effectively. During the first tutorial, a roundtable discussion of effective teamwork skills was conducted. This was aimed at address some of the common issues with teamwork, and highlighting techniques to overcome them. Students were then introduced to their teams, and asked to choose a team name. Students were asked to complete a team policies and expectations contract (modified from [17]). This contract outlined what was expected of each student when working in a team, such as communicating promptly and completing assigned work on time. The contract also contained a policy for dealing with social loafing or uncooperative members within teams. Students were encouraged to modify or add policies at their own discretion. The contract ensured that all students understood the policies set out by the course, and gave them a sense of ownership over the performance of their team. During the second tutorial, a teambuilding exercise was conducted using the LEGO Serious Play™ Platform. Students used a guided LEGOTM building experience to share previous team experiences, with a goal of helping to build trust between members of the group.

#### D. Peer-Evaluation

Peer- and self-evaluation was included as the major tool in reducing social loafing, monitoring conflicts within teams and promoting collaborative learning. Two online peer evaluation tools, CATME and TEAMMATES were used in various iterations of the course. Students preferred to use TEAMMATES as it was significantly less time required to complete an evaluation at the cost of accuracy and repeatability. The peer evaluation instrument was used to rate the performance of each team member in terms of contributing to the team, interaction with the team, keeping on track, quality of work, and more. Peer- and self-evaluation surveys were conducted after the submission of a major deliverable. Students were given participation marks for taking part in the surveys and based upon the results of the final peer evaluation survey, a modifier was applied to their final report mark. The results of each of the peer evaluations was released to the students anonymously so that students could receive feedback regarding how the rest of the team perceived their contributions and communication. The peer evaluation tools allowed students to confidentially communicate feedback to each other, and course directors. Intervention into poorly performing teams was done based upon these peer evaluations.

Despite the work on developing strong teams, and the rigorous peer evaluations, one of the major complaints with the course has been team dysfunction. Primarily it is related to social-loafing, real or perceived. Often, some students become very engrossed in the project, leading them to spend significantly more time on the project than other members of their group. While the other team members contributed in the form of ideas and workload at a level that, in another group, would be considered equal, their perceived contribution in that group is lower. Identifying these groups and working with

them to normalize expectations or identify new ways of collaborating can help to prevent conflicts.

Another common complaint from students is that they feel their ideas and opinions are not respected by their team mates. This can lead to students taking a passive role in their teams, and eventually lower levels of perceived participation. Despite updated training on how to promote contribution from everyone, the issue still arose. These groups require early intervention and continual monitoring to prevent issues.

#### E. Design Process and Deliverables

The structure of the deliverables was set up to follow the engineering design process. The design process highlighted for this course was the popular VDI 2221, Systematic Approach to the Design of Technical Systems and Products [20].

Design fixation has led to students skipping major steps in the design process, or beginning with a final design in mind, and working backwards in the design process to tailor preliminary design steps to meet their desired design. This led to many students' designs failing to solve the desired problem, not meeting constraints, or arriving at a poorly optimized solution. To emphasize the importance of sequentially following the design process, reports corresponding to VDI 2221 design process "results" were collected at predetermined intervals during the term.

Following the submission and marking of each report, they were returned, and course instructors met with each team to discuss their reports, and any errors. Students were given time to reflect, ask questions, and make improvements to their ideas so that they could be used in subsequent design steps. These review sessions were essential in ensuring that students understood the subject matter and constantly worked to improve their designs. Frequent and face-to-face feedback and discussion was found to be by far the most important part in ensuring that students remained on track and internalized feedback from their deliverables.

Following the completion of the students' Definitive Layout, and 2 weeks before the final competition, students were required to build and test a prototype. The prototype was crucial in ensuring that students identified unforeseen errors in their design, limitations of the materials and/or manufacturing methods.

The final design report contained descriptions of the final design, CAD models, and testing results. It was also used as a final reflection on the overall design process. Students were asked to use the knowledge and experience that they had gained over the design process and reflect on how they would have approached each of the design phases differently.

## IV. CONCLUSIONS

Developing a design project course for first and second year students can be difficult, but the tools available to course developers can help create a successful program. By understanding the skills and knowledge that the students have developed, a project can be tailored to be challenging, yet attainable. 3D printing and other rapid prototyping tools can allow projects to be designed, built and tested, all during a

single term. By leveraging freely available online tools, we were able to implement the major components of PBL and CL.

For most students, this is their first opportunity to fully design, analyze, build and test a design. Whether or not students are able to create a high performing design, they learn valuable lessons in design and manufacturing, as well as practical applications of the theory presented in their engineering courses. Most difficulties in running this course are due to teamwork problems. Special consideration for teamwork training, monitoring and interventions must be made to ensure students have a successful project.

Including design activities, particularly team-based design projects, during the early years of engineering curriculum can help to develop this skill and practices that industry demands.

# A Practical Approach for Teaching Finite Element Analysis for Senior Undergraduate Mechanical Engineering Students

Khaled S. Al-Athel

Mechanical Engineering Department

King Fahd University of Petroleum & Minerals

Dhahran, Saudi Arabia

kathel@kfupm.edu.sa

**Abstract**—This paper discusses the common trends in teaching finite element analysis (FEA) in mechanical engineering programs and then presents a fresh look into a practical approach to teaching FEA. A case study on teaching FEA at King Fahd University of Petroleum & Minerals (KFUPM) is presented by discussing the syllabus, course structure, nature of exams, and the lab work.

**Keywords:** *Finite element analysis, teaching, mechanical engineering, undergraduate students*

## I. INTRODUCTION

Finite Element Analysis (FEA) is one of the subjects where one would find some variations in the way it is taught in mechanical engineering departments. Most schools started teaching FEA at the graduate level due to the nature of the subject as it is heavily based on mathematics and programming. FEA taught at the graduate level usually focuses more on the theory and enable students to develop skills to write their own programs or codes rather than utilize a commercial software. In addition, such courses usually are based on research topics instead of practical engineering applications [1].

This was mostly true till the 90s where many commercial software became available and the need to write an FEA code became less necessary. With that, many mechanical engineering departments started offering FEA at the undergraduate level as a senior elective course in addition to keeping graduate level FEA with the same objectives. Some engineering programs integrate some FEA aspects into engineering courses (structural mechanics, vibration, etc.) [1, 2]. This works well as an introduction to FEA, but without a dedicated course to FEA, students will not have the minimum needed theoretical background and hands-on practice on commercial codes.

Shaikh [3] presented a study on the role of introducing an FE commercial code in teaching an undergraduate FE course. This obviously had a positive impact but course still was based on theory and had the same simply supported beam project for all students. Zhuge and Mills [4] presented a project-based approach to teaching FEA for undergraduate students. The course covers the usually FE theory but focuses more on

projects where students could pick a practical topic of their interest and go in detailed analysis using FEA. A simple module was presented by Hossain [5] but for a quarter module (instead of the traditional fall/winter semesters). This restricted the course to simple examples using the FE software due to the lack of time. Moazed et al. [6] presented a different course structure that is based heavily on lab session and less on theory. The course was offered for Mechanical Engineering Technology (BMET) program, hence the course being more practical. The course had two lab sessions per week, in addition to the lectures, and covered topics in structural mechanics, thermal analysis, and dynamics. The course has an excellent model but lacks in theory, as it is not intended for ME B.Sc.

In this paper, a practical approach to teaching FEA to undergraduate students is presented with details on the topics covered, course structure, and samples from exams and projects. The approach presented covers the minimum needed theory for mechanical engineers while focusing heavily on utilizing commercial FE software for engineering design and analysis.

## II. MINIMUM FE THEORY NEEDED

Usually, the amount of theoretical topics needs to be covered in the course is what dictates how far someone can go in covering practical FE examples using FE commercial software. Table 1 lists the common theoretical topics usually covered in undergraduate FEA courses and discusses whether they should be covered or not (from the authors' perspective).

One of the main theoretical aspects of FEA is the derivation of the stiffness matrix and matrix equations. There are many different approaches used, commonly the direct stiffness method, potential energy approach, Galerkin's residual method. These methods serve the same purpose, regardless of the advantages/disadvantages in applying them. Graduate FEA courses might require students to learn how to derive their own elements to serve a certain behavior, and therefore they need to learn how to derive such matrices and equations. Undergraduate engineering students only need to learn how the equations were derived in order to understand how to link them with the physical behavior. Therefore, the direct stiffness method serves that purpose and is very easy for students to follow and understand. That being said, as the course moves

from 1D elements to 2D and 3D elements, the direct stiffness method becomes tedious and lengthy, hence the need for one of the advanced methods. The potential energy approach also serves that purpose and is easy to follow and understand. Its only drawback is that it applies only to linear analysis. This is not an issue as the majority of FEA undergraduate course do not cover nonlinear topics (which is suggested). There is no need for undergraduate students to learn all the methods. The direct stiffness method is sufficient for lectures and HWs, whereas the potential energy approach is useful for more advanced topics to be covered in the lectures.

TABLE I. Theoretical topics to be covered in an FE course

Topics	Comments
Spring, Bar (Truss) Elements	Covered with direct stiffness method
Beam Elements	Covered with direct stiffness method and potential energy
Frames and Grids	Covered
Plane Stress & Plane Strain Using Rectangular elements	Covered with potential energy
Plane Stress & Plane Strain Using Linear-Strain Triangle (LST)	Covered
Axisymmetric Elements	Covered with potential energy
Isoparametric Formulations	Not covered. This is only useful for code writing and not useful for practical engineers when using commercial codes
3D FEA	Not covered. The formulation is very similar to 2D but very lengthy for hand calculations. 3D can be covered in practical examples in lab sessions
Plates & Shells	Not covered. The theory is more advanced and will require substantial time from the lecture hours to cover it with adequate number of examples. It can be covered in practical examples in lab sessions
Heat Transfer	Covered without details on stiffness equation derivation. The approach is already covered in the mechanical part of the course. This could be given as a read assignment for students if the instructor deemed important.
Thermal Analysis	Covered without derivation.
Structural Dynamics	This depends on the independent ME programs. If structural dynamics or vibration is a core course, then this could be covered. If not, then it should not be covered, as it would require teaching the basic vibration theory in addition to the FEA theory. This could be considered as a suggestion for additional topics.
Additional Topics	Every mechanical engineering department should have additional topics based on the industrial and research topics that are considered relevant to the department and the region where the university is located.  Examples for such topics: <ul style="list-style-type: none"><li>• Coatings</li><li>• Composite materials</li><li>• Piezo electric materials (PZTs)</li><li>• Introduction to CFD</li></ul>

### III. SUGGESTED PRACTICAL APPROACH FOR TEACHING FEA

The suggested practical way to teach FEA for undergraduate mechanical engineering students is to limit the theory to what is needed to understand how FE works. The rest should focus on how to utilize commercial FE software in design and analysis of practical applications. The link between the theory and practice comes from utilizing the understanding of how FE works and converting it into practical use of FE software on how to properly model the problem and apply boundary conditions (BCs) and loads (problem idealization is commonly used for to describe this).

