

# Progress in Canadian Mechanical Engineering

Proceedings of the 2018  
Canadian Society for Mechanical Engineering (CSME)  
International Congress  
Sunday May 27<sup>th</sup> – Wednesday May 30<sup>th</sup>, 2018  
York University, Toronto, Ontario, Canada

# **CSME International Congress 2018**

## **“Progress in Canadian Mechanical Engineering”**

**Sunday May 27<sup>th</sup> – Wednesday May 30<sup>th</sup>, 2019**

**York University  
Toronto, Ontario, Canada**

**SPONSORED BY**  
**The Canadian Society of Mechanical Engineering**

**EDITED BY**  
**Aleksander Czekanski, MBA, PhD., P.Eng., FCSME**

**Published by**  
**York University Libraries**

The CSME International Congress promotes a technical program that focus on topics and themes relevant to Mechanical Engineers. One of the primary roles of CSME is to train and update the mechanical engineering community on new advances and emerging fields. It is through the Congress that we provide a platform for community members to acquire and disseminate such information to each other as well as discuss recent research challenges and practical importance to the profession and its related field.

The papers in the proceedings are on the following topics:

- Fluid Mechanics
- Mechatronics, Robotics and Control
- Advance Energy Systems
- Manufacturing
- Computational Mechanics
- Student Paper Competition
- Heat Transfer
- Biomechanics and Biomedical Engineering
- Engineering Analysis & Design
- Materials Technology
- Environmental Engineering
- Mechanical Engineering Education

## Acknowledgments

Preparation for the 2018 CSME International Congress was made possible by the dedication, time and effort from the members of the CSME Organization Committee and the York University Libraries.

Sincerely,

Aleksander Czekanski MBA, PhD, P.Eng, FCSME  
York University  
Chair, 2018 CSME International Congress

# TABLE OF CONTENTS

Note: Conference proceedings in *italics* are not included in printed proceedings.

## FLUID MECHANICS

1

<b>Wind Loads on Cyclists Due to Passing Vehicles.....</b>	2
William Lubitz and Bryan Rubie	
<b>Numerical Investigations of Aerodynamic Noise Due to Flow Past a Bluff Body.....</b>	8
Sultan Alqash and Kamran Behdinan	
<b>Vibration Analysis of a Double Circular Pzt Actuator for a Valveless Micropump.....</b>	13
Behzad Parsi, Lihong Zhang and Vlastimil Masek	
<b>Microfluidic Platform for Studying Biofilm Formation of Oil-Degrading Bacteria.....</b>	19
Saeed Rismani Yazdi, Corey Stevens, Peter Davies and Carlos Escobedo	
<b>Pneumatic Pressure Control Droplet Microfluidic System: an Open-Source Droplet Microfluidic System.....</b>	24
Run Ze Gao, Marie Hebert, Carolyn L. Ren	
<b>Drag Reduction and Heating.....</b>	28
Jerzy M Flöryan, S Shadman and M.Z. Hossain	
<b>A Comparison Between Cyclone Separator Efficiency Enhancement Using Ferrous Powder and Additional Tangential Chamber.....</b>	32
Walid Mazyani, Ali Ahmadi and Mina Hoofar	
<b>Changes in The Leidenfrost Transition Point During the Evaporation of Water and N-Heptane Droplets on Hot, Porous Stainless Steel Surfaces.....</b>	35
Nick Lipson and Sanjeev Chandra	
<b>Computational Fluid Dynamics Simulations of Flow in the Renal Arteries After Stent Graft Implantation.....</b>	40
Tianyi Xia, Matthew Doyle, Thomas Forbes and Cristina Amon	
<b>Numerical Simulation of an Over-Expanded Supersonic Nozzle Flow.....</b>	45
Faisal Al Qurooni, Ali Vakil, Ehab Elsaadawy and Sheldon Green	
<b>Motion of Pigments in Thin Paint Films.....</b>	55
Marina Curak, Nazli Saranjam and Sanjeev Chandra	
<b>Particle Image Velocimetry Data Processing on a GPU Cluster.....</b>	59
Cameron Dallas and Pierre Sullivan	
<b>A Droplet Deformation and Fragmentation in a High Speed Air Jet.....</b>	62
Maryam Medghalchi and Nasser Ashgriz	
<b>Dynamics of a Free Pitching Flexible Cantilever Naca0012 Airfoil at Transitional Reynolds Numbers.....</b>	66
Crystal Itwar Barrett, Dr. Dominique Poirel and Dr. Asad Asghar	
<i>The Evaluation of a Free-Flow Electrophoresis Device with a Velocity Gradient for Enhanced Protein Fractionation</i>	
Matthew Courtney, Tomasz Glawdel and Carolyn Ren	
<b>A Prediction Tool for Spatially Decaying Freestream Turbulence.....</b>	71
Dwaipayan Sarkar and Eric Savory	
<b>Water Droplet Impact And Spreading on a Narrow Gap.....</b>	77
Dr. Jordan Bouchard and Sanjeev Chandra	

<b>Flow Over a Wall-Mounted Finite-Length Square Cylinder.....</b>	81
Junting Chen, Ram Balachandar and Ronald Barron	
<b>Piercing a Liquid Droplet by A Gas Jet.....</b>	84
Maryam Ebrahimiazar, Amirreza Amighi and Nasser Ashgriz	
<b>Shear Layer Instabilities in a Counter-Flowing Wall Jet.....</b>	89
Sachin Sharma, Vimaldoss Jesudhas, Ram Balachandar and Ron Barron	
<b>An Immersed-Boundary (IB)-Based 3D Tornado Model and its Application.....</b>	93
Xixiong Guo and Jun Cao	
<b>A Model to Predict the Residual Layer Thickness in the Injection Molding Process.....</b>	98
Roozbeh Mollaabbasi, Ehsan Behzadfar and Seyed Mohammad Taghavi	
<b>An Experimental Study of Yield Stress Fluid Displacement Flows in a Moving Annulus.....</b>	102
Amin Amiri, Roozbeh Mollaabbasi, Faïçal Larachi and Seyed Mohammad Taghavi	
<b>Modeling the Effect of Produced Water on Asphaltene Deposition in a Production Tubing Using Population Balance.....</b>	107
Roozbeh Mollaabbasi, Dmitry Eskin and Seyed Mohammad Taghavi	
<b>Gust Response of a Two-Dimensional Nonlinear Wing.....</b>	112
Xiaoyang Zhang, Mojtaba Kheiri and Wen-Fang Xie	
<b>A Multi-Color Technique for Three-Dimensional Flow Characterization.....</b>	117
Kadeem Dennis and Kamran Siddiqui	
<b>Estimation of Shock Stand-Off Distance Using the Curved Shock Theory and its Validation via Numerical Modelling.....</b>	122
Zelalem Arega Worku, Evgeny Timofeev and Sannu Molder	
<b>An Experimental and Theoretical Investigation into Airflow Through Air Box of a Potato-Rock Separator.....</b>	128
Prabir Basu, Jacob Melvin Bobby Sagayaraj, Akash Kulshreshtha and Lyle Gauthier	

## MECHATRONICS, ROBOTICS AND CONTROL

134

<b>Effect of Photoacoustic Radar Chirp Parameters on Profilometric Information.....</b>	135
Zuwen Sun and Natalie Baddour	
<i>Using Visual Feedback Assisted Active Control to Investigate the Hydrodynamic Resistance of Nanoliter-sized Droplets in a Microchannel</i>	
Marie Hébert, Jan Huissoon and Carolyn Ren	
<b>Bearing Fault Signature Extraction Under Time-Varying Speed Conditions via Oscillatory Behavior-Based Signal Decomposition (OBSD).....</b>	139
Huan Huang, Natalie Baddour and Miang Liang	
<b>Optimization of Interaural Intensity Difference Based Binaural Sonar Sensing System for Object Detection.....</b>	144
Payman Rajai and Mohammed Jalal Ahamed	
<b>Design of Electronic Stability Control (ESC) Systems for Car-Trailer Combinations.....</b>	148
Mutaz Keldani and Yuping He	
<b>Dry Surface Micromanipulation Using an Untethered and Magnetic Microrobot.....</b>	153
Omid Youssefi and Eric Diller	
<b>Adaptive Yaw Control of Three-Axle Road Vehicles Based on Mass, Yaw Inertia and CG Position Identification.....</b>	158
Yubiao Zhang, Ami Woo, Baris Fidan and Amir Khajepour	

<b>Discrete 2D Fourier Transform in Polar Coordinates.....</b>	164
Xueyang Yao and Natalie Baddour	
<b>Sensor Filtering and Position Tracking of a Simulated Planar Bipedal Robot.....</b>	169
Stefano Rossi and Stephen Andrew Gadsden	
<b>Modeling and Estimation of Reaction Constants in Hydrogen Peroxide Deterioration Reactions.....</b>	175
Hung Yi Chiang, Andrei Buin, Faraz Ahmadpour and Stephen Andrew Gadsden	
<b>Online Tuning Rule Based Adaptive Speed Control Algorithm for DC Motors Using Recursive Least Squares with Forgetting.....</b>	181
Kwang-Seok Oh and Jaho Seo	
<b>Modeling of Structural and Environmental Effects on Microelectromechanical (MEMS) Vibratory Gyroscopes.....</b>	186
Md. Kaes, D.S-K Ting and Mohammed Jalal Ahamed	
<b>Lagrangian, Hamiltonian, and Energy-Based Control for Space Tethered System.....</b>	191
Junjie Kang and Zheng Hong Zhu	
<i>Piezoresistive chopped carbon fiber/polydimethylsiloxane composite yarns for deformation sensing in textile fabrics</i>	
Hossein Montazerian, Abbas S. Milani and Mina Hoofar	
<b>Direct Switching Position Control Algorithms For Pneumatic Actuators Using On/Off Solenoid Valves.....</b>	197
Yile Zhang and Gary M. Bone	
<b>Design and Simulation of the First Joint for a Prospective 5 Degrees of Freedom Manipulator With MR Actuators.....</b>	202
Sergey Pisetskiy and Mehrdad Kermani	
<b>Comparative Analysis of Optitrack Motion Capture Systems.....</b>	209
Joshua Furtado, Hugh Liu, Gilbert Lai, Herve Lacheray and Jason Desouza-Coelho	
<b>Impact Force Reduction Strategies to Achieve Safer Human-Robot Collisions.....</b>	214
Behrad Rouzbeh and Gary M. Bone	
<b>Estimation and Control of a Double-Inverted Pendulum.....</b>	220
Bowen Xu, You Lyu and Stephen Andrew Gadsden	
<b>Comparison of Sliding Mode Controller and State Feedback Controller Having Linear Quadratic Regulator (LQR) on a Two-Wheel Inverted Pendulum Robot: Design and Experiments.....</b>	225
Mikail S. Arani, Hamid Ebrahimi Orimi, Wen-Fang Xie and Henry Hong	
<b>Robust Cooperative Close Formation Flight Control Of Multiple Unmanned Aerial Vehicles.....</b>	230
Qingrui Zhang and Hugh H. T. Liu	
<i>A Decentralized Model Reference Adaptive Controller for Modular Reconfigurable Robots</i>	
Gokhan Gungor, William Melek and Baris Fidan	
<b>Propeller Performance in Presence of Freestream.....</b>	235
Mojtaba Hedayatpour, Mehran Mehrandezh and Farrokh Janabi-Sharifi	