Lab sessions should go in parallel with the suggested topics in Table I. It is important to discuss mesh dependency to students from the beginning to establish it as a regular part of the process. In addition, model validation should be done early on to teach students the concept of validation and verification of computational results. A special lab session with prepared examples should be given when going into 2D and 3D analysis to cover advanced topics such as types of symmetry, stress singularity, mesh convergence, etc.

Due to the nature of the course, hand calculations should be given in assignments, as they tend to be lengthy, while keeping the theory-based exam limited to simple theoretical discussion and short calculations. Final exam should be based on solving a practical problem including all the necessary steps in FE modeling and analysis. Lab assignments are based on the topics covered in a weekly basis. Course projects should be kept to the students to choose a topic of interest or choose a topic related to his/her capstone senior design project, or apply FEA to any other project from another course. Table II lists a suggested grading scheme. Students are encouraged to work in teams for their projects, but individually for their assignments. The course is designed such that assignment are used to test students' understanding of the FE theory, whereas the midterm is used to test the understanding of the basic concepts of FE.

TABLE II. FEA Course Grading Scheme

Assessment	Weight	Comments
Assignments	25%	Assignments are a mix of: <ul style="list-style-type: none"><li>- Hand calculation problems (for lengthy problems students are encouraged to use MATLAB or other similar software)</li><li>- FE software problems.</li></ul>
Project	25%	Students can work in groups of their choice. Students should pick project topics based on: <ul style="list-style-type: none"><li>- Their interests, or</li><li>- Their senior capstone projects, or</li><li>- Other courses projects</li></ul>
Midterm	20%	Simple hand calculations, conceptual questions, discussions, etc.
Final Exam	30%	Practical engineering problem(s) where students submit a soft copy of a report that would include: <ul style="list-style-type: none"><li>- Problem idealization</li><li>- FE model details</li><li>- Requested results (figures)</li><li>- Results and Discussion</li><li>- Suggested validation approach</li></ul>

#### IV. CASE STUDY

This section provides examples from when the FEA course was offered in the new structure in the fall semester 2017/2018 at the mechanical engineering department at King Fahd University of Petroleum & Minerals. At the end, comments from the students are given to share students' perspective of the course structure. A sample home assignment including both hand calculations as well as FE software problems is given as an example to the assignment structure. A short version of the final exam problem is shown here for reference. And finally, some of the course projects are listed to highlight the how far students can reach with the suggested course structure.

##### A. Assignment Problems

Assignments are developed in a way that students would utilize an FE software to solve the problem and then be able to validate using hand calculations. A couple of typical assignments are listed in Table III for reference and so the reader would follow the structure suggested for the assignments. Assignments at the beginning of the course tend to have more hand calculations and less practical problems to be solved by the software as they are mostly truss and 1D beam problems. That being said, one can have practical 1D problems as the first example shown in Table I. As the course moved toward 2D and 3D problems, one can assign problems similar to examples 2 and 3.

##### B. Exam Problems

As mentioned in Table II, there are two exams in this structure. The midterm is supposed to have short hand calculations and some conceptual questions. These usually the typical exams that are given in such courses. The focus here will be on the nature of the final exam using an FE software. The course is supposed to teach students the concepts of FEA to be applied to practical problems and analyzed using an FE software. Therefore, it is suggested in this structure that the final exam should be a practical problem where students would use their FE software skills to analyze it while utilizing their theoretical knowledge of FEA. Table IV lists a practical problem on thermal barrier coatings (TBCs) that was taken from an actual research [7] but simplified to for the course level and was offered in the final exam. Students are expected not only to solve the problem using the software, but include all the necessary steps that they have been doing in the lab and assignments (idealization, mesh sensitivity, validation approach, etc.)

##### C. Course projects

Students were asked from the second week to form groups of their own and choose topics (they can also work individually). Students were encouraged to utilize their capstone projects, or projects from other senior level courses. If neither is applicable, then they can choose a topic of their interest. Table V lists some of the projects that student worked on with sample FE results. Projects are worth 25%, were 5% is evaluated by two other faculty members in a poster session, and 20% is evaluated based on the project report.

TABLE III. Examples of FEA course assignments

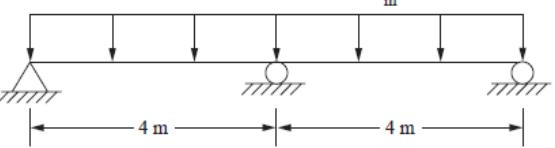

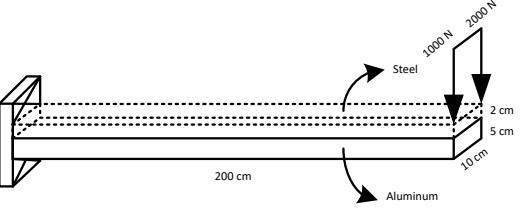

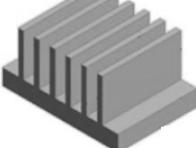

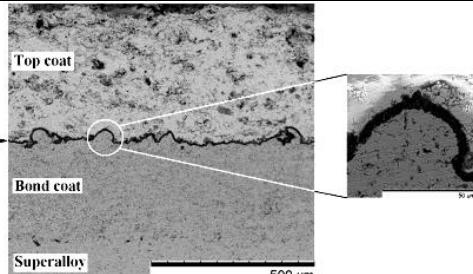

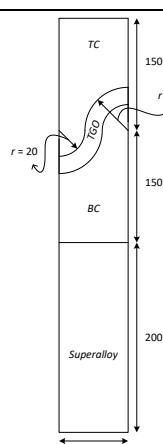

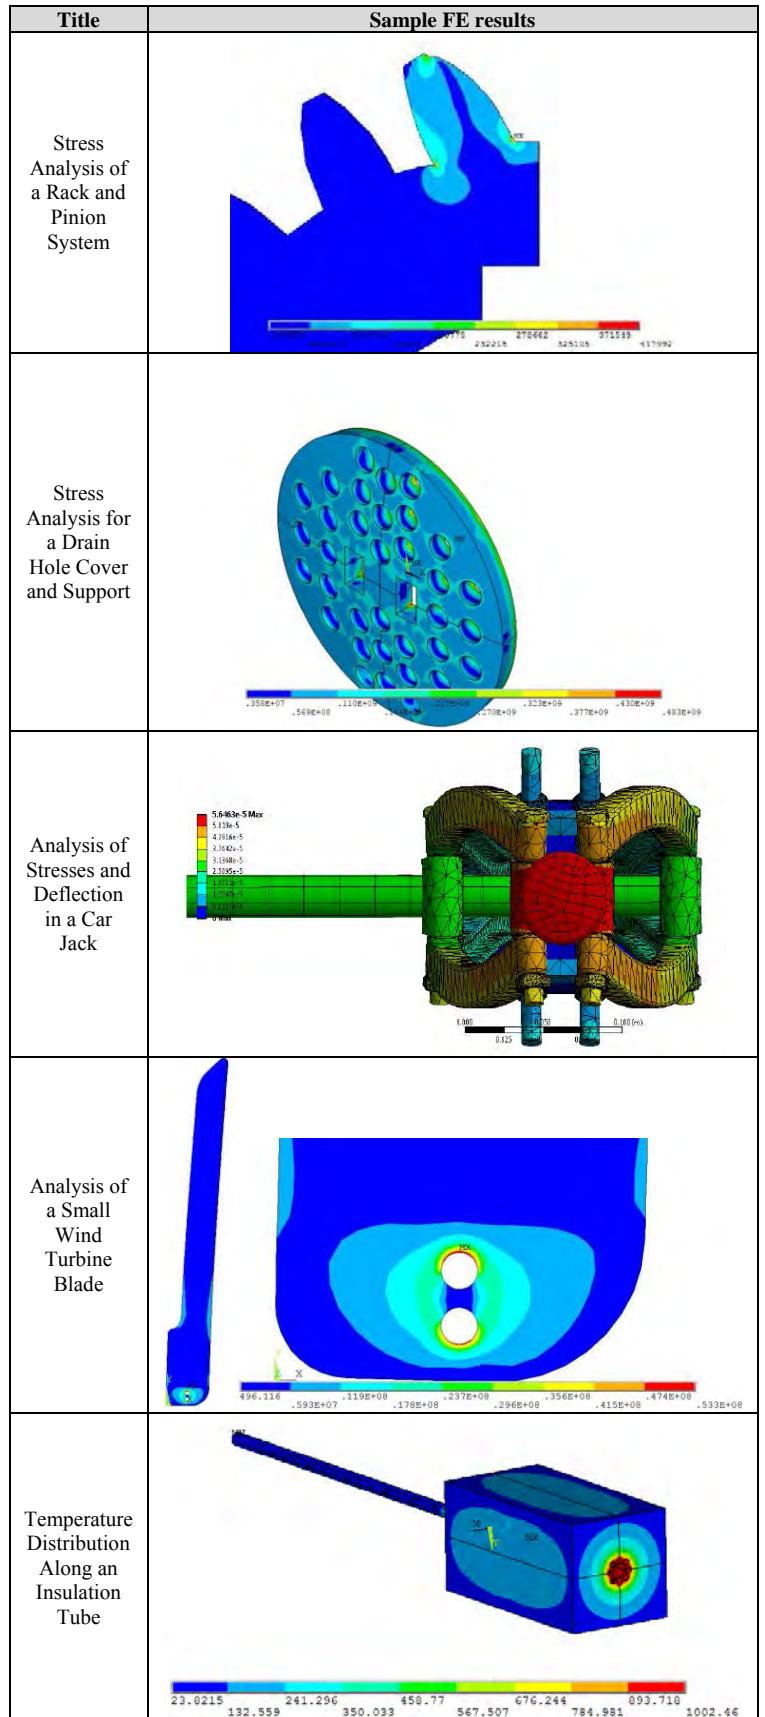

Example	Description
1	 <p>As an engineer with background in FEA, your supervisor asked you to design a beam made of ASTM A36 steel (<math>E = 210 \text{ GPa}</math>) with allowable stress of 160 MPa to support the load as shown in the initial design figure. An "I" shape (wide flange) beam is to be used. Compare the stresses when using different W460 sections. What is the safety factor of each case? Suggest <u>one</u> section to be your final choice</p> <ol style="list-style-type: none"> <li>1. Discretize the problem using four elements (for hand calculation validation).</li> <li>2. Show your FE model with the loads and BC.</li> <li>3. List the units you are using for the dimensions, load, and material properties.</li> <li>4. Provide a table with columns for the W460 size, maximum <math>\sigma_x</math>, and safety factor.</li> </ol>
2	 <p>Stiffeners are common in engineering applications. The purpose of using another material as an added beam layer, or as a stiffener, is to increase certain properties or enhance the behavior, such as to make the structure stiffer. Consider an aluminum beam (<math>E = 70 \text{ GPa}</math>, <math>v = 0.3</math>) with dimensions length <math>L = 200 \text{ cm}</math>, width <math>W = 10 \text{ cm}</math>, and height <math>H = 5 \text{ cm}</math>. A steel beam (<math>E = 200 \text{ GPa}</math>, <math>v = 0.3</math>) is added on top of the aluminum beam with dimensions' length <math>L = 200 \text{ cm}</math>, width <math>W = 10 \text{ cm}</math>, and height <math>H = 2 \text{ cm}</math>. The beam is loaded with applied forces of 1000 N and 2000 N at the free end as shown in the figure.</p> <ol style="list-style-type: none"> <li>1. Discretize the problem</li> <li>2. Provide mesh sensitivity analysis</li> <li>3. Evaluate the deflection at the tip of the aluminum beam with and without the steel beam. Comment on the effect of adding the thin steel beam on the deflection of the aluminum beam.</li> <li>4. Plot the contours of the von-Mises stress and the von Mises strain and comment on the results</li> </ol>
3	 <p>Dimensions are given in another detailed 2D figure</p> <p>Heat sinks are used to enhance heat dissipation from electronic devices. In this case study, a heat sink made of aluminum is used for the study. A fan forces air over all surfaces of the heat sink except for the bottom of base, where a heat flux <math>q' = 1000 \text{ W/m}^2</math> is prescribed. The surrounding air is <math>28^\circ\text{C}</math> with a heat transfer coefficient of <math>h = 30 \text{ W/(m}^2\text{C)}</math>.</p> <ol style="list-style-type: none"> <li>1. Idealize the problem</li> <li>2. Perform mesh sensitivity analysis</li> <li>3. Discuss your approach for validation of the model</li> <li>4. Study the steady-state and transient thermal response of the heat sink</li> </ol>

TABLE IV. Final exam problem

TABLE V. Samples of students' projects

Section	Description																									
Background	 <p>Thermal barrier coatings (TBCs) are widely used in gas turbines. They protect the engine blades from high temperature. The TBC system, as shown in the figure, is used as a coating for gas turbine blades and consists of a ceramic top coat (TC) that reduces the metal temperature; a metallic bond coat (BC) to enhance the bonding between the top coat and the underlying superalloy, and to also protect the superalloy from oxidation and hot corrosion. Due to hot temperature corrosion, a thermally grown oxide (TGO) layer develops at the top of the bond coat. The concern in TBC systems is the fracture failure between the TC and the BC (TGO) either by normal separation (vertical) or by shear fracture.</p>																									
Problem	 <p>Consider a TBC system consisting of a TC, TGO, BC, and part the substrate for your analysis as in the figure. A flat interface is assumed between the bond coat and the substrate (both metallic), and a sinusoidal interface is assumed between the top coat, TGO, and the bond coat. The turbine blade is operated under a heat flux of <math>20 \text{ W/mm}^2</math> at the surface, and the superalloy has a temperature of <math>25^\circ\text{C}</math> at the bottom. Investigate the effect of the thermal loads on the stresses developed and indicate if, and where, local fracture failure might occur. The interface between the TC and the BC (and TGO) fails at 200 MPa for tensile fracture, and 80 MPa for shear fracture. Material properties are given in the table</p> <table border="1" data-bbox="285 1584 750 1848"> <thead> <tr> <th>Material</th> <th><math>E</math> (GPa)</th> <th><math>\nu</math></th> <th><math>\alpha</math> (<math>1^\circ\text{C}</math>)</th> <th><math>k</math> (W/(m.<math>^\circ\text{C}</math>))</th> </tr> </thead> <tbody> <tr> <td>Top coat</td> <td>205</td> <td>0.18</td> <td><math>12 \times 10^{-6}</math></td> <td>2.6</td> </tr> <tr> <td>TGO</td> <td>180</td> <td>0.27</td> <td><math>8.3 \times 10^{-6}</math></td> <td>5.5</td> </tr> <tr> <td>Bond coat</td> <td>150</td> <td>0.30</td> <td><math>14.3 \times 10^{-6}</math></td> <td>31.0</td> </tr> <tr> <td>Substrate</td> <td>203.4</td> <td>0.35</td> <td><math>8.6 \times 10^{-6}</math></td> <td>21.9</td> </tr> </tbody> </table>	Material	$E$ (GPa)	$\nu$	$\alpha$ ( $1^\circ\text{C}$ )	$k$ (W/(m. $^\circ\text{C}$ ))	Top coat	205	0.18	$12 \times 10^{-6}$	2.6	TGO	180	0.27	$8.3 \times 10^{-6}$	5.5	Bond coat	150	0.30	$14.3 \times 10^{-6}$	31.0	Substrate	203.4	0.35	$8.6 \times 10^{-6}$	21.9
Material	$E$ (GPa)	$\nu$	$\alpha$ ( $1^\circ\text{C}$ )	$k$ (W/(m. $^\circ\text{C}$ ))																						
Top coat	205	0.18	$12 \times 10^{-6}$	2.6																						
TGO	180	0.27	$8.3 \times 10^{-6}$	5.5																						
Bond coat	150	0.30	$14.3 \times 10^{-6}$	31.0																						
Substrate	203.4	0.35	$8.6 \times 10^{-6}$	21.9																						

#### D. Students' comments

Students were asked towards the end of the course to submit anonymous feedback regarding the course structure and the way it was taught. It is important to note that most engineering and science courses at KFUPM tend to have two major exams instead of one midterm exam. Also assignments are usually worth between 10-15% of the overall grade.

- The method of making the homework worth 25% is a very good approach to make students learn, but the problem is that the students are not used to it. A recommendation that I have is to create a texting group for communications instead of blackboard discussion board which is not convenient.
- This is an effective way of teaching (especially the idea of giving conceptual short exam problems and heavy assignments where students can learn). I suggest teaching the software part should be 50% or more of the course because I think it is the most important part.
- The instructor changed the way of teaching for this course. He made it more about practicing and thinking. The assignments are the major part of that. I liked it, some did not. Maybe they don't like spending long hours on assignments.
- I suggest having video tutorials as they are much more effective than step by step guidelines for the software solved problems. We can learn listening and watching much better than just reading.
- The theory is lengthy and quite boring, he tried all he can to make it not.
- The teaching philosophy is awesome. He really cares about the students understanding. He teaches in a manner that is tailored to the conceptual understanding of the subject. The only complaint that I have is the difficulty in following in class. This is not because of the teacher, rather because of the nature of the subject. Outside of the class, when I have the ability to turn pages on a book, understanding the material is not a problem

There were other comments but related to topics other than the structure of the course and the link between theory and practice. Overall, students responded well to keeping the lengthy hand calculations for students to solve at home as part of the assignments, while focusing more on the use of an FE software in solving practical engineering problems in the lectures and the lab.

#### V. CONCLUSION

This paper presented a modified approach in teaching undergraduate FEA course with more focus on the practical use of FEA. This was based on offering the course as an elective for senior level students at the mechanical engineering department at King Fahd University of Petroleum & Minerals.

A list of suggested FE theory topics is listed and discussed. Many of the classical topics were removed as they do not add anything to the practical knowledge needed for the students. Cutting many of the theoretical topics gave more room for the practical side of the course to expand and cover a wider range of practical examples. Around 50% of the lectures were offered in a PC lab were the lecture would focus on solving an engineering problem.

The assignments are carefully designed to ensure a good link between theory (and hand calculations) and utilization of an FE software. Students can solve the problems using the software, but then would use hand calculations for validation and verification of their results. Projects were left to students to work individually or as groups, and pick a topic of their interest. The topic has to be approved by the instructor to ensure that a substantial FE work can be done in the project. Final exam is where the real outcome of the course is tested. Students are given an actual and relevant engineering problem. They are asked to read a little background to understand the topic. Then they are asked to prepare a report on analyzing the problem from idealization till the discussion of the FE results.

Students' comments at the end of the course were mostly positive as they liked this approach. Most of the negative comments were not related to the course structure or the grading scheme.

#### ACKNOWLEDGMENT

The author would like to thank King Fahd University of Petroleum & Minerals (KFUPM) for their support and providing the needed resources to teach the course in the new suggested format.

alex.czekanski@lassonde.yorku.ca

**Abstract**— Design education is the backbone of the undergraduate Mechanical Engineering (ME) curriculum at Lassonde School of Engineering (LSE). ME students take project-based design courses every year of their program. Students in the design courses were surveyed and interviewed, in order to examine the key learning outcomes and their development over the undergraduate years. Early-stage coding and analysis on the interview data have resulted in (1) the identification of possible threshold concepts in each year of project-based design learning, (2) the variation and changes in the meaning of design across cohorts, and (3) the three-level factors to design team success. Recommendations are proposed for the instructional training and course structure to enhance their support for design team project experience and outcomes.