## ADVANCED ENERGY SYSTEMS

240

<b>Temperature Measurements of N-Heptane Injection and Combustion in the Ignition Quality Tester (IQT™).....</b>	241
Osama Hmood, Edgar Matida, Dave Gardiner, Luc Menard, Omar Ramadan, Aaron Wilcox and Gary Webster	
<b>A New Mechanical Band Pass Filter Design for Energy Harvesting.....</b>	246
Alireza Keshmiri and Nan Wu	

<b>Analysis of Thermal Losses in Air-Water Interfacial Solar Heating Systems.....</b>	251
Shuzhe Wang and Paul O'Brien	
<b>Inlet Channel Effects on Archimedes Screw Generators.....</b>	256
Adil Khan, Scott Simmons, Murray Lyons and William Lubitz	
<b>Investigation of Short-Side-Chain Ionomer and Membrane for Proton Exchange Membrane Fuel Cells.....</b>	261
Samaneh Shahgaldi, Adnan Ozden and Xianguo Li	
<i>Optimization of Advanced Space Propulsion Technique: Solar Sail</i>	
<i>Ujjwal Grover and G. Vidya Sagar</i>	
<b>Thermal Management for Efficient Fast Refill of Compressed Natural Gas.....</b>	267
Aiqing Lan, Ri Li and Joshua Brinkerhoff	
<b>Energy Benefits of Integrating Transportation Energy with a Net Zero Energy Solar Building Using Captured Waste Hydrogen from Electrochemical Plants and Bio-Gas from Various Bio-Gasification Processes.....</b>	272
Shahryar Garmsiri and Marc A. Rosen	
<b>Predicting the Consumption Speed of a Premixed Flame Subjected to an Unsteady Stretch Rate.....</b>	278
Meysam Sahafzadeh, Larry Kostiuk and Seth Dworkin	
<b>Wind Turbine Wake Effect Visualization and Lidar Measurement Techniques.....</b>	283
Michael Mckinnon and David Johnson	
<b>Polymeric Triboelectric Nanogenerator: Effects of Polymer Type, Geometry, and Porosity on Triboelectrification.....</b>	287
Hossein Abdoli and Siu N. Leung	
<b>Effects of Steam Injection on the Performance of Natural Gas Combined Cycle Power Generation System.....</b>	292
Nitin Varia, Dipal Patel, Bale Reddy and Tangellapalli Srinivas	
<b>Numerical Simulation of Gas-Liquid Phenomena in the Cathode of a Stirred Tank Reactor Proton Exchange Membrane Fuel Cell.....</b>	296
Xichen Wang, Biao Zhou and Mengcheng Jiang	
<b>Gas-Liquid Phenomena with Dynamic Contact Angles in The Cathode of a Parallel Proton Exchange Membrane Fuel Cell.....</b>	300
Xichen Wang, Biao Zhou and Mengcheng Jiang	
<b>Synthesis of Diamond-Like Carbon by PECVD on Different Substrates for Fuel Cell Applications.....</b>	304
Ibrahim Alaefour, Samaneh Shahgaldi, Jian Zhao and Xianguo Li	
<b>Effects of Oxyfuel Combustion on The Performance of Natural Gas Combined Cycle Power Generation System.....</b>	308
Nitin Varia, Dipal Patel, Bale Reddy and Tangellapalli Srinivas	
<b>Advanced Exergy Analysis of LiCl-H<sub>2</sub>O Absorption Air Conditioning System.....</b>	311
Julia Aman, Paul Henshaw and David S-K Ting	
<b>State of Charge and Parameter Estimation of Electric Vehicle Batteries.....</b>	317
Richard Bustos, Abu Raihan Mohammad Siddique, Tarajit Cheema, Stephen Andrew Gadsden and Shohel Mahmud	
<b>Optimal Charging of Li-Ion Batteries Based on an Electrolyte Enhanced Single Particle Model.....</b>	323
Xianke Lin, Xiaoguang Hao, Zhenyu Liu and Weiqiang Jia	
<b>3D Numerical Study of Hill Mounted VAWT.....</b>	328
Belkacem Belabes and Marius Paraschivoiu	

<b>The Effect of Nanoparticle Concentration on MQL Performance When Machining Ti-6Al-4V Titanium Alloy.....</b>	335
Abdelkrem Eltaggaz and Ibrahim Deiab	
<b>Multi-Objective Optimization During Machining Ti-6Al-4V Using Nano-Fluids.....</b>	339
Hussien Hegab, Waleed Abdelfattah, Shahryar Rahnamayan, Atef Mohany and Hossam Kishawy	
<b>Comparison of Wc-10Co-4Cr Coatings Properties Produced by HVOF and HVOLF Processes for Application in Petrochemical Industry.....</b>	345
Anas Atieh, Abdulaziz Alhazaa and Rohit Upadhyaya	
<b>Compressive Instabilities in Metal-Coated Polymer Microtrusses.....</b>	349
Bharat Bhaga and Craig Steeves	
<b>Simulating Layup Defects During Tow Steering in Automated Fiber Placement.....</b>	355
Nima Bakhshi and Mehdi Hojjati	
<b>Computational Modelling of Radiofrequency Cardiac Ablation to Study the Effect of Cooling on Lesion Parameters.....</b>	360
Carolyn Berkmortel, Hamed Avari and Eric Savory	
<b>FEM Assisted Observations of Cutting Forces, Temperature and Chip Curling in Oblique Machining.....</b>	365
Salman Pervaiz and Sathish Kannan	
<b>3D Printing of Metallic Structures from a Green Ink.....</b>	371
Chao Xu, Arslane Bouchemit, Gilles L'Espérance, Louis Laberge Lebel and Daniel Therriault	
<b>A Study of the Thermal and Mechanical Properties of Recycled Crosslinked HDPE.....</b>	375
Jardel Nobrega Dos Santos and Raghavan Jayaraman	
<b>Non-Contact Auxiliary Fixture for Better Machining of Thin Flexible Workpiece Using Eddy Currents.....</b>	378
Robinderpal Singh and Ibrahim M. Deiab	
<b>Shaker Vibration Test of Epoxy Composites Reinforced with Pristine and Functionalized Carbon Nanotubes.....</b>	384
Mohammad Rafiee, Fred Nitzsche and Michel Labrosse	
<b>The Effect of High Strain Rate on the Piezo-Resistance of Polydimethylsiloxane with Carbon Nanotubes .....</b>	388
Farouk Wahsh and Aleksander Czekanski	
<b>Design of Hard Compaction Rollers for Automated Fiber Placement on Complex Mandrel Geometries.....</b>	392
Tom Trung Zacchia, Farjad Shadmehri, Jeffrey Fortin-Simpson and Suong Van Hoa	
<b>The Effect of Minimum Quantity Lubrication on the FSW Process Performance.....</b>	396
Wisam Al-Wajid, Ibrahim Deiab and Fantahun Defersha	
<b>Review Paper On Digital Manufacturing &amp; Design.....</b>	400
Mukhtiar Singh	

<b>A Novel Finite Strain Visco-Hyperelasticity Based Constitutive Model for Elastomers.....</b>	408
Rohan Thakkar and Aleksander Czekanski	
<b>Modal Participation Factors and their Potential Applications in Aerospace: A Review.....</b>	412

## STUDENT PAPER COMPETITION

545

<b>Assessment of Aliphatic Based Soot Inception in Laminar Diffusion Flames.....</b>	546
Nemanja Ceranic and Seth Dworkin	
<b>Glass Micro-Cutting by Spark Assisted Chemical Engraving.....</b>	551
Lucas A. Hof and Rolf Wuthrich	
<b>A Finite Element Model to Study the Effect of Porosity Location on the Elastic Modulus of a Cantilever Beam.....</b>	555
Stephen Handrigan and Sam Nakhla	
<b>Microfluidic Method of Viscosity Measurement in Propane-Saturated Bitumen.....</b>	561
Mira Kim, Nader Mosavat and David Sinton	
<b>Effect of Body Forces Due to Aircraft Acceleration on Ventilation Airflow and Contaminant Dispersion in Passenger Aircraft Cabins.....</b>	566
Hossam A. Elmaghraby, Yi Wai Chiang and Amir A. Aliabadi	
<b>Quantitative Natural Gas Discrimination for Pipeline Leak Detection Through Time-Series Analysis of an MOS Sensor Response.....</b>	576
Matthew Barriault, Mahyar Mohaghegh Montazeri, Allen O'brien, Homayoun Najjaran and Mina Hoofar	
<b>The Influence of Powder Size and Packing Density on the Temperature Distribution in Selective Laser Melting.....</b>	581
Diego Augusto de Moraes and Aleksander Czekanski	
<b>Experimental Results and Proposed Electromechanical Model for Vibrational Communication in Mining and Oil-Gas Drill Strings.....</b>	585
Md Shahriar Islam, Nathan Peter and Travis Wiens	
<b>Investigation into The Influence of Fused Deposition Modeling (FDM) Process Parameters on the Thermal Properties of 3D-Printed Parts.....</b>	590
Ahmed Elkholly and Roger Kempers	
<b>Sonification of Flow Instabilities in CFD Aneurysm Models .....</b>	597
Daniel E. MacDonald, Thangam Natarajan, Richard C. Windeyer, Peter W. Coppin and David A. Steinman	

## HEAT TRANSFER

602

<b>Droplet Impact, Spreading And Freezing on Metallic Surfaces of Varying Wettability.....</b>	603
Yuntao Pan, Kewei Shi, Xili Duan and Greg Naterer	