**Keywords-** *design education; project teams; mental models; threshold concepts*

## I. INTRODUCTION

What is engineering design (ED)? Design engineering is embedded in the contexts of techno-scientific, socio-cultural, and econo-organizational realities; it also serves as a central convergence point for transdisciplinary knowledge integration to occur [1], [2]. As such, many scholars have made efforts to define the nature of engineering design [3]–[5], and the abilities of a design engineer [6]–[10].

How educators understand design abilities shapes curricular decisions that structure student learning. In the context of our design curriculum, an early and repeated engagement of engineering students with project-based learning in engineering design serves multiple purposes. First, the design projects closely resemble the practice environment, providing an opportunity to more accurately grasp the nature of the complex engineering work [10]. Projects involve change management, knowledge integration, and interpersonal work that require practice and feedback. Students “act out the role of designer” [6], the opportunity for which is not often available in individual, separately topic-based courses.

Second, the design projects empower students to take active ownership and receive recognition for their creative work. Producing tangible outcomes builds confidence, motivates engagement, and is expected to motivate prolonged engagement in the engineering field [11]. At the same time, because of the ‘realness’ students perceive in the project experience, design projects become an educational environment where students “come to care about the valuable things involved” (Peters 1965, quoted in [11]) – and reveal what things are actually valued in the institutional program. All such aspects are expected to enable reflection and deep changes in the way students understand and relate to their work in engineering design.

However, the preference for project-based learning for engineering design lacks in comparison a robust empirical and theoretical explanation of the actual learning processes that take place. *How do students learn engineering design, or develop as design engineers?* This is not a straightforward question; and as we have delved into the study of design learning in our curricular setting since 2015, we have undergone changes in our own ‘mental models’ of ED teaching and learning. Mental models are “our understanding of the causal structures of the system, the boundary we draw around the system, the time horizon we consider relevant, or our goals and values... our framing or articulation of a problem” [12]. Student perspective data from our longitudinal study has pushed us to articulate and have an honest look at our choices, assumptions, and expectations as educators.

This paper focuses on the unexpected findings from student interviews that link design project teams’ interpersonal dimensions much more closely to the design performance than previously expected. Originally, teamwork skills were considered complementary but not core to the design team performance. We will demonstrate how students’ experience-based insights can be used to develop a useful framework of design team effectiveness that potentially enhances the teaching content and strategies for design projects. Design is indeed social and ethical in nature [13], [14]. The findings helps start to fill the gap in otherwise strongly cognitive-focused understanding of design education [15], and takes

further the affective and moral attitudes into practical team competencies.

The paper also summarizes key findings in the potential threshold concepts in design learning. Threshold concepts are learning outcomes that are difficult to achieve, but once achieved, they are irreversible and transformative [16]. This fits well with the view of learning as experiential ‘process of change’ or ‘process of becoming’ [17]. The threshold concept theory allows the researcher to focus on difficult, transformative learning outcomes (rather than attempt to document all results of learning). Student perspectives offer much value in this research because they are highly self-aware of the transformative changes, and the struggles they experienced in that transformation.

Therefore, in order to build our understanding of how students learn engineering design, this paper addresses two questions: (1) What key changes do students experience? (2) What enables design project team success for students? The results on design learning trajectory and design team success are expected to contribute useful teaching and learning materials, and also inform course design decisions on the sequence and focus of training.

## II. CONTEXT OF THE STUDY PARTICIPANTS

The undergraduate Mechanical Engineering (ME) curriculum at Lassonde School of Engineering (LSE) has a strong design focus. Students take a full project-based design courses every year in their winter semester. The general first year design course focuses on problem solving process and techniques (from problem identification to prototyping). Second and third year design courses are for ME students only. The capstone (final year) course is multidisciplinary, involving students from ME, Electrical Engineering and Computer Science (EECS), and Earth Sciences and Space and Engineering (ESSE).

Project-based format is chosen because of the expectation that it mimics real-life practice, and enables ‘learning by doing.’ Most importantly, spending time to move through one complete cycle of design process is of critical importance, for design abilities are expected to be demonstrated in practice - theoretical knowledge of design methodologies must be applied in practice. There is a possible weakness that students are not asked to abstract the design methodology based on their experience, which may or may not contribute to their ability to perform in different methodological frameworks (or innovate their methodologies).

ME students are exposed to multiple design philosophies and approaches in their first year and capstone courses (which are common courses to LSE students, working with peers across departments). In 2<sup>nd</sup> and 3<sup>rd</sup> year ME design courses, however, the course deliverables closely follow the conventional design process developed by Pahl and Beitz [7], which is a well-known conventional design methodology in the ME context [18]: conceptual design, embodiment design, prototype report and final report are submitted. Earlier reports are especially important for facilitating frequent feedback, and managing project timelines. Recognizing the importance of teamwork skills, the following modules are integrated into the

courses via lectures, assignments and tutorial activities: team contract, peer evaluation, problem-solving style assessment, conflict resolution skills, and personal reflection.

## III. METHODOLOGY

### A. Data Collection

Data were drawn from a larger longitudinal study on the program effectiveness and learning processes in engineering design. In particular, this paper draws data from second (UG2) to fourth (UG4) students in Mechanical Engineering, who participated in the **In-Program Survey** by and the **in-depth interviews** that followed. The survey participants were recruited through class announcement and an online link posted on the learning management system; in some courses some class time was allotted to conduct the survey in paper format. Research staff visited classes in a way that no researcher was also a teaching assistant or instructor in the class visited.

In-depth interviews included in this paper were conducted by two female members of the research team (including the first author). Both interviewers represent racialized minorities as well the female presence in an otherwise male-dominant undergraduate program in ME. Interview participants were recruited through the In-Program Survey (by indication of interest), and by posting recruitment message on the learning management system. The total numbers of participants in the In-Program Survey and in-depth interviews are included in Table I.

TABLE I. NUMBER OF RESEARCH PARTICIPANTS

Data Collected in	<i>In-Program Survey</i>	<i>In-Depth Interview</i>
Sept 2015 – Aug 2016	Only Entrance Survey conducted	UG3: 3 male
Sept 2016 – Aug 2017	UG2: 73 UG3: 21	UG2: 2 female, 4 male UG3: 2 male
Sept 2017 – Aug 2018	UG2: 32 UG3: 36 UG4: 17	UG4: 2 male Recruitment ongoing

### B. Data Analysis

Written survey responses were reviewed and categorized based on key themes that emerged. The category labels (open codes) were compared to identify possible properties and dimensions that would help relate and group the labels further.

Coding of interview data adapted the Grounded Theory analytic procedures outlined by Strauss and Corbin [19]. Interview transcripts were first coded by paragraphs (open coding), offering a quick summary of each transcript. Relationships between open codes, and hence specific sections of the data, were identified (axial coding). Several versions of potential categories emerged and guided the subsequent data collection. For example, in 2017, a potential model of design learning in team projects was developed. In 2018, a new focus on the *factors/features of design team success* resulted from added data analysis (Table III). Once the potential categories were chosen, student data were extracted and organized based on the categories. The summaries and category-based enabled volume reduction of the data to be analyzed.

For some questions, student responses were simply summarized and organized for easy presentation (e.g. Fig. 1). However, interviewees in 2018 were asked to review the preliminary findings from 2017 as well, and invited to confirm/disconfirm, elaborate, and add nuances.

#### IV. FINDINGS

##### A. Key Outcomes in Undergraduate Design Learning

Third and fourth year students were asked to identify key learning outcomes related to design projects in each year of their program. These are summarized below (Fig. 1):

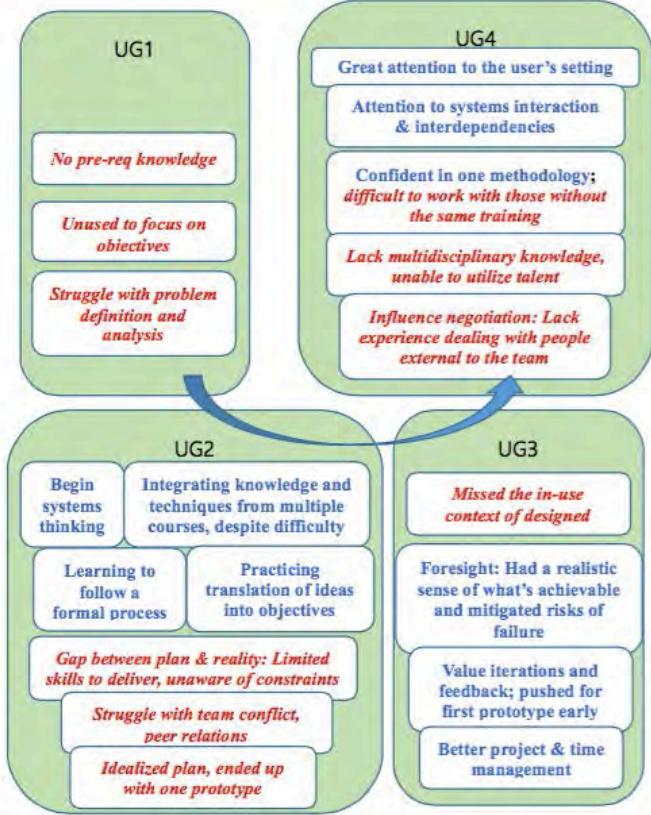

Figure 1. Transformative Outcomes in Design Learning

The *italicized* text represents self-identified evidence of struggles; **bolded** text represents self-recognized demonstration of newly achieved abilities. Both attest to the experiences of irreversible change suggesting possible threshold concepts in learning engineering design in our ME context.

UG1 was a general first year, with design projects that emphasized problem identification and did not require a final product beyond the first prototype. UG2 was the first time ME students had to complete the design cycle, testing prototypes and producing a final outcome. UG3 followed a similar project and course structure. UG4 introduced a new environment for ME students: working in teams with students trained 3 years in different disciplines. Repeat experience in a similar project environment demonstrated more achievements in previously identified challenges; Entering a new project environment identified more new challenges to work on.

Survey responses also confirm the importance of the formal methodology in training thinking habits (Table II). Students were asked to self-identify biggest changes in their approach to design projects. The following key categories emerged:

TABLE II. KEY CHANGES IN APPROACHING DESIGN PROJECTS, FROM UG1 TO TIME OF SURVEY

Categories and Sample Quotes from 2016-2017 Survey	
<b>From haste actions →</b>	<b>To following a methodical, systematic process</b>
"Headed straight for the problem solution" → "Follow steps to get the problem solution (word logical chart, friction block diagram)" (#31, male, UG2)	"try to come with solution on spot" → "have a systematic approach now" (#8, male, UG2)
<b>From lacking knowledge foundations →</b>	<b>To developing deeper understanding</b>
"getting used to so much material at once" → "acquire a deep understanding of the material" (#1, female, UG2)	
<b>From unrealistic, arbitrariness →</b>	<b>To realistic designs with complexity</b>
"ambitious and impractical" → "keep design simple and functional" (#28, male, UG2)	"fantasy world, did not understand limitations at all" → "take into account important aspects like cost, effectiveness, ease of use, ergonomics and aesthetics" (#4, female, UG3)

Students' description and explanation of their approaches to engineering design also allude to a 'mental model' of engineering design that guides their action [9]. A crucial part of evolving the mental model is the feedback one receives from real world experiences. An early and repeated exposure of to the experience of engineering design has given students opportunities to become aware of their own limitations and achievements, reflect and practice new habits and skills.

##### B. The Meaning of Design in Engineering Context

An important part of the mental model is the understanding of the *nature* of engineering design, and the students' relationship to the design activity. Design can be recognized as a formal process, an intermediary plan for an artefact (representing characteristics of an artefact), or an output product. One third year student captured the ambiguous use of the term 'design': "Design is both the process in which engineers create and test new ideas (aka the 'design process') but also can refer to a specific style of something ("a certain design was preferred" for example)" (O4, male, UG3, 2016-2017). Most students chose to describe 'design' in single definitions. Survey responses to the question, "What does 'design' mean, in engineering context?" were first categorized by the type of definition (e.g. design as process, as action, as product, as attribute). The results from 2016-2017 data are presented in Figure 2.

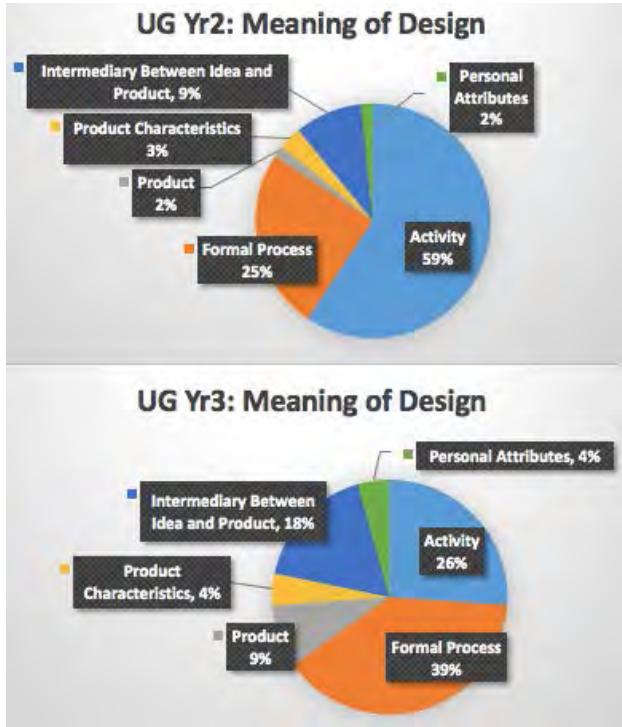

Figure 2. Comparison of UG2 and UG3 Meanings of Engineering Design

It is interesting to note that third year students have a more distributed understanding of what design typifies (a formal process, an output product, and an intermediary between the two). Interview data confirms that students gain a greater recognition of design as a formal process, rather than simply doing something (activity). However, the survey captured a much greater range of responses. For example, the appreciation of the intermediary artefact (that facilitates the translation from an idea to product) was not as clearly self-articulated by the interviewees (even though the work producing the intermediary artefact was described in detail).

It is important to appreciate the diversity of meanings that persist despite sharing the same curriculum (which has a tendency to create conformity to a limited number of views). Using the term ‘design’ as a personal attribute, or a characteristic of oneself, suggests a different identity relationship to the work of design than viewing ‘design’ as a separate product. Translation of an idea into a physical reality, and creativity, remain prevalent goals of design for second and third year students. Referring to some of the interview data, there is a deeply motivating aspect in making something become a physical reality:

*[I thought] maybe this isn't for me sometimes. Going into second year then, having the actual project, then something amazing happened. I kept doing it, and I think at this point [I] decided, I'm doing for myself. (S9, female, UG2, 4)*

Purpose of engineering design was an embedded part of students’ definition of engineering design. The same survey data were categorized based on the implied goals of design in

the engineering context. The results from 2016-2017 data are presented in Figure 3.

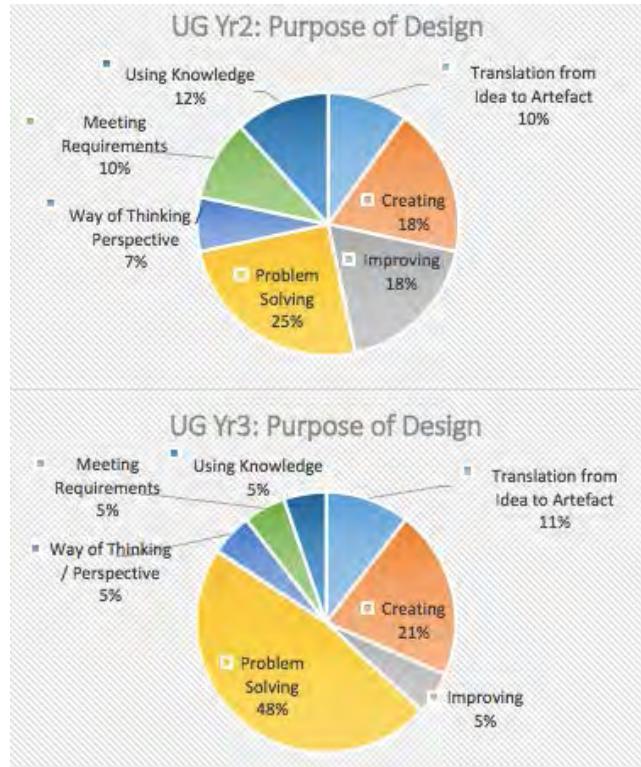

Figure 3. Comparison of UG2 and UG3 Goals of Engineering Design

The close connection between purpose and meaning of design suggests a further investigation into the motivations, aspirations, and values students bring to engineering design. It is also interesting to note that ‘social impact’ was mentioned in a few responses to the question about the meaning of design, but mentioned much more frequently as reasons to choosing engineering. This aspect is dealt much more effectively in survey and interview data relating to student motivation, and their desired future roles as engineers. These data are not included in this paper.

### C. Three Levels of Design Project Team Enablement

A significant part of student responses regarding design projects involved experiencing and addressing challenges to team success. There were three distinct types of factors that attributed to team success, with the key concepts organized in the following table. This distinction offers increased clarity and a holistic view of the skills, values, and processes required for an effective team. This also helps explain why, despite separate efforts to establish, e.g. conflict resolution procedures or communication plans, teams might struggle.

Female students, despite fewer in number, offered much more breadth and precision in the use of terminology (Appendix I). Abstracted further by combining both male and female participant voices, the results are summarized in Table III.

TABLE III. KEY FEATURES OF EFFECTIVE DESIGN TEAMS

	<i>Level 1</i>	<i>Level 2</i>	<i>Level 3</i>
Description	Individual's Meaningful Connection to the Project	Processes that Enable Effective Engagement and Contribution	Team Culture and Values that Foster Effective Levels 1 & 2
Example Features	Commitment Priority Responsibility Perceived purpose Motivation Learning Leading Overall understanding of project	Identification of each member strengths and needs Communication management Decision making Task development Task allocation Knowledge management Expectation management Conflict resolution Consensus building Conversations for understanding Role clarification	Mutual respect Fairness in recognition Truthfulness Value for the person Goal of shared success Inclusivity Friendship and belonging

#### **Level 1: Meaningful Connection to the Design Work**

From students' perspective, a team is successful in its most basic level if all individuals are contributing effectively. Individuals bring their own motivation, behaviour, attitudes, unique needs and strengths. They also carry multiple responsibilities and competing priorities outside the project. For a team working to its "maximum potential" (S9, female, UG2, 13), where people *want* to do the work, and work hard, an individual must be **connected meaningfully to the design project**. "[T]hey're doing something more for themselves, and they want it, they're motivated to complete it and to do well in it" (A2, male, UG2, 131). A meaningful connection involves perceived value and importance of the project work, a willingness and desire to achieve a level of standard in that work. A shared understanding of the purpose, scope, and processes of the project is also an important part of that connection (e.g. A1, A2, A3). Openness to learning, and the willingness to collaborate with the team also demonstrate a meaningful connection (e.g. A1).

However, it is also possible to limit team success even when individuals come in with high motivation and ability. It is possible demotivate members, burn out responsible members with unequal work distribution, leave talents under-utilized, or fail to form a cohesive team. "[It is important] to have a friendly environment [so] that it's not something hostile [such] that they don't want to do something" (A2, male, UG2, 131). Each member needs to feel valued in the team, in order to stay connected to the project. The initial motivation and contribution levels can change by the team processes and the team culture. This leads to the Level 2 and Level 3 factors to design team success.

#### **Level 2: Practical Strategies to Enabling Level 1**

Level 2 deals with practical strategies to enable effective contribution and meaningful engagement of team members:

*[You must] figure out a way where everyone is involved. Sometimes for team meetings, or brainstorming, you want to get everyone's opinion, you want everyone to be present and to be part of it.* (A1, male, UG2, 117)

Such practical strategies to ensure member engagement, integration, and contribution included: identifying individual members' strengths and learning needs (e.g. A1, A3, S7), balancing autonomy and peer learning (S7, A2), structuring meetings for active input (S9), adapting communication strategies for members with different needs (S7), holding constructive conversations when Level 1 is not working (S9), adapting managerial styles (A2), managing expectations and building a common understanding of the team processes (S7, S9, A1), inviting input and feedback (S7, A3, A1), and checking into individual experiences and well-being (S7).