<b>Preparation and Properties of Nanoparticle-Enhanced Composite Phase Change Material with Ceramic Porous Media.....</b>	608
Runfeng Li, Yang Zhou and Xili Duan	
<b>Effect of Dispersing Copper Oxide Nanoparticles to RT-35 Filled Circular Thermal Energy Storage System.....</b>	613
Soroush Ebadi, Mohammadhossein Hajiyani, Syeda Tasnim, Amir Abbas Aliabadi and Shohel Mahmud	
<b>Experimental Investigation of Ice Accretion on Horizontal Axis Wind Turbines.....</b>	620
Mustafa Elhajare, Kevin Pope and Xili Duan	
<b>Testing and Analysis of Freezing Phenomenon in Conventional Carbon Steel Pipes.....</b>	623
Milad Rezvani Rad, Rick Marsden and André McDonald	
<b>A New Three-Layer Model for Horizontal Slurry Flow.....</b>	629
Alireza Sarraf Shirazi and Ian Frigaard	
<b>Adsorbent-Adsorbate Pairs for Solar Thermal Energy Storage in Residential Heating Applications: A Comparative Study.....</b>	636
Kapil Narwal, Roger Kempers and Paul O'Brien	
<b>Thermal Management of Electrical and Electronic Systems Using PCM.....</b>	643
Yazeed Alomair, Muath Alomair, Syeda Tasnim, Hussien Abdullah and Shohel Mahmud	
<b>Investigation of Latent Heat Thermal Energy Storage System for Airconditioning Applications.....</b>	647
Muath Alomair, Yazeed Alomair, Syeda Tasnim, Hussein Abdullah and Shohel Mahmud	
<b>Development of Absorbents with High Contact Area for Applications in Desiccant Coated Heat Exchanger.....</b>	652
Yunxi Li, Benwei Li and Zhigang Wang	
<b>Effectiveness-NTU Relationships of Parallel-Plate Moving Bed Heat Exchangers.....</b>	656
Pedro Isaza and Markus Bussmann	
<b>Numerical Simulation of Fluid Flow and Heat Transfer of the Supercritical Water in Different Fuel Rod Channels.....</b>	663
Huirui Han and Chao Zhang	
<b>Feasibility Study of Synthetic Oil Based Nanofluids for Use in Thermal Oil Heaters.....</b>	668
Ian Mullett, Xili Duan, Zongming Wang and Yishan Li	
<b>Effects of High Pressure Coolant on Machining Temperature and Machinability of AISI 304 Stainless Steel.....</b>	673
Yassmin Seid Ahmed and Stephen Clarence Veldhuis	
<b>Thermal and Hydraulic Performance of a Novel Evaporator Coil for Refrigeration Systems.....</b>	678
Hossam Elkady, Mostafa Elsharqawy, Sameh Saad and Kazi Ahmed	
<b>One-Dimensional Fully Coupled Heat and Moisture Transfer Using the Finite Volume Method.....</b>	683
Lam Dang, Wey Leong and Alan Fung	
<b>Thermal Management of PQ Transformer for a Passively Cooled Power Module.....</b>	690
Anshuman Dey, Navid Shafiei, Rahul Khandekar, Kevin Lau, Wilson Eberle and Ri Li	
<b>Analytical Heat Conduction Model of Annular Composite Fins.....</b>	696
Chen Feng, Subramaniam Yugeswaran, Michael Gibbons and Sanjeev Chandra	
<b>Continuous Fiber Polymer Composites (CFPCS) for Thermal Applications.....</b>	701
Yehia Elsayed, Ahmed Elkholy, Garrett Melenka and Roger Kempers	
<b>Thermal Conductivity of Beta-Arsenene Under Biaxial Tensile Strain: A First Principle Study.....</b>	707
Armin Taheri, Carlos Da Silva and Cristina Amon	
<b>The Design of Infrared Mirror Coatings for the Enhanced Performance of Incandescent Lighting.....</b>	713
Mohsen Rostami, Nima Talebzadeh and Paul O'Brien	

<b>Composite Heat Sink LED Cooling.....</b>	718
Michael Gibbons, Chen Feng and Sanjeev Chandra	

## BIOMECHANICS AND BIOMEDICAL ENGINEERING

721

<b>Integration and Simulation of Microfluidic Platforms and Terahertz Time-Domain Spectroscopy Systems.....</b>	722
Rasha Al-Hujazy and Christopher Collier	
<b>In Pursuit of an Optimum Optical Imaging Technology for Early Detection of Dental Caries.....</b>	726
Elhaz Baradaran Shokouhi and Nima Tabatabaei	
<b>Helical Spring Design Optimization for Endoscopic Devices Using a Design-Of-Experiments and Response Surface Approach.....</b>	730
Hamid Ebrahimi, Albert Yee and Cari Whyne	
<b>Focused Ultrasound Surgery of Breast Cancer: A Computational Study on a Realistic Patient Model.....</b>	734
Moslem Sadeghi-Goughari, Soo Jeon, Toktam Beheshtian and Hyock-Ju Kwon	
<b>Controlled Deflection Of Diamagnetic Biocompatible Aqueous Droplets.....</b>	738
Stephanie Buryk-Iggers, Jennifer Kieda and Scott Tsai	
<b>Characterization of the Electrodes of DEP-Based Micro-Separator.....</b>	739
Arash Dalili, Erfan Taatizadeh and Mina Hoorfar

# FLUID MECHANICS

# Wind Loads on Cyclists due to Passing Vehicles

William David Lubitz\*, Bryan Rubie

School of Engineering  
University of Guelph  
Guelph, Canada

\*wlubitz@uoguelph.ca

**Abstract**— Cyclists on rural highways travel at much lower speeds than motor vehicles. There is concern that unsteady aerodynamic loads produced as a large vehicle passes a cyclist can cause instability and loss of control, potentially initiating a traumatic accident for the cyclist. Large lateral spacing can be provided between cyclists and motor vehicles using wider paved shoulders, however this adds cost to road construction, so there is a need to balance the needs of cyclist safety and paved shoulder width. Understanding the nature of the unsteady wind loads experienced by a cyclist when a motor vehicle passes is a necessary first step in determining optimum paved shoulder widths. An experiment was conducted that directly measured the lateral forces on a full scale model cyclist, static pressure and wind speed as motor vehicles passed a cyclist. As a motor vehicle passed, the cyclist first experienced a large transient lateral forcing, followed by lower magnitude forcing. The magnitude of the force was well correlated to the measured static pressure, while induced transient wind speeds were relatively low (on the order of 1 m/s). As would be expected, the magnitude of forcing increases with vehicle size and speed, and decreases as lateral spacing between cyclist and vehicle increases. The results were used to develop an expression to predict tipping moment as a function of passing vehicle characteristics and offset distance.

**Keywords**-bicycle; wind load; aerodynamics; passing vehicles

## I. INTRODUCTION

The passing of a large vehicle like a truck can be an unsettling experience for a cyclist travelling on a rural highway. The wakes of large vehicles produce aerodynamic forces on cyclists and other road-side objects. There is concern that unsteady lateral forces on a cyclist produced by a large passing vehicle could cause a cyclist to become unstable and lose control, potentially initiating a traumatic accident.

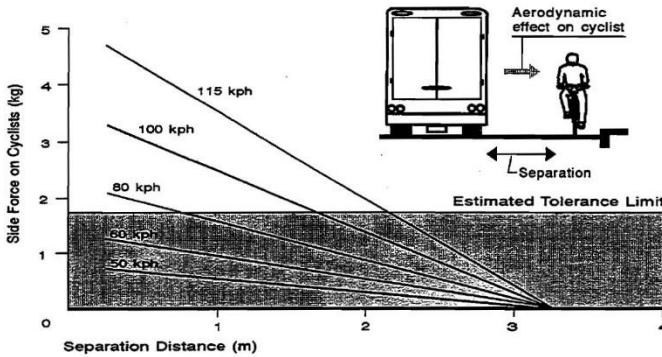

If available, cyclists on rural highways generally utilize paved shoulders for travel, allowing them to travel outside the regular travel lane. Wider paved shoulders allow cyclists to travel with greater lateral separation from large vehicles, reducing the aerodynamic forces experienced by a cyclist induced by passing vehicles. However, shoulder paving cost increases with width, and the safety benefits of increased shoulder paving width must be balanced with costs [1]. Currently, information is still needed

on minimum safe lateral spacing between the travel paths of bicycles and large vehicles on rural highways. Minimum safe spacing depends on the aerodynamic forces induced on a cyclist by large vehicles passing at highway speeds, and the maximum such forces that a cyclist can experience and remain stable [2].

There is little quantitative information available on the forces induced on cyclists by wakes generated by passing large vehicles. Several publications on bicycle infrastructure design [3-5] reproduce the same plot of lateral aerodynamic “force” exerted on a cyclist by a passing truck as a function of speed and separation distance (Fig. 1). A 1976 US government report [6] was the earliest incarnation of this plot that was found. No information on the source of the plot was provided except a note that it was from “prior research.”

It is apparent Figure 1 is at best an idealization. While force is approximately proportional to the square of the vehicle velocity, the linear relationship between separation distance and force seems physically unlikely. The reporting of a force in units of mass (kg) is worrisome (note that lbs was used by Smith [6]), and it is unclear if average or peak lateral forces are reported. No guidance is given on how the estimated tolerance limit of 1.73 kg (17 N) was derived. Despite these limitations, the 17 N lateral force limit and Fig. 1 appear to be the current accepted standard in the bikeway design literature for aerodynamic forces on cyclists due to passing vehicles. For example, Llorca et al. [2] recently applied this same linear relationship with zero effect at 3.0 m in their analysis of motor vehicles passing cyclists.

Only one prior study was located that attempted to directly measure the wind loads that would be induced on a cyclist (as opposed to other object) by a passing vehicle [7]. Two propeller anemometers were placed at the roadside, and the induced wind was measured as a heavy goods truck was driven past at a range of speeds and offset distances. However, the impact on a cyclist was estimated using assumptions of cyclist area and drag coefficient, rather than by a more direct form of measurement. They observed that as the truck passed, a wind speed “pulse” occurred in the lateral direction that was first away from, and then towards, the direction of the vehicle. As vehicle speed increased, the amplitude of this pulse increased while the time duration decreased, and it was noted that the rapid change in wind direction was likely to be particularly destabilizing.

**Figure 1. Aerodynamic force on a cyclist due to a passing large truck. From [4].**

Research has been conducted in the similar areas of wind loads caused by large trucks on overhead sign bridges [8], temporary roadside signs and barriers [9] and pedestrians [10]. Recently, Lichtenegger and Ruck [11] experimentally measured forces on a range of plates beside and above passing vehicles ranging from passenger cars to large buses and trucks (lorries). The winds induced on railway station platforms due to passing express trains have also been studied [12, 13].

While these studies encompass a range of situations and investigative methods (field measurements, simulations, theory), they agree on the features of the aerodynamic forcing experienced by a stationary or relatively slow moving object (such as a bicycle) being passed closely by a high-speed vehicle. The most concerning effect of a passing large vehicle is an initial sharp pulse of increased pressure, which occurs over a time period of a few tenths of seconds, and is followed immediately by a period of decreased pressure. This is accompanied by wind speed gusts on the order of 1 m/s, also over a time period of order 0.1 s. The magnitude of these pressures and gusts increases with frontal area of the passing vehicle and decreases with vehicle streamlining. The initial pressure pulse is followed by increased turbulence and a return to pressures nearer ambient. The passage of large gaps in vehicles (e.g. between truck cab and trailer) and the blunt tail of a vehicle also induce pulses of pressure and wind speed variation from ambient levels, although these are typically lower than those associated with the passing of the front of the vehicle. An example of the transient forcing, pressure and air speed from the experiments for this project is shown later in Fig. 4.