It is important to note that individuals may need different styles of onboarding or integration before they can engage comfortably with the rest of the team:

*Two of our members were very quiet. I was really close with one of them and my friend was close with the other. We said, I'm in charge of this one, etc., we said we're going to make sure you are in the loop [...] That allowed us to have a conversation, and helped him express himself.*  
(S7, female, UG2, 25)

Disengaged members and team conflicts pose significant challenges to project teams, and students actively reflect on how they might encourage and enhance motivation and performance of individuals. Level 2 processes would include strategies to mitigate challenges and resolve conflicts:

*If everyone is upset with that obviously they're going to something about it. And instead of making everyone upset, I could just go up to that guy and try to convince him - you need to start working or this project will not work as smoothly as it could. There would be problems, there would be conflicts, other people will start saying we're doing too much work and he's not doing any work, why do we have to do work? So, to avoid those conflicts, I would just approach the person ahead of time.* (A1, male, UG2, 148)

*[S]ometimes it takes people have to realize, you have try and show them, that that's what they want to do, that that's something they should focus on and be motivated to do.*  
(A2, male, UG2, 150)

*[W]e had a member who thought they were smart and said they knew what they were doing ... it got better but it was a lot of work with him... the rest of the team project was making sure everyone had a chance to say.* (S7, female, UG2, 12)

Students also commented on the factors that make each team and situation different. Part of being able to lead a team was to recognize the circumstantial or historical variations that require adapted responses to create effective team strategies:

*I think language is a big one. Recognizing language is different to everyone. I may be saying one word but you might think it means something else. Your personal background and*

*life has effect. If you value other things above this project and others value it, then that's going to be an issue. If you have any personal issue, let us know, don't tell us what, but we have the right to know.* (S7, female, UG2, 74)

*When we're working with teams, it's good, cause if you have people of different skill sets and different mindsets [...] the head project manager, you want that person to be less like nitty gritty details and more of a by the book, or figuring out the main of how the over arching things that you want to happen. I guess other people would be doing certain jobs and tasks and I guess they could be creative through it.* (A2, male, UG2, 119).

*It might depend on the project or the situation you're in. Usually there are many different ways to do things. But there are circumstances where there might just be one certain way, and [...] you'd like to be someone like that. That they'd be able to focus and have their blinders on to that certain way.* (A1, male, UG2, 120)

In general, male students spoke of Level 2 strategies in terms of convincing someone to do what one believes is correct. The diversity people brought to the team were given meaning only in terms of the project tasks. Factors outside the scope of the project activities were not considered. In contrast, S7, one of the two female interviewees, offered articulate insights on how an individual's behaviour can be interpreted, as information to help adapt Level 2 responses. Furthermore, an individual's ability to contribute was understood as an outcome of internal and external systems that shape a person's holistic well-being:

*In [one] phase there might be a leader but it doesn't mean someone else can't take charge. Someone who will make sure things are going on time, and make sure everyone is doing ok, and making sure they're mentally and emotionally ok to do it.*

*I recognized, 'hey you're not behaving the way you usually do,' then they say, 'yeah, there's this thing that's causing me stress.' That's a leader's point of view, to make sure everyone's doing okay. If I am the leader, there are aspects that I don't know anything about so might say, 'hey why don't you take charge of this?' The leader is the role of... who initiates conversation, but they don't need to be in charge.* (S7, female, UG2, 29-30)

A team leader, without a formal title, was seen as a person who recognizes the factors to individuals' effectiveness and wellbeing, and facilitated Level 2 processes. The leader's responses helped to correct maladaptive behaviours, meet individual needs, provide support, and create engagement. These interactions served as a catalyst to change individual motivation, behaviour, attitudes, strengths.

Students who establish effective Level 2 processes set certain standards and espouse particular values that help the team mature and adapt. At the same time, in spite of good intentions and known strategies, significant challenges have emerged that thwart the efforts at effective Level 2 processes. The contrast between Level 2 enablers and inhibitors led to the identification of Level 3 factors to team success, presented in the next section.

### **Level 3: Team Culture that Enables Effectiveness of Levels 1 and 2**

Level 3 characterizes the team culture by its core values that are expressed in practical ways. Level 3 recognizes that the emotional and relational qualities of team experience have a significant impact on Level 2 and Level 1 effectiveness. For example, even in the case of a conflict, shared values for **honest conversation** and **respect** helped turn the conflict into an opportunity for team building: “[E]verybody spoke and said what they wanted to say in a very respectful way, everyone came out feeling more satisfied” (S9, 33). On the other hand, individuals who did not value communication impeded mitigation processes (Level 2) that left Level 1 issues unresolved: “[A] lot of people view communicating as a very fluffy and unnecessary thing, but it reaches a point where I can't have conversation with you because you don't think you need to have it” (S9, 31). Members can passively disengage as well as actively shut down conversations and hinder team effectiveness: “[T]he problem is that a conversation isn't an argument. To me, we had a lot more arguments than conversations, anytime a conversation was initiated it was shut down” (S7, 70).

Level 3 also directly sustained individuals' engagement and contribution levels in the project (Level 1):

*[W]e had a lot of different ideas and different thought processes and that helped with problem solving, because we were friends, we didn't have to be fake nice so we could be honest and be productive. Because we were genuine, we got everything done on time, all that was really good.* (S7, female, UG2, 12a)

**Trust, friendliness, inclusivity, and respect** created a mutually empowering relational culture (Level 3), which enabled effective role integration and task-work facilitation (Level 2).

Students also experienced how disrespect could manifest in different ways to hinder team effectiveness:

*So how some people think they're too good for the group this is a big problem, I work with people who have big egos so I don't feel for them, I don't give them credit for things they didn't do, I don't care, they didn't do the work, they don't get the credit, then the people who do the work, I give them the credit and I boost them. Ethics: people who don't follow those will never be successful in engineering.* (S1, male, UG3, 122).

*I didn't realize how important it was [to address the issue of disrespect or dysfunction]. I thought it just happened naturally... it was a really interesting learning [experience] [...] He took over, at one point you keep fighting for something, and get nothing [...] Sometimes he thought I was challenging him just because I was clarifying. Unnecessary animosity [...] him trying to prove me wrong, constantly competing with one another, the lack of communication, it was really bad [...] It got better but it was a lot of work with him [...] not accepting the random bits of shut-down, saying hey you're acting like a jerk, [making it clear that] criticism for no reason isn't acceptable.* (S7, female, UG2, 55, 49, 59b, 12c, 59a).

Disrespect can be based on unconscious biases that view peers as less than equal. S1 dealt with a male peer who showed off his material wealth, treated project tasks as not important enough for himself but expected of peers like S1. The confusion of socioeconomic status as merit to project credit, with simultaneous exemption from labour, belittled S1 and the importance of the project work itself. On the other hand, S7 dealt with hostility from a male peer who asserted his dominance over the team, and refused to take S7's input seriously, as legitimate. While this kind of disrespectful attitude has been seen between male peers, the subtle sexism was distinct in the personal offense one took as a challenge to the hierarchy (male dominance, has a right to speak without responsibility over behaviour; female submissiveness, has no right to speak up nor disagree with the dominant male).

Both S1 and S7 had very positive team experiences that emulated Level 3 qualities, of collaborative, mutually empowering culture. It only took single individuals – who took their privileged position to impose a hierarchical relationship – to make Level 3 very difficult to achieve.

In contrasting high performance team experience and poor team experience, it is also important to note how each member's Level 1 contribution can affect the Level 3 characteristics of the team. Likewise, one person's poor contribution in Level 1 can affect Level 2 processes, Level 3 culture, and another person's Level 1 connection to the team. From S7's example:

*[W]e were able to say 'I trust that you're going to read the [meeting minutes] even if you couldn't make it', or 'I trust you'll finish your part of the project without me having to nag you.' [...] I would send a notice about the meeting an hour before, and they would all show up to the meeting, they were able to get started themselves if I was late. (S7, 28).*

*[W]e worked on a proposal, I said, 'hey I'll do this and this, but I don't know this, so can you do it?' [...] He didn't do it, it ended up not being done. It was really hard to communicate. We started on passive aggressively, sometimes I just didn't want to go to the meeting. (S7, 36).*

Each team member can affect other members in important ways, whether negative or positive, whether intended or not. All three levels of team success are mutually reinforcing.

## V. DISCUSSION

The sequence of the key learning outcomes, in the context of the ME curricular design, reveals interesting possibilities in structuring the learning experience to support the learning outcomes. Sometimes course directors receive feedback on what is not working, but much less on what *is* working. There are features about the second year design course that created a pivotal experience for many transformative learning outcomes. Many of these were solidified by the similar course experience in the third year. There were first year material that had a clear connection to the upper year learning outcomes, but could be presented and structured to make that connection clearer. Students felt much more challenged in the fourth year with a changed course environment, while they built much confidence through a familiar course environment that was repeated (albeit

with greater complexity in the project content) in the third year experience. There may be a trade-off between building confidence (solidifying achievement in potential threshold concepts) and expanding students' perceived horizon of the learning that lies ahead (growth, awareness of the lacking capabilities, broadening the understanding of the field). Engineering design educators need to be conscious of the trade-offs, diligently collecting evidence to confirm or disconfirm our beliefs about what achieves the intended learning objectives.

Listening to student perspectives also demonstrated a huge value in identifying learning outcomes that we had not anticipated. This is a direct feedback into our own mental models about what constitutes engineering design learning. Without recognizing such valuable learning outcomes, it may leave certain effective learning experiences or course design features to be dropped in the continuous improvement efforts. Sterman emphasized the importance of going beyond just the simplistic use of feedback to 'improve' decisions. He explained how learning must involve a better understanding of the complex systems that constitute an implicit picture of reality, or how the learner frames the problems in the first place. This indeed applies to the educators themselves, to be in continuous inquiry of what design education in engineering is, how it takes place, and what our roles are.

Evidence suggests that it is possible to lose motivated individuals, and that each member may need different procedures to become fully engaged in a team. Then it becomes important that, before a member becomes or continues to be someone "who doesn't want to do anything" (A3, 146), the team makes effort to adapt and establish Level 2 processes and Level 3 culture. "[R]elationship building should've been done since the beginning of the project. I always try to go out for lunch with the group before we work. I try it a lot... I think that's so important" (S7, 73). The importance of Level 1 contributions cannot be understated; however, an individual member's contribution to team success now includes – beyond task delivery – interactional and relational work that facilitates team procedures (Level 2) and establishes a sustainable team culture (Level 3). Because of the mutually reinforcing reflexivity between each of the three levels, the degree of team effectiveness may be a summative result of:

$$\text{Team Effectiveness} = aL1 + bL2 + cL3 + d(L1L2) + e(L2L3) + e(L1L3) + f(L1L2L3)$$

where the weight of each level factor may vary between first to fourth year students.

Disrespect is considered a moral injury to the respect and worth of a person [20]. There is an overall inadequate language and problem identification within male-dominant culture for misbehaviour, disrespect, power dynamics, and subtle discrimination based on socioeconomic status and sex – this may extend to other minority experiences, such as ESL, race, personalities, and disability. Engineering design educators, especially as they are involved in developing team leaders, will need to be better equipped to model and raise the level of student proficiency in equity, diversity, and inclusion.

The existing level of student leadership and excellence should not be ignored. The ethical sensitivities, creativity, relational competencies and proactive action students bring to team life are indeed impressive. Students offered profound insights on which meaningful educational problems exist, how they are engaging in them, and what resources they would like from the institution. Students are partners and co-creators of our educational program success, as this research has taught us.

#### ACKNOWLEDGMENT

For the larger study that embeds this paper, we gratefully acknowledge the financial support by Quanser, National Sciences and Engineering Research Council (NSERC), Lassonde School of Engineering and Queen Elizabeth II Graduate Scholarships in Science & Technology (QEII-GSST) program.

**Abstract**— A great deal of work has been done within the engineering community to identify the threshold concepts that students must master in order to transform from novice to practitioner. At the same time, engineering regulatory bodies have established a set of graduate attributes that help ensure graduating engineers are prepared to practice professional engineering. Students and recent graduates have identified that one area in which they felt lacking in skills and confidence was solving the complex and multi-faceted problems encountered in the engineering work place. This seems to indicate that students have not fully mastered one or more discipline-specific threshold concepts. This paper presents a framework engineering educators can use to identify, map, and monitor those concepts as key indicators used to track graduate attributes.

**Keywords:** *threshold concepts; graduate attributes; engineering education; key indicators; benchmarks*

## I. INTRODUCTION

Engineers Canada reports that 69,015 undergraduate engineering degrees were conferred over the five year span from 2012 to 2016 [1]. This trend is expected to continue as the overall number of enrolments increases yearly. But are these graduates confident that they can apply their acquired knowledge and skills in the workplace?

Engineering education research has identified a number of threshold concepts that learners must master as they make their way from novice to practicing engineer. At the same time, engineering accrediting bodies, including the Canadian Engineering Accreditation Board (CEAB), have identified a set of graduate attributes to ensure graduates are prepared for a professional career. Each accredited engineering program is responsible for identifying and monitoring a set of benchmarks or key indicators for each of these graduate attributes.

This paper discusses the pilot test of a mapping framework used to determine the relationship between existing key indicators and established threshold concepts. This information can help shape the continual improvement process as programs work to strengthen the undergraduate engineering experience.

## II. BACKGROUND

### A. Engineering Education

Over the last 100 years engineering education has shifted from a hands-on practical approach to one that focuses on engineering science and analysis [2][3]. Currently there are moves toward outcomes-based curriculum, increased design experience in the undergraduate curriculum, and educating “engineers who can engineer” [4]. There are currently 43 schools offering 281 different accredited engineering programs in Canada. These programs range from the more traditional offerings of civil, mechanical, and electrical engineering, to disciplines as varied as aerospace, biomedical, environmental, sustainable design, petroleum, and software engineering [5].

Canadian engineering schools have been accredited since 1965. This process ensures that graduates of engineering programs meet the high standards necessary to become professional engineers. An accreditation review examines the depth and breadth of the science, mathematics, engineering science, engineering design, and complementary studies curriculum, as well as 12 graduate attributes that ensure proficiency in discipline-specific knowledge and skills, employability skills, and professional responsibility [6].

### B. Graduate Attributes

All graduating engineers must be technically competent. They must have mathematical, scientific, and discipline-specific knowledge, and be able to analyze and solve complex engineering problems. They must know how to conduct investigations in order reach valid conclusions. They must be able to design solutions and systems for open-ended problems, and use engineering tools appropriately. This professional body of knowledge forms the core of every engineering program.

Graduate attributes move beyond these technical abilities to include a set of qualities required of graduates as they become practicing engineers. In order to be employable graduates must be able to work both individually and as part of a team. They must be able to communicate effectively and continue to learn throughout their careers. Most importantly, engineers must be able to make professional, responsible, and ethical decisions for which they are accountable. The challenge for engineering

programs is to choose appropriate indicators that demonstrate their students are meeting each of these graduate attributes.

### C. Threshold Concepts and Threshold Practices

Long before Meyer and Land coined the term ‘threshold concept’ [7], educators were questioning whether students actually understood what was being taught in a class [8][9], and looking for ways to help overcome common bottlenecks in student learning[10].

Meyer and Land defined a threshold concept as a portal, a way of thinking about something in a “new and previously inaccessible way”[7]. They considered it a space between where a learner is and where that learner needs to be in order to make the transition from novice to experienced practitioner in a discipline. Some learners master threshold concepts quite easily, while others struggle in a transitional state called liminality. With new knowledge to learn and misconceptions and misunderstandings to unlearn, this liminal state can involve disorientation and ambiguity as a learner moves between a state of knowing and not knowing.

A threshold concept is identified by five key characteristics: it is (1) transformative, (2) troublesome, (3) irreversible, (4) integrative, and (5) bounded. Land nicely summarizes these in a 2013 interview for Tomorrow’s Professor Newsletter [11]:

"New conceptual understandings pull together (integrate) various stands of understanding into a new understanding that fundamentally changes (transforms) the way students think about the subject. Because the process involves the loss of a familiar way of thinking and the security it provides, the process of crossing the threshold commonly causes some mental and emotional discomfort (troublesome). There's some debate about whether these new understandings are reversible or not, but once a student "gets it," it seems hard for them to "un-get it." "Bounded" seems the least obvious descriptor perhaps because its meaning derives more from contextual concerns than specifically conceptual ones."

Over the years, the definition of a threshold concept has expanded to include threshold skills and practices [12][13]. Like a threshold concept, a threshold skill is considered to be transformative, integrative, and troublesome. It is, however, considered only semi-irreversible, since learners tend to lose certain skills if they are not practiced, practice being the fifth characteristic. The idea of partial understanding exists for threshold concepts, where a learner can apply the concept, but not explain it in an abstract way. With threshold skills this is considered partial mastery where a learner can only demonstrate certain parts of the skill or practice, or knows that the skill should be used, but cannot to use it properly.

### D. Threshold Concepts in Engineering

Much work has been done to identify threshold concepts within specific engineering disciplines, but a research study out of the University of Western Australia created the first Integrated Engineering Threshold Concept Inventory (IETCI) [13]. These concepts, which include a number of graduate attributes, are grouped into three main categories: (1) learning to become an engineer, (2) thinking and understanding like an engineer, and (3) shaping the world as an engineer.

Funded by National Sciences and Engineering Research Council of Canada (NSERC)

Learning to become an engineer includes recognizing the role an engineer plays in society, the values and responsibilities associated with being an engineer, and the engagement in and responsibility for one’s own learning. It also includes the thresholds associated with teamwork and communicating. Thinking and understanding like an engineer encompasses the abstraction, modeling, and theories required to master the core concepts within one’s discipline, and shaping the world as an engineer includes engineering design, and the approaches, thinking skills, and integration of concepts an engineer uses in his/her day-to-day practice.

Mastery of these engineering threshold concepts, skills, and practices should indicate graduates are well on their way to becoming capable engineers. It then seems logical that the graduate attributes identified and monitored as part of an accreditation’s graduate attribute assessment should be linked to these thresholds.

This research established and piloted a framework for engineering educators to examine the level to which the graduate attributes identified for engineering accreditation measure mastery of the threshold concepts identified in the integrated engineering threshold concepts inventory.

## III. PROCESS

The Graduate Attribute – Threshold Concepts (GATC) framework allows an engineering program to analyze the relationship between graduate attribute key indicators and the threshold concepts identified in the IETCI. These results can be used to make curriculum and accreditation tracking decisions during the required continual improvement process.

### A. Framework

Analysis of program data using the GATC framework is a three stage process: (1) extraction of accreditation data, (2) mapping graduate attribute indicators and exemplars to threshold concepts, and (3) interpreting the results.

The first stage requires access to the program’s most recent CEAB accreditation documentation. Fig. 1 shows the result of this stage where accreditation table 3.1.2, found in the EN\_6C\_vXX spreadsheet, is copied exactly as is into the CEAB312 worksheet of the GATC working document.

This data is used to populate the TC Analysis mapping worksheet used in phase 2. Fig. 2 shows this transfer of CEAB data into a form where each learning activity is separated out into its own mapping row. The person or team doing the analysis now needs to identify the exemplar (problem, assignment, exam question, lab, or project) associated with the learning activity listed in the Activity column. Fig. 2 also shows two exemplars, one for each of the first two activities.

A	B	C	D	E
1	Indicators and Learning Activities Assessed			
2	Table 3.1.2: Graduate Attribute			
3		Indicator		Relative Level:

	I.2 Apply engineering knowledge and skills to solve real world problems.		ENPE461	
	I.2 Apply engineering knowledge and skills to solve real world problems.			ENME339
	I.2 Apply engineering knowledge and skills to solve real world problems.			SE survey
	I.2 Use assumptions that successfully simplify a complex problem.			