There are a few important differences between the case of lateral forcing on a moving cyclist that could cause loss of balance, and forcing of stationary objects such as signs and walls. First, while all prior literature has focused on forces on cyclists or other surfaces, arguably the most important phenomena from the passing of a large vehicle would be not a transient lateral force on the cyclist, but rather the resulting transient lateral moment around the contact line between the wheels and the road surface. A lateral force exerted only a centimeter above the ground would do much less to unbalance a traveling cyclist than the same force exerted at the level of the cyclists shoulders or head (provided the wheels do not slide sideways, which given the forces we will discuss below is a reasonable assumption). In the experiments and discussion that follow, it will be lateral moments that are

measured and considered, rather than just lateral force, although at times “force” will be used because moment will be the force measured by a load cell multiplied by a known moment arm.

The time periods of transient forcing of the cyclist are also very important. Unlike signs or walls, cyclists actively respond to transient forcing, by adjusting steering and body position, in order to maintain a balanced riding position. A cyclist could easily respond to a large force (or moment) being applied smoothly and gradually over a long period of time. However, the same forcing applied in a few milliseconds could cause an immediate instability that would be very difficult to correct and could lead to a loss of balance. Unlike for fixed objects, forcing timing matters, as does the nature of the cyclist’s response.

Bicycle-specific measurements of the aerodynamic forces induced by large passing vehicles are still needed. It is not feasible to calculate highly accurate wind and pressure forces on a bicycle and rider because they are a geometrically complex bluff-body, unlike the uniform flat plate or cylindrical tubes typical of highway signs and sign bridges, immersed in a highly transient flow. While there is a large body of research on the aerodynamics of both cyclists and motor vehicles, most has been conducted with the goal of reducing the steady state aerodynamic drag of the vehicle itself. These studies don’t address crosswinds or unsteady flow, and are of little use for this research. Also, studies that do investigate crosswinds are generally not directly applicable. For example, Moulton et al. [14] investigated the crosswind loads on a streamlined bicycle, and Tew and Sayers [15] measured crosswind effects on bicycle wheels. However, different forces due to crosswind effects would be expected for a conventional upright non-streamlined bicycle (which is essentially a collection of bluff bodies), rather than a rotating wheel or streamlined human powered vehicle. The authors could find no direct measurements of lateral aerodynamic forces on a non-racing cyclist due to transient events such as passage of a large vehicle.

Given the temporal and spatial transience of the flow, this situation cannot be reliably modelled using CFD tools unless field data is available to validate the CFD simulations. The geometry of an unstreamlined bicycle and rider is quite complex, and it is not feasible to directly measure the induced pressures using pressure taps. Therefore, measuring the forces induced on a full size bicycle was selected as the most feasible approach. This research project sought to address this lack of fundamental data by directly measuring the lateral force caused by passing vehicles on upright, diamond frame, single rider, non-streamlined bicycles. It should be noted that the experiment documented below was a relatively modest, resource-constrained affair. While some conclusions are provided to some of the questions and issues raised above, significant scope remains for additional experimental study.

## II. METHODOLOGY

A stationary instrumented bicycle with full scale model rider, three-dimensional sonic anemometer (RM Young 81000) and omni-directional static pressure sensor were placed in a line adjacent to the vehicle travel path in Fig. 2. The test vehicle would first pass the model cyclist, then the pressure probe, and last the sonic anemometer. Horizontal spacing was 1.20 m between the

centers of the anemometer and pressure probe, and 1.00 m between the pressure probe center and the leading edge of the front bicycle tire. The anemometer and pressure probe were mounted on vertical poles at a sampling height of 1.15 m. Lateral moment on the bicycle, static pressure and three-dimensional wind speed were measured simultaneously as vehicles passed.

Static pressure was measured using a parallel plate two-port static pressure probe like that of Robertson [16]. A Setra 265 differential pressure transducer was mounted immediately below the pressure probe. The reference side of the transducer was connected to a rigid tank housed within an insulated container (the white box in Fig. 2) that included a small rigid syringe to allow setting of the reference pressure, allowing recording of both positive and negative pressures relative to ambient pressure.

Characteristics of the truck and the model bicyclist are summarized in Table 1. Projected areas and centroids were determined by analysis of photographs taken specifically for measurement purposes using a long telephoto lens to minimize parallax errors. ImageJ (<https://imagej.nih.gov/ij/>) was used for the actual image analysis.

All testing was done on a closed course. Cones and pavement markings located prior to the bicycle and sensors allowed the vehicle driver to laterally position the vehicle as it passed the instruments. Two optical switches placed on the roadway 10 m apart adjacent to the instruments directly measured the speed of the passing vehicle. The distance between vehicle path and the line of instruments was measured directly by wetting the roadway before the vehicle passed, and measuring the distance to the tire tracks left by the vehicle immediately after it passed. The method was accurate to  $\pm 1$  cm.

The bicycle wheels were set in a low-profile heavy aluminum channel, and the tires were inflated to a very high pressure to produce minimal resistance to rotation in the lateral direction. The bicycle brakes were permanently set to prevent forward or backward rolling of the bicycle. A dummy rider was constructed incorporating a solid wood, metal and plastic frame, plus additional packing material inside a full length 8 mm neoprene wetsuit. Boots, a foam head and cycling helmet and diving gloves were attached rigidly to the body frame at the locations of feet, head and hands. The dummy was rigidly affixed to the bicycle at the handlebars and pedals, positioned in a semi-upright riding position. The dimensions of the combination bicycle and rider are also given in Table 1.

Lateral force on the model cyclist was directly measured using a custom-built load cell. A temperature-compensating load cell was constructed by placing four surface-mount strain gauges wired in a full Wheatstone bridge on the surface of a thin wall aluminum tube. Spherical rod-end joints were placed at each end of the tube. The tube was oriented horizontally with one end connected to the downtube of the bicycle above the pedals at a height of 0.59 m above the ground. The other end was affixed to a heavy low-profile rigid frame. The load cell provided the only lateral support of the bicycle. Before each set of tests the load cell was calibrated in-situ using precise weights and a pulley system to apply tensile and compressive lateral forces up to 15 N. The

Wheatstone bridge was connected via shielded cables to a custom-built amplifier.

All instrumentation was connected to a netbook computer using a National Instruments USB-6008 data acquisition device (for switches, barometer, load cell, lateral component of wind speed) and serial-to-USB converter (all anemometer channels). A custom-written LabView application simultaneously collected and stored measurements of optical switch output, pressure, force and lateral wind speed component at 1000 Hz. Note that the update rate of the anemometer was 32 Hz, meaning that the lateral wind speed is oversampled. Additionally, all channels of anemometer output (three wind speed components and temperature) were recorded at a rate of 32 Hz by recording the anemometer serial output.

**Table 1. Vehicle and model cyclist parameters.**

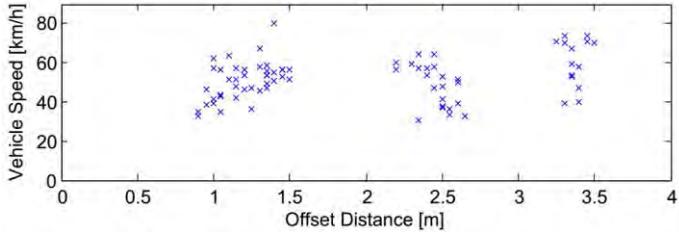

Parameter	Model Bicyclist	Truck
Description	Semi-upright, with helmet, on 26" wheel mountain bike	2001 Dodge Ram, 4 wheel drive, full size pickup truck
Drag Coefficient	0.9 – 1.1 [17]	0.47 [18]
Frontal Area	0.74 m <sup>2</sup>	3.17 m <sup>2</sup>
Overall Height	1.72 m	1.84 m
Overall Length	1.67 m	5.49 m
Side Area	0.71 m <sup>2</sup>	
Centroid Height Above Ground	0.87 m	
Centroid Horizontal Distance from Front	0.94 m	

### III. RESULTS

Data was collected for passes of the truck at a range of offset distances and vehicle speeds, as shown in Fig. 3. Maximum speeds were limited by the need to bring the vehicle up to test speed, settle at that speed, pass through the test area, and decelerate safely. Pressure, wind and loading fluctuations were negligible when the truck passed at a speed of  $U_v$  less than 30 km/h.

**Figure 2. Overview of experimental setup. Vehicles passed on right side, in same direction as cyclist.**

**Figure 3. Test data speed and offset distances.**

Measurements of lateral force, lateral wind speed component and static pressure from a typical run are shown in Figure 4. The data is presented time-offset based on the vehicle speed, so that the three traces represent measurements that would be observed at a single location for any given time.

Lorca et al. [2], and Lichtneger and Ruck [11] suggest that the lateral force  $F$  on a roadside object might be modeled as

$$C_f = 2F/\rho A_v U_v^2 \quad (1)$$

where  $\rho$  is air density,  $A_v$  is frontal area of the passing vehicle and  $U_v$  is the relative velocity of the passing vehicle. The coefficient  $C_f$  is a dimensionless value that accounts for the streamlining and shape of both the passing vehicle and the cyclist. A peak pressure difference coefficient  $C_p$  can be similarly defined as

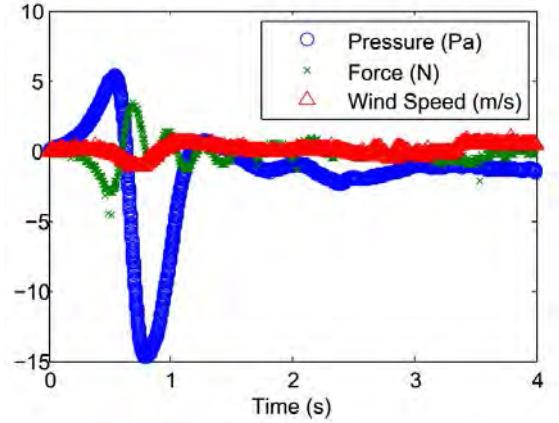

$$C_p = 2P/\rho U_v^2 \quad (2)$$

where  $P$  is  $\rho$  is air density and  $U_v$  is the relative velocity of the passing vehicle. The coefficient  $C_p$  is a dimensionless force coefficient with a similar role to  $C_f$ .

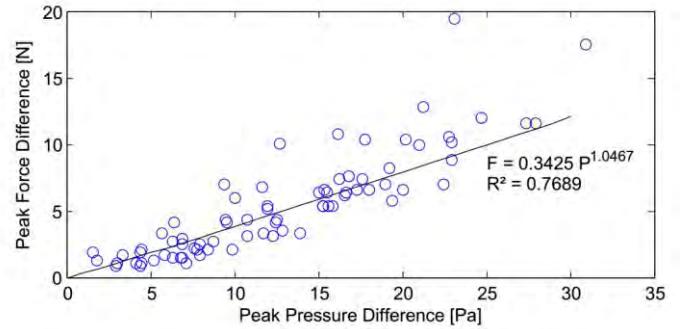

The initial pulse of pressure and air velocity (and resulting transient moment on the cyclist) are larger than any of the fluctuations that followed, both in terms of overall magnitude, and in terms of time rate of change of the quantities. In this study, the magnitude of the difference between the first positive peak and negative “peaks” of pressure, air speed and moment were extracted from the time-series data for each run. (For example, in Fig. 4, the peak differences in pressure, force and wind speed are 20 Pa, 6.4 N and 2.0 m/s, all occurring within the first second.)

Fig. 5 shows the measured peak force difference versus measured peak pressure difference. (While the experiment was configured to measure a torque, all tests had the same moment arm and the load cell itself measures force.) The relationship between the two is approximately linear, within measurement uncertainty. This suggests measurements of pressure, which are simpler experimentally and can be found in the literature (e.g. Lichtneger and Ruck [11] or Sanz-Andrés and Santiago-Prowald [12]) can be used to give reasonable approximations of the side force (or moment) that could be expected on a cyclist.

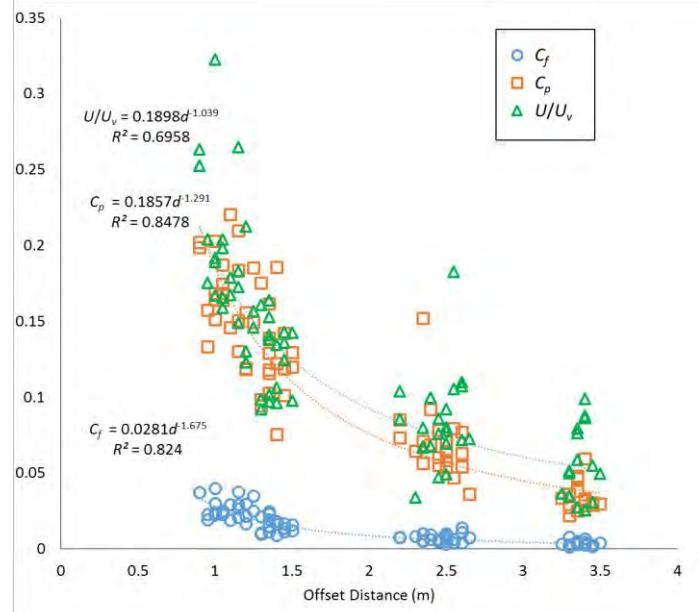

Fig. 6 shows the peak differences of pressure, force and wind speed  $U$  as a function of offset distance. It can be argued that offset distance could be normalized by the square root of the vehicle frontal area, however, verification of this theory was not possible since only a single vehicle was tested.

**Figure 4. Example pressure, load cell force and wind speed magnitude. Vehicle speed 53.3 km/h, offset distance 1.35 m.**

**Figure 5. Peak differences in pressure and force observed for each test case.**

**Figure 6. Measured peak differences versus offset distance.**

Fig. 7 shows an updated version of Fig. 1 based on the experimental measurements presented here. Peak force was assumed to vary with vehicle velocity squared, and the measured force was used with Eqn. 2 and the fit equation for  $C_f$  in Fig. 6. The resulting forces were multiplied by 0.59 m (the experimental moment arm) to get tipping moments, in N·m. This gives a predictive equation for tipping moment  $M$  of

$$M = \frac{1}{2} \rho A_v U_v^2 (0.0281 d^{-1.675}) L \quad (3)$$

where  $L$  is the experimental moment arm (0.59 m) and  $d$  is the offset distance in units of meters.

Although no supporting evidence was found for the 17 N “tolerance limit” reported (and re-reported in the literature) [3-6], here it has been converted to a moment by multiplying by the 0.87 m centroid height of the bike and rider in this experiment (Table 1) and is included in Fig. 7 for comparison purposes. Due to the power law relation used to fit the data, the model shown in Fig. 7 is unrealistic at offset distances less than about 1 m. Since offset distance is measured from vehicle side to the centerline of the cyclist, vehicles passing with offsets much less than 1 m would risk physically contacting the cyclist.

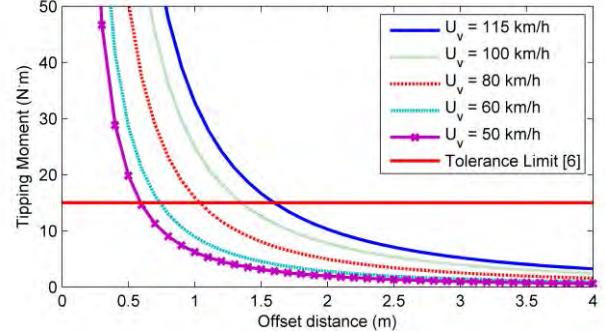

Both experimental results (Fig. 6) and the tipping moment model (Eqn. 3; Fig. 7) suggest that tipping moment decreases asymptotically with offset distance. No supporting evidence was found to support the assumption of no forcing at offset distances greater than 3.0 m shown in Fig. 1. The magnitudes of the experimental forces and moments, and those predicted by the resulting model, were of similar magnitude to those in Fig. 1 and those observed by Lichtneger and Ruck [11] for a small flat surface alongside a roadway at cyclist height.

Finally, readers are cautioned that the uncertainty of Fig. 7 is high, owing to the scatter in the experimental data from which it was derived and the limited nature of these preliminary experiments (e.g. only one test vehicle).

#### IV. CONCLUSIONS

The results of this experimental study suggest that the peak forcing on a bicycle is reasonably well correlated to the peak static pressure pulse (within experimental scatter), and also to the peak wind speed magnitude. This means that (1) measurements of wind speed and/or pressure may be sufficient in future experiments, and (2) extrapolation from studies of similar objects, such as signs and walls near roadways, should likely give representative forcing for bicycles.

The relationship in Fig. 1 appears to be a reasonably practical approximation for general planning. The most notable deficiency is that vehicle size and aerodynamic considerations are not illustrated. Fig. 7 presents a possible improvement to this relationship, however, it is not yet validated. During this study, it became apparent that there is little understanding of what levels and types of transient forcing cyclists can safely compensate for in practice. This would be an interesting and relevant area for future investigation.

**Figure 7. Estimated tipping moments for the cyclist and vehicle from the current study.**

**Abstract**— Landing gears (LG) are primarily designed to support all the loads of an aircraft during landing, taxiing, and taking off. To ease inspection and maintenance, the aerodynamic design is not refined, where many components are exposed to the air flow generating what so-called aeroacoustics noise. To understand the underline physics and investigate both the flow field and its associated acoustic field, a two-dimensional (2D) case of flow past a circular cylinder was simulated using ANSYS Fluent. Two different Reynolds numbers,  $Re$ , 150 and 90,000 were examined. For low  $Re$ , two distinct numerical conditions steady and unsteady flow were simulated and compared to examine the effect of the time dependency on the associated acoustic field. For high  $Re$ , the acoustic field was computed using the built-in Ffowcs William and Hawkings (FW-H) acoustic analogy solver in Fluent. The results show the importance of considering the time variable to extract the corresponding flow data. The far-field noise prediction highly depends on the location of the near-filed data and its associated integral source terms (surface/volume).

**Keywords**-Reynolds number; acoustic analogy; near-field; far-field; pressure fluctuations

## I. INTRODUCTION

The aircraft noise was recognized as an environmental problem in the early 1950s, when the turbo-jet powered aircraft was introduced to the markets. Since then, the aircraft noise issue has been dominated by jet noise, known as propulsive noise. In the early 1970s, aircraft noise was successively reduced after the introduction of the first twin cycle bypass turbofan engines [1]. Due to the noise reduction of the propulsive noise that originates from jet-engines, the airframe itself becomes the major contributor to the overall noise. As a result of decades of research and development into noise reduction, by the year 2000 the aircraft noise level had become 20-30 dB quieter compared to the first generation of turbofan powered aircraft. The US and European communities have set a target to minimize the noise level by 50% near airport areas by 2020 [2]. By 2050, the overall noise level emission of flying aircraft should be further reduced by 65% [3]. When the

aircraft approaches the airport, the engines are almost at low speed which reduces its noise contribution. That yields to put a high portion of the generated noise on the airframe itself. Among the airframe components, the landing gears have been identified as a main source of noise during the approach phase, when they are fully deployed prior to landing for both aircraft types: long range and short range. It has a significant noise level due to its complex structural design that consists of many components with different lengths and sizes.

For a commercial aircraft, the noise generated from the airframe has received much attention in recent years. This has led the Federal Aviation Administration (FAA) to impose strict regulations on the aircraft noise level [4]. All these demands created pressure on industries and academic communities to develop improved techniques for noise reduction and better methods for its prediction. To ease inspection and maintenance, the aerodynamic design is not refined. As a result, many components such as, hydraulic cables, electric wiring, torque links, front and rear braces are exposed to the air flow. Therefore, the flow separation over the LG components constitutes the main noise source mechanism through unsteady wake flow and large-scale vortex instability and deformation [5]. In the literature, there are three distinct approaches to study flow field and associated acoustic field around the LG within certain limitations. Those approaches are experimental, empirical, and numerical. The main difference between flow around landing gears and that around simple geometries, like single or tandem circular cylinders, is the three-dimensionality flow characteristic. For that reason, the experimental studies for the isolated or installed LG system are recommended but too expensive. Thus, the numerical approach becomes an alternative candidate to resolve this issue. Although current computational approaches are infeasible to handle all the turbulence scales that inevitably exist in cases of complex geometry such as a LG, there are some computational fluid dynamic (CFD) approaches that have been utilized to resolve this issue. The most popular methods are Direct Numerical Simulations (DNS), Large-Eddy Simulations (LES), and Reynolds Averaged Navier-Stokes (RANS). Recently, there is a common CFD method known as Detached-Eddy Simulations (DES). The DES approach is a combination of LES and RANS

solvers, the LES takes care of the large-scale separated flow regions, while RANS handles the modeling of the turbulence boundary layer [6].

Any aeroacoustics problem consists of two fields as its name implies fluid dynamics and acoustics, respectively. It is a two-step process: 1) sound generation based on the study of the aerodynamic flow which generates sound/noise sources and then, 2) sound propagation based on the investigation of the acoustic field spreading in a medium at rest that generated from step 1. The Lighthill's acoustic analogy is considered as the first pioneering work in sound generated aerodynamically and is named after Jims Lighthill [7] in 1952. In 1954, he assumed that the turbulent fluctuations of the stream are equivalently represented by a distribution of quadrupole sources in the same volume of the flow. In 1955, Curle [8] modified the Lighthill's analogy to include the effect of solid boundaries. In 1969, Ffowcs Williams and Hawkings [9] considered both the influence of the solid surfaces and the turbulence in arbitrary motion and developed the FW-H analogy. The FW-H analogy is considered as the generalized Lighthill's acoustic analogy which makes it more common and applicable for a wide range of applications. Van Mierlo et al. [10] studied the influence of the main landing gear (MLG) inclination angle on the noise level using ANSYS Fluent. However, they did not include the contribution of the quadrupole sources corresponds to the volume integral due to its high computational cost. Thus, the selection of the surface always coincides with the wall of the bluff body. The same approach was used by Long et al. [11] to study the far-field noise of a simplified nose landing gear (NLG). They noticed that the directivity of the noise is a dipole like source. Another method based on CFD and the FW-H equation with penetrable surface has advanced considerably. For instance, Lockard et al. [12] compared the results and noticed that the noise predicted based on solid surface agreed well with the near-field CFD results, and that noise predicted based on the penetrable surface was highly suspected to be corrupted by the pseudo-sound created at the closing FW-H surface in the wake region. Also, Spalart et al. [13] and Sanders et al. [14] argued that by calculating the noise based only on a solid surface would lead to inaccurate results even at a Mach number as low as 0.115. The results revealed a typical discrepancy of 3 dB compared to the permeable surface.