Figure 1: GATC phase 1 – CEAB data

Graduate Attribute	Indicator	Level	Activity	Exemplar
Knowledge base	1.2 Use mathematics to describe and solve engineering problems.	Introductory	MATH375	Solve first order differential equations with applications
		Intermediate		
	1.3 Use technical knowledge to inform engineering activities.	Advanced		
Problem analysis		Introductory	ENGG201	Perform hydrostatic pressure calculations and basic fluid flow calculations
		Intermediate		

Figure 2: GATC phase 2 – TC analysis – exemplars

Mapping begins once an exemplar has been identified for each of the activities. Each of the threshold concepts included in the inventory is listed in a column across the top of the worksheet. Fig. 3 shows a few of the threshold concepts in the ‘learning to become an engineer’ and the ‘thinking and understanding like an engineer’ categories of the IETCI. The task for the analysis team is to determine if each exemplar maps to one or more threshold concept. It is expected that some exemplars will map, while others will not. If a map is found, the intersecting cell is marked with an ‘x’. Resources including a concept map of IETCI, a summary table of the threshold concepts identified in the IETCI, and a suggested categorization and mapping of threshold concepts identified in other research studies, are provided in the spreadsheet to help analysts identify potential threshold concepts. Fig. 3 shows the first exemplar mapped to three of the threshold concepts in the abstraction, modelling, and theories section, and the second exemplar mapped to one. Once each exemplar has been examined, the mapping process is complete.

The GATC report is broken into two parts: an examination of the graduate attributes and threshold concepts, and the tracking of threshold concepts. The examination of graduate attributes and threshold concepts reports three things useful in determining if the exemplars they are tracking are ones that show the transformation learners make as they move from novice to practitioner: (1) the percentage of exemplars that are mapped to at least one threshold concept, (2) the number of threshold concepts mapped to each graduate attribute (see Fig. 4), and (3) a breakdown of which threshold concept categories (learn, think, shape) are mapped to each graduate attribute (see Fig. 5).

Activity	Exemplar	Abstraction, modelling and theories									
		use of memory	Engineering as gendered	Confidence in the mathematical models	System identification and definition	Judging whether a model is satisfactory	Proofs	Creating visual or symbolic representations	Relating visual or symbolic representations of systems to physical systems	Relating mathematical representations of systems to physical systems	Describing systems mathematically
MATH375	Solve first order differential equations with applications		x						x	x	
ENGG201	Perform hydrostatic pressure calculations and basic fluid flow calculations								x		

Figure 3: GATC phase 3 – TC analysis – mapping

### Threshold Concepts per Graduate Attribute

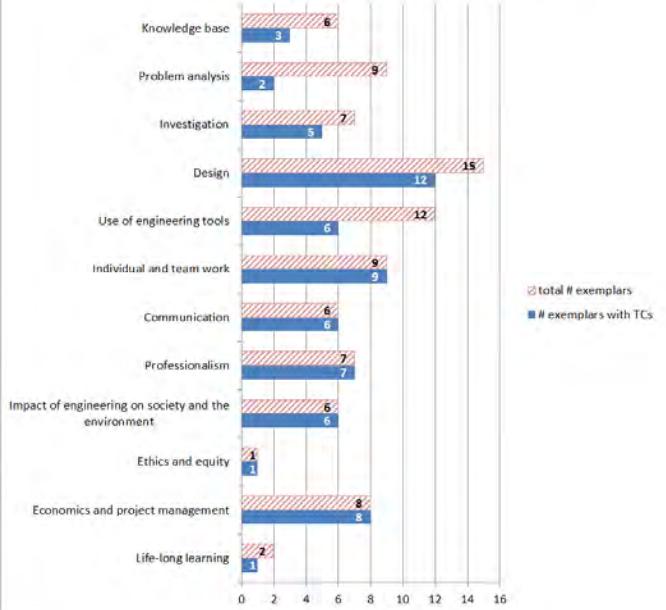

Figure 4: GATC report part 1 – grad attributes & threshold concepts

### Breakdown by Threshold Concept Type

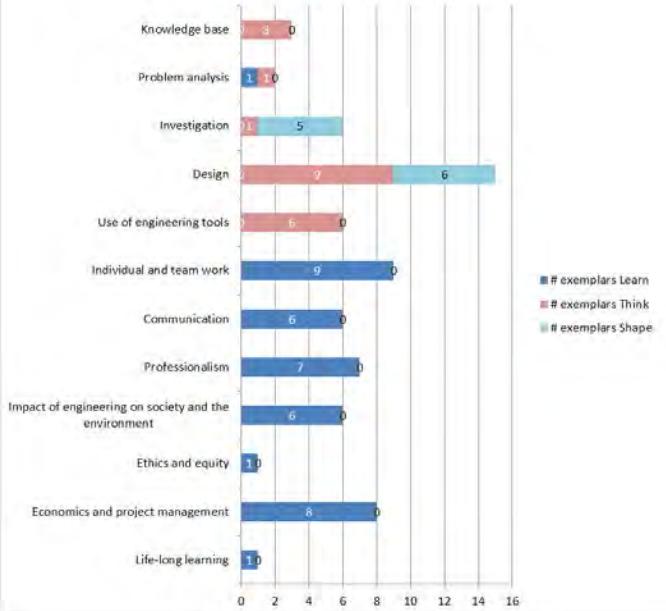

Figure 5: GATC report part 1 – breakdown by threshold concept type

The second part of the report specifies the percentage of threshold concepts that were mapped to at least one graduate attribute (see Fig. 6). It also identifies the number of mappings for each threshold concept. This allows the analysts to quickly identify any unmapped threshold concepts that are important to their discipline, and should be considered as potential exemplars.

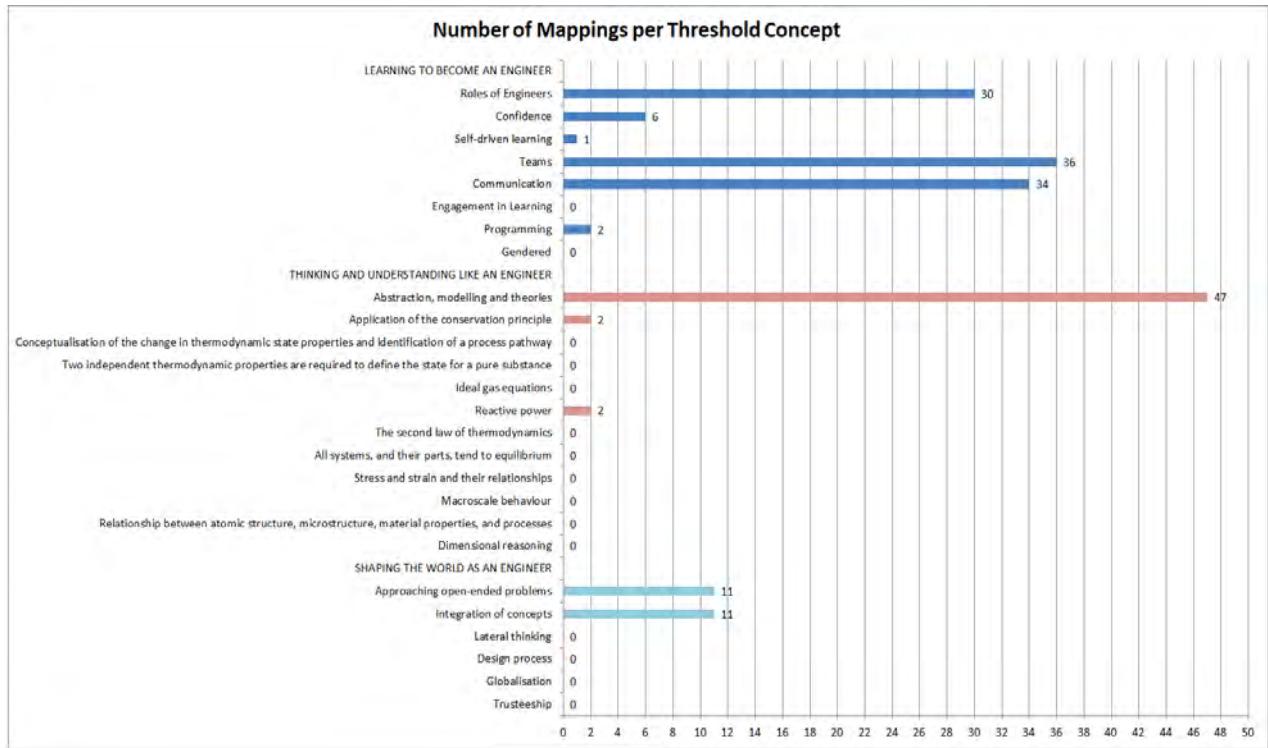

Figure 6: GATC report part 2 – number of mappings per threshold concept

### B. Application

The GATC framework was piloted with two programs that underwent their CEAB accreditation reviews in 2017. It was reported to be easy to use, and in both cases took less than one hour to load the graduate attribute data, and enter and map the exemplars.

The first program had 47 exemplars with 46 mapped to threshold concepts (97.7%), while the second had 88 exemplars with 66 mapped to threshold concepts (75.0%). This percentage is not a reflection of the quality of the program or the choice of indicators. It is simply an indication of how many of the selected benchmarks are threshold concepts, and where they are focused. If a graduate attribute does not map to any of the threshold concepts, or there is an imbalance of mapping across the threshold concept types ('learn', 'think', 'shape'), then the program should consider modifying their choice of exemplar to one that tracks a significant point in a student's transformation from novice to practitioner.

The first program had 29 of the 57 threshold concepts mapped from its graduate attributes (59.9%), and the second program had 32 of the 57 threshold concepts mapped from its graduate attributes (56.1%). A higher percentage of mappings does not necessarily mean a "better" program. It simply identifies a threshold concept that has been associated with a number of graduate attribute exemplars. Programs are encouraged to look at the threshold concepts that have few or no mappings. If these are important concepts within the discipline, then consideration should be made to add graduate attribute exemplars to monitor student learning associated with these threshold concepts.

### IV. DISCUSSION

Users in both pilot tests recognized the value of the GATC framework as part of the continual improvement requirement of the accreditation process. It was easy to use, and helped identify areas where graduate attributes could be better mapped to discipline-specific threshold concepts. One program recognized that a critical graduate attribute indicator had inadvertently been omitted from their CEAB submission. Had the GATC framework analysis been done prior to submission this omission would have been caught. The other program identified gaps within the 'learn', 'think', and 'shape' categories of threshold concepts tracked and will reevaluate the choice of exemplars to provide broader coverage of these categories.

### V. FUTURE WORK

Future work on the GATC framework will focus on two key areas: (1) expanding the pilot study to gather feedback from other interested programs, and (2) integrating the findings of discipline and topic specific threshold concept research into the GATC framework's topic search resource to help users more easily map their graduate attribute indicators.