In this study, since the LG system is too complex and contains multiple bluff bodies, 2D flow past a circular cylinder with two different Re numbers were simulated. This simplified case will pave the road to understand the underlying physics of both flow structure (near-field) as well as its associated noise propagation (far-field). Different turbulent models were examined according with the flow anticipated behavior (laminar/turbulent). The FW-H solver in Fluent was utilized to study the far-field noise prediction.

## II. ACOUSTIC ANALOGY FORMULATIONS

### A. Lighthill Acoustic Analogy

Lighthill formulated a wave equation of acoustic analogy where the source derived by comparing the exact equations of motion of a fluid with the equations of sound propagation in a medium at rest as follows [7],

$$\frac{1}{c_o^2} \frac{\partial^2 \rho'}{\partial t^2} - \nabla^2 \rho' = \frac{\partial^2 T_{ij}}{\partial x_i \partial x_j} \quad (1)$$

$$T_{ij} = \rho v_i v_j + P_{ij} - c_o^2 \rho' \delta_{ij}. \quad (2)$$

where ( $\rho' = \rho - \rho_o$ ) indicates density perturbation,  $T_{ij}$  is the Lighthill's stress tensor,  $P_{ij} = p' \delta_{ij} - \tau_{ij}$  refers to the compressive stress tensor with  $p'$  being the fluctuating pressure and  $\tau_{ij}$  being the total stress tensor equal to  $\sigma_{ij} - p \delta_{ij}$  with  $\sigma_{ij}$  refers to the residual stress tensor. Note that  $v_i$  and  $v_j$  indicate the velocity components in  $x_i$  and  $x_j$  directions, respectively, and  $c_o$  is the speed of sound.

### B. Ffowcs Williams and Hawkings Acoustic Analogy

Curle [8] expanded the Lighthill's analogy considering a rigid surface; after that, Ffowcs Williams and Hawkings further generalized the theory considering a rigid object in arbitrary motion as follows [9],

$$\left( \frac{\partial^2}{\partial t^2} - c_o^2 \frac{\partial^2}{\partial x_i^2} \right) (H(f) \rho') = \frac{\partial^2}{\partial x_i \partial x_j} (T_{ij} H(f)) - \frac{\partial}{\partial x_i} (F_i \delta(f)) + \frac{\partial}{\partial t} (Q \delta(f)) \quad (3)$$

$$F_i = (P_{ij} + \rho v_i (v_j - u_j)) \frac{\partial f}{\partial x_j} \quad (4)$$

$$Q = (\rho_o u_i + \rho (v_i - u_i)) \frac{\partial f}{\partial x_i} \quad (5)$$

Where  $f$  represents the body surface as function of  $f(x, t) = 0$ ; in which  $f < 0$  and  $f > 0$  refer to inside and outside of rigid body, respectively. The right-hand side of (3) is the source terms; the first term shown explicitly in (2) physically means unsteadiness inside the fluid expressed in quadrupole source as Reynolds stress which is called turbulent-induced term, the second term is dipole source due to local fluctuating stresses exerted by the surface on the fluid and third term is monopole source generated by mass-flux fluctuating around the surface. The last two terms are represented in (4) and (5) which are called loading noise and thickness noise, respectively.

The differential form of FW-H shown in (3) can be written in terms of fluctuating pressure based on the following relationship ( $p' = c_o^2 \rho'$ ) which shows the isentropic relation. There are three important functions used in the above equations namely Kronecker delta,  $\delta_{ij}$ , Heaviside,  $H(f)$ , and the derivative of the Heaviside function  $H'(f) = \delta(f)$  is the Dirac delta. The turbulent term associated with the quadrupole source is in volume integration. Hence, the decision of including the contribution of the volumes in fluid around rigid body to

integrate and evaluate the integration kernel is difficult. Thus, it requires a better algorithm/numerical technique to handle the computational cost and memory management. This approach is still under investigation and deserves more developments.

### III. NUMERICAL SET UP

A two-dimensional case of flow past a circular cylinder was simulated using ANSYS Fluent. First, the flow domain was designed using ANSYS Workbench. The computational domain was extended 5 times and 20 times the cylinder of unity diameter,  $D$ , upstream and downstream, respectively. The vertical dimension is  $5D$  equally in both Y-directions from the cylinder center. Then, the domain was meshed using an unstructured method of a triangular. However, close to the cylinder wall the structured mesh with rectangular shape elements were utilized to account for the boundary layer (BL) effect. The total number of cells is 22370. After that, the boundary conditions (B.C's) were assigned within corresponding input values. All the numerical modeling process is shown in Fig. 1(a), (b), and (c) starts from the domain, mesh, and B.C's, respectively, including the values of B.C's as shown in Table I.

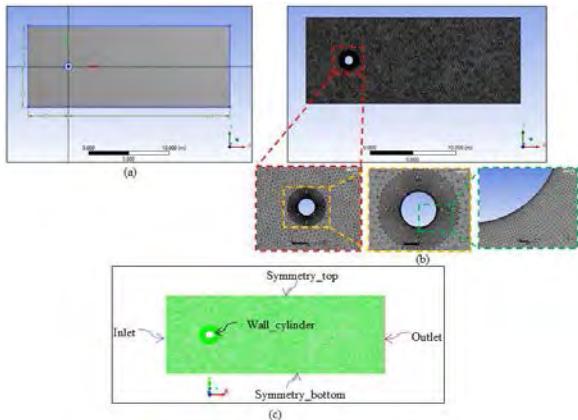

Figure 1. Numerical Modeling: (a) Computational domain, (b) Mesh generation, and (c) Boundary conditions

TABLE I. BOUNDARY CONDITIONS

B.C.	Value	Remarks
Inlet	$V = 1$ [m/s]	They are common for incompressible flows
Outlet	Gauge Pressure = 0 [Pa]	
Wall_cylinder	Stationary wall, $V_{wall} = 0$ [m/s]	With no-slip condition
Symmetry_top	No values needed to be entered	To ensure that flow does not form B.L.
Symmetry_bottom		

Two different Reynolds numbers were examined  $Re=150$  and 90,000. In case of low  $Re$ , two distinct numerical conditions steady and unsteady flow were simulated and compared to examine the effect of the time dependency. For both flow conditions the viscous laminar model was utilized. In case of high  $Re$ , the acoustic field was computed using the built-in FW-H solver available in Fluent. For this case, the same computational domain is utilized, but the DES with a Spalart-Allmaras (one-equation) model is used to capture the turbulent flow.

### IV. RESULTS AND DISCUSSION

The pressure distribution around the cylinder was computed for both cases and validated with analytical as well as experimental data [16] and showed good agreement as shown in Fig. 2. The analytical pressure coefficient,  $C_p=1-4\sin^2\theta$ , with respect to different azimuthal angles around the cylinder ( $0^\circ \leq \theta \leq 180^\circ$ ) depicts the symmetrical pattern of the inviscid flow. This symmetry indicates that the integrated surface pressure force in streamwise direction is zero (i.e., no drag force effect). This is an example of the d'Alembert paradox for inviscid flow past an immersed body. However, the experimental data show completely different flow behavior upstream and downstream the bluff body. It strongly depends on the Reynolds numbers as shown in Fig. 2 below, where both the numerical results of laminar and turbulent successfully reproduce the flow behavior upstream and downstream. For the laminar, the separation occurs at around  $\theta=87^\circ$  which creates a broad wake and very low pressure within large drag coefficient. In contrast, the turbulent flow has a boundary layer that is more resistant which delays the separation point to occur at about  $\theta=120^\circ$  and then a smaller wake and higher pressure within about 75% less drag coefficient is resulted.

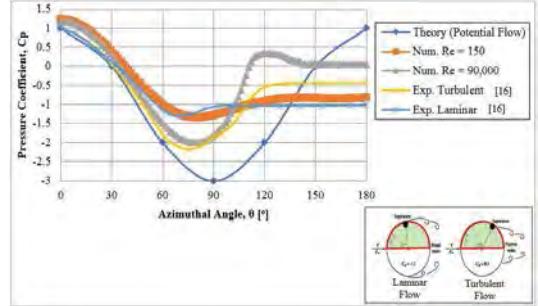

Figure 2. Pressure coefficient profile around the upper surface

The purpose of steady-state simulation is to investigate the mean flow patterns around the bluff-body. The results showed that only the mean velocity and pressure can be captured as shown in Fig. 3(a) and (b), respectively. This is evidence that the acoustic field cannot be extracted, but the results could be utilized as an initial value for simulating unsteady case. On the other hand, the unsteady flow simulation includes the transient behavior which then clearly depicts the flow motion as shown in Fig. 3(c), (d), (e) and (f). The flow instability downstream known as von Karman Street was successfully captured.

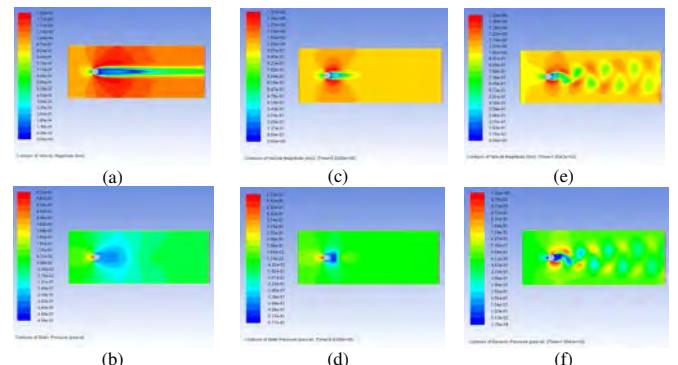

Figure 3. Near-field results of flow around circular cylinder with  $Re=150$

Because the flow depends on time, it is important to calculate the time step. For example, in the region behind the circular cylinder a vortex shedding will be created. From the experiments [15], the Strouhal number,  $St = fD/v$  is 0.172, then the period,  $T=1/f$  is found to equal 5.8139 seconds if the frequency,  $f$  is calculated. By assuming the number of time steps is  $n = 20$ , then  $\Delta T = T/n = 0.291$  seconds, so then, the first vortex shedding can be captured. Note that the lift coefficient,  $C_L$ , has a sinusoidal pattern which is an indication of the sustained vortex shedding that takes place in the wake region as shown in Fig. 4.

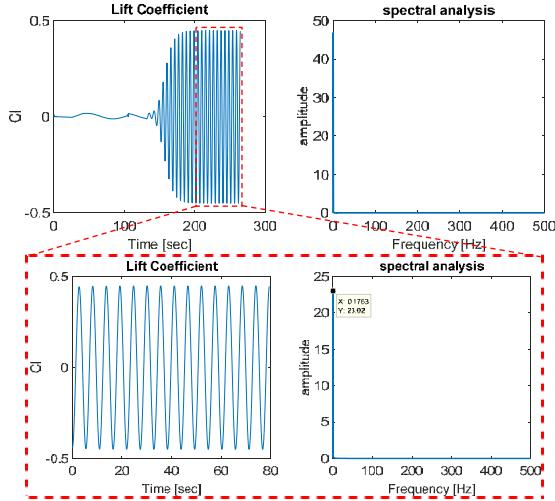

Figure 4. Lift Coefficient time history and frequency content for  $Re=150$

The associated acoustic pressure fluctuations for  $Re=150$  were collected at two receivers, receiver 1 and receiver 2 located at  $90^\circ$  above the circular cylinder within 0.665 m and 2.432 m, respectively. Fig. 5 shows that the far-field pressure fluctuations at both locations preserved the periodicity pattern. That because the near-field flow pressure oscillated with sinusoidal type of behavior when the flow instability occurs.

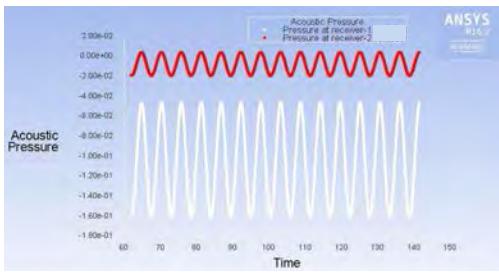

Figure 5. Acoustic pressure fluctuations at two different locations

From Fluent the drag force,  $F_d$ , is found to equal 0.696 N, then the drag coefficient,  $C_d$ , was calculated using this relation:  $C_d = 2F_d/\rho V^2 A$ , where  $A$  is the projected area normal to the flow direction (i.e. for a 2D cylinder is equal to the diameter), and it turned out to be equal to 1.392 which differs by about 7.2% from the experimental value [15].

For  $Re=90,000$ , the near-field data that corresponds to the far-field acoustic prediction is captured as seen in Fig. 6. The wall of the circular cylinder is selected to extract all the

relevant acoustic source date such as velocity and pressure. In case of 2D, the source correlation length is assigned to be about  $5D$  since the Fluent assumes that the sound sources are perfectly correlated over the specified correlation length and zero outside. The acoustic pressure signals at the two receiver locations were detected and shown in Fig. 7(a). Also, the spectral of the receiver signals are plotted using the Fast Fourier Transform (FFT). Then, the sound pressure level (dB) versus the frequency (Hz) is calculated as shown in Fig. 7(b) and (c). Due to the turbulence behavior, different size of eddies generated, but the small-scale eddies are not captured within this number of cells. The results prove that the noise generated is a broadband as detected by receivers 1 and 2. In this case, the pressure fluctuations are no more preserving the periodicity and revealed asymmetric behavior. This indicates that a higher frequency creates a more rapid variation in air pressure and results in a higher pitch.

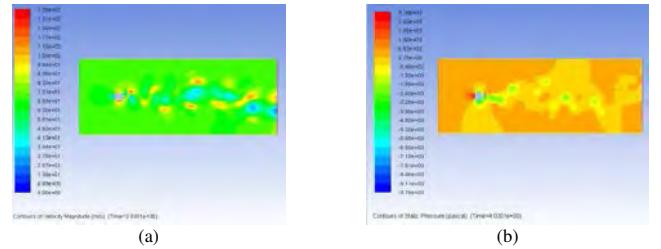

Figure 6. Numerical results of flow around circular cylinder with  $Re=90,000$

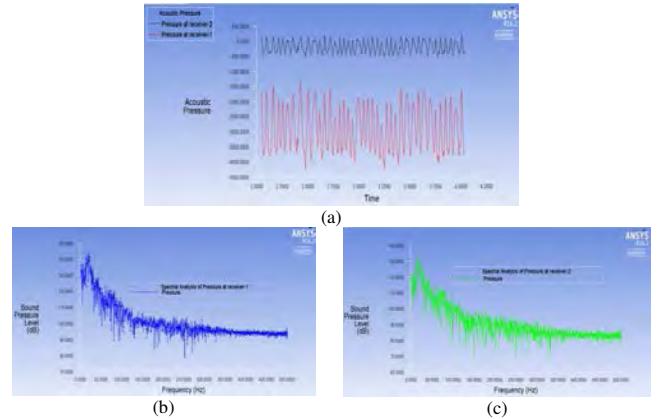

Figure 7. Acoustic results of flow around circular cylinder with  $Re=90,000$

## V. CONCLUSION

In order to understand the physics of both flow and acoustic fields of landing gear systems, 2D flow past a bluff body (circular cylinder) was simulated using ANSYS Fluent. Two distinct  $Re$  numbers 150 and 90,000 were examined. The time dependency consideration affects the extraction of near-field flow data as well as the far-field noise prediction. The FW-H solver in Fluent does not include the contribution of the quadrupole sources (volume integration). Thus, type and location of the surface data are crucial in capturing the far-field noise level. Further investigations are needed to adjust for all source terms. An efficient algorithm/numerical technique in terms of computational cost and memory management are highly required to tackle such complex case like a LG.

**Abstract**— In the conventional mechanical micropumps, the motion from one component (such as gear or diaphragm) produces pressure difference, which is needed to move fluid. In this paper, we propose a new method to use double PZT layers as an actuator for a valveless micropump, which is designed for pumping blood. Due to the high surface tension of blood, one PZT actuator is not strong enough to produce sufficient displacement. So instead of one PZT layer, a double-PZT layer is utilized to produce movement force. In this research, the analytic equations of a double circular PZT layer are derived to express the natural frequency of the system. The finite element method (FEM) simulation is utilized to verify the analytic equations. Then the required input voltage is applied to maximize the functionality of the system, whose simulation results are compared with the experimental measurement setup. Finally, a typical valveless micropump with the proposed double PZT layer is simulated by using COMSOL Multiphysics software. The flow rate of this configuration is compared with a single PZT actuator to demonstrate the effect of the proposed double-PZT actuator on the application to the valveless micropumps.

## I. INTRODUCTION

The concept of microfluid was introduced 40 years ago, with the advent of inkjet printing nozzle by IBM (E. Bassous et al. 1977 and Petersen K E 1979) [1]. In 1993, Peter Gravesen et al. published a review paper about micro pumping technology and different actuating principles [2]. Afterwards many new fabrication technologies and in turn new micropump technologies have been developed, such as the positive displacement micropump by Cunneen et al in 1997 [3], the electro-osmotic micro-pump by Chen et al. in 2005 [4], the pneumatic PDMS micropump by Jeong and Konishi in 2007 [5], the piezoelectric micro-pump by Samira Kaviani et al in 2014 [6], and the high pressure peristaltic micropump by Loth and Förster in 2016 [7]. These are just some examples of the new technologies and fabrication methods in the microfluidic

area, where the micropump design is highly dependent on specific applications.

In this paper, a valveless micropump with a double PZT layer actuator is developed to pump blood sample. In general, being applied a voltage, a piezoelectric (PZT) layer bends inwards into the micropump [8]. This action pushes the fluid out of the chamber through the outlet valve. In suction mode, when the voltage is removed, the PZT layer would back up to allow the fluid to enter the chamber. This reciprocating process causes the pumping action. A recent attempt of improving PZT micropump was done by Hu et al. in 2017 [9], who added a new layer to the previous design to decrease the resonant frequency as an advantage of the newly designed device. The authors verified the FEM model with experimental setup. An accurate analytic modeling for a single circular piezoelectric actuator was developed by Mo et al. [10]. They investigated the effect of the thickness ratio and the radius of the piezoelectric layer, which is bonded to a metallic layer with the maximum deflection by using their proposed analytic model. A recent analytic modeling based on the thin plate theory and Kelvin–Voigt laws for a single piezoelectric actuator was proposed by Esfahani and Bahrami [11]. They also studied the vibration analysis of an edge clamp for a rectangular PZT actuator in a fluid environment. They considered the effect of fluid on the system by adding a damping coefficient to their equations, and then solved the governing equation by a numerical method. In [12], they also investigated the effect of the input voltage, viscoelastic elements, damping coefficient, and excitation signal on the system response. They verified their proposed modeling with the FEM method by using COMSOL Multiphysics software.

This paper is organized as follows. In Section 2, the governing equations of double PZT layer with a bonding layer will be presented and then the natural frequency will be calculated. In Section 3, the FEM simulation will be presented to verify the analytic solution. Then the required voltage, which can maximize the functionality of the system, will be computed. By utilizing a high voltage amplifier and a signal generator, we construct the test bench of our prototype system. The measurement result will be compared with the FEM result. In Section 4, we use COMSOL Multiphysics software to help design a typical valveless micropump. With reference to the

computated natural frequency of the system, a high AC voltage with the same frequency is applied to the system to investigate the effect of the double PZT layer on the output flow rate. Finally, we draw a conclusion in Section 5.

## II. DYNAMIC MODEL

The primary purpose of a double PZT layer actuator is to provide large bending displacement in the transverse direction. As illustrated in Fig. 1, two piezoelectric layers are glued with each other by a bonding layer. Two PZT layers are assumed to connect each other by a massless and linear bonding layer. The radius of the bonding layer and PZT layers is  $r_0$  and the thicknesses of PZT layers and bonding layer are  $t_p$  and  $t_b$ . In this model, because of the thickness of electrodes is less than  $0.5 \mu\text{m}$ , the effect of the electrode on deflection of the PZT layers will be ignored [13].

Figure 1. The schematic view of a double PZT layer with a bonding layer.

The axisymmetric governing equations can be obtained by utilizing LaGrange method as follows:

$$T_1 \left( \frac{\partial^2 w_1(r,t)}{\partial r^2} + \frac{1}{r} \frac{\partial w_1(r,t)}{\partial r} \right) = m_1 \frac{\partial^2 w_1(r,t)}{\partial t^2} + k(w_1(r,t) - w_2(r,t)) + f_1(t) \quad (1-1)$$

$$T_2 \left( \frac{\partial^2 w_2(r,t)}{\partial r^2} + \frac{1}{r} \frac{\partial w_2(r,t)}{\partial r} \right) = m_2 \frac{\partial^2 w_2(r,t)}{\partial t^2} - k(w_1(r,t) - w_2(r,t)) + f_2(t) \quad (1-2)$$

where  $T_1$  and  $T_2$  are the tension,  $w_1$  and  $w_2$  are displacement,  $k$  is the stiffness coefficient of the bonding layer,  $m_1$  and  $m_2$  are the mass per unit area. To compute natural frequencies,  $f_1$  and  $f_2$  should be equal to zero. The PZT layers are clamped along the edge such that there is no displacement and as a result the boundary equations can be written as follows:

$$w_i(r_o, t) = 0, w_i(0, t) \neq \infty. \quad (i=1 \text{ or } 2) \quad (2)$$

Moreover, the PZT layers have no initial displacement:

$$w_i(r, 0) = w_0, \frac{\partial w_i}{\partial t}(r, 0) = 0 \quad (3)$$

By applying the separation variation method,  $w_1$  and  $w_2$  can be rewritten as follows:

$$w_1(r, t) = R_1(r)Z(t) \quad (4-1)$$

$$w_2(r, t) = R_2(r)Z(t) \quad (4-2)$$

$$Z(t)T_1 \left( \frac{\partial^2 R_1(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_1(r)}{\partial r} \right) = m_1 R_1(r) \frac{\partial^2 Z(t)}{\partial t^2} + \quad (5-1)$$

$$k(R_1(r)Z(t) - R_2(r)Z(t))$$

$$Z(t)T_2 \left( \frac{\partial^2 R_2(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_2(r)}{\partial r} \right) = m_2 R_2(r) \frac{\partial^2 Z(t)}{\partial t^2} - k(R_1(r)Z(t) - R_2(r)Z(t)) \quad (5-2)$$

Let's assume that  $Z(t) = Z_0 e^{-i\omega t}$  then:

$$Z_0 e^{-i\omega t} T_1 \left( \frac{\partial^2 R_1(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_1(r)}{\partial r} \right) = m_1 R_1(r) Z_0 e^{-i\omega t} (-\omega^2) + k(R_1(r) Z_0 e^{-i\omega t} - R_2(r) Z_0 e^{-i\omega t}) \quad (6-1)$$

$$Z_0 e^{-i\omega t} T_2 \left( \frac{\partial^2 R_2(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_2(r)}{\partial r} \right) = m_2 R_2(r) Z_0 e^{-i\omega t} (-\omega^2) - k(R_1(r) Z_0 e^{-i\omega t} - R_2(r) Z_0 e^{-i\omega t}) \quad (6-2)$$

These equations can be rewritten as:

$$Z_0 e^{-i\omega t} T_1 \left( \frac{\partial^2 R_1(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_1(r)}{\partial r} \right) = m_1 R_1(r) Z_0 e^{-i\omega t} (-\omega^2) + k Z_0 e^{-i\omega t} (R_1(r) - R_2(r)) \quad (7-1)$$

$$Z_0 e^{-i\omega t} T_2 \left( \frac{\partial^2 R_2(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_2(r)}{\partial r} \right) = m_2 R_2(r) Z_0 e^{-i\omega t} (-\omega^2) - k Z_0 e^{-i\omega t} (R_1(r) - R_2(r)) \quad (7-2)$$

With simplification:

$$T_1 \left( \frac{\partial^2 R_1(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_1(r)}{\partial r} \right) = -m_1 \omega^2 R_1(r) + k(R_1(r) - R_2(r)) \quad (8-1)$$

$$T_2 \left( \frac{\partial^2 R_2(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_2(r)}{\partial r} \right) = -m_2 \omega^2 R_2(r) - k(R_1(r) - R_2(r)) \quad (8-2)$$

Let's define  $\nabla R_i = \frac{\partial^2 R_i(r)}{\partial r^2} + \frac{1}{r} \frac{\partial R_i(r)}{\partial r}$ . By substituting  $\nabla R_i$  into the equations, the following equations will be obtained:

$$T_1 \nabla R_1 + (m_1 \omega^2 - k) R_1(r) + k R_2(r) = 0, \quad (9-1)$$

$$T_2 \nabla R_2 + (m_2 \omega^2 - k) R_2(r) + k R_1(r) = 0. \quad (9-2)$$

By eliminating  $R_2$  from these equations, the following equation can be obtained:

$$(\nabla + C_1^2)(\nabla + C_2^2)R_1 = 0 \quad (10)$$

where  $C_1$  and  $C_2$  are equal to:

$$\begin{aligned} C_{1,2}^2 &= \frac{1}{T_1 T_2}(-(m_2 T_1 + m_1 T_2) \omega^2 + (T_1 + T_2)k) \pm \\ &(2T_1 T_2 k^2 + T_2^2 m_1^2 \omega^4 + T_1^2 m_2^2 \omega^4 + T_2^2 k^2 + T_1^2 k^2 - \\ &2m_2 \omega^2 T_1^2 k + 2m_1 T_2^2 \omega^2 k - 2m_2 m_1 T_1 T_2 \omega^4 + \end{aligned} \quad (11)$$

$$2m_1T_1T_2k\omega^2)^{\frac{1}{2}})$$

The solution of this equation can be represented as Bessel function as follows:

$$R_{1i} = a_i J_i(C_1 r) + b_i Y_i(C_1 r) \quad (12)$$

By applying the first boundary condition, since  $R_{1i}(0, t) \neq \infty$ ,  $b_i$  should be equal to zero and also by applying the second B.C,  $R_{1i}(r_o, t) = 0$ , it can be shown that:

$$J_i(C_1 r) = 0 \text{ or } J_i(\delta) = 0 \quad (13)$$

where  $\delta$  is the root of Bessel function. Now by solving this simple algebraic equation, natural frequencies  $\omega$  of the system can be calculated. Material properties of the system are shown in Table I.

TABLE I. MATERIAL PROPERTIES OF PZT AND BONDING LAYER.

Mechanical property	Bonding layer (Epoxy Resin)	PZT (Lead Zirconate Titanate)
Mass density	2000 ( $Kg/m^3$ )	7500 ( $Kg/m^3$ )
Elastic modulus	5.17 (GPa)	9.5 (GPa)
Poisson's ratio	0.31	0.30

### III. FEM MODELING AND EXPERIMENTAL SETUP

To validate the analytic solution, FEM method and experimental setup are utilized. Two piezoelectric actuators with the radius of 14 mm, which are glued to each other by a bonding layer, are simulated in Comsol Multiphysics software. Fig. 2 shows the mode shapes of the system that are calculated by FEM simulation.

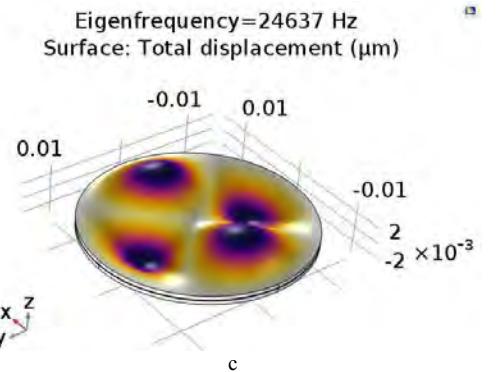

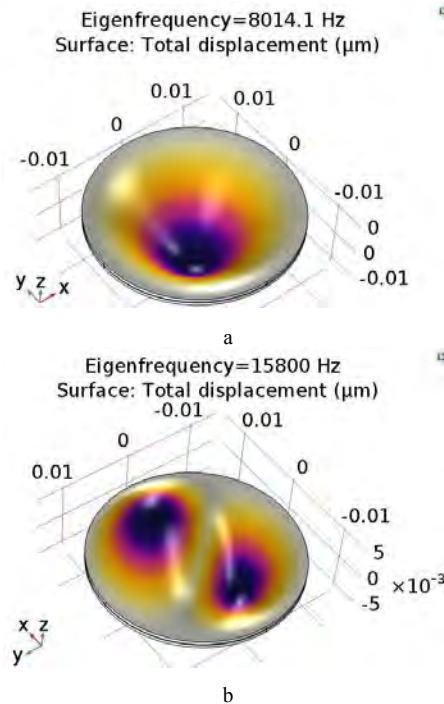

Figure 2. The natural frequency of double PZT layer with bonding layer in Comsol Multiphysics software a) The first mode shape, b) The second mode shape, c) The third mode shape.

The maximum stress occurs at the boundary condition. The Tresca stress at the boundary as a function of frequency is shown in Fig. 3. The result demonstrates that the maximum displacement and maximum stress will occur at the first natural frequency  $\omega_1$ . As a result, the maximum functionality of the system is at the first natural frequency. Table II shows the natural frequency, which is calculated by analytic solution and FEM modeling. The absolute percentage error (APD) is calculated by the following equation [14-15]:

$$\epsilon_i = 100 \left| \frac{(\omega_{F_i} - \omega_{A_i})}{\omega_{F_i}} \right| \quad (14)$$

where  $\omega_{F_i}$  is natural frequencies calculated by FEM simulation, and  $\omega_{A_i}$  is natural frequencies calculated by analytic solution.

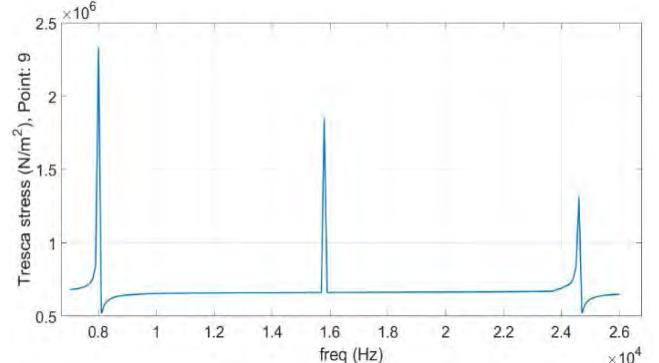

Figure 3. The Tresca stress at the boundary of the system for the first, second, and third natural frequencies.

TABLE II. THE FIRST, SECOND AND THIRD NATURAL FREQUENCY

Resonant frequency	Analytical Solution (Hz)	FEM Modeling (Hz)	Absolute percentage Error (APD)
1	7947.35	8014.1	0.83
2	15678.86	15800	0.76
3	24507.32	24637	0.52

The result shows the accuracy of the analytic model. We can see that this analytic model is very valuable, since the designer can use it to estimate the natural frequency of a new double PZT layer very quickly for different dimensions without

any expensive FEM simulation. The transverse vibration of the double PZT layer will be turned into a time-dependent vibration when the input voltage signal changes as a function of time. The important point is to find the best input signal, which can maximize the efficiency of the system. In order to reach this goal, after calculating the natural frequencies, the first natural frequency will be chosen to apply to the system. So a high voltage signal with the same frequency  $\omega_1$  will be applied to the system and the maximum deflection will be measured by FEM simulation and experimental setup. Fig. 4-a shows the excitation voltage, which is equal to  $200\sin(\omega_1 t)$ . The system response is shown in Fig. 4-b. The maximum stress, which occurs at edge, is shown as a function of time in this figure. This figure reveals that the maximum deflection of the system with respect to that excitation signal is equal to  $121 \mu\text{m}$ .

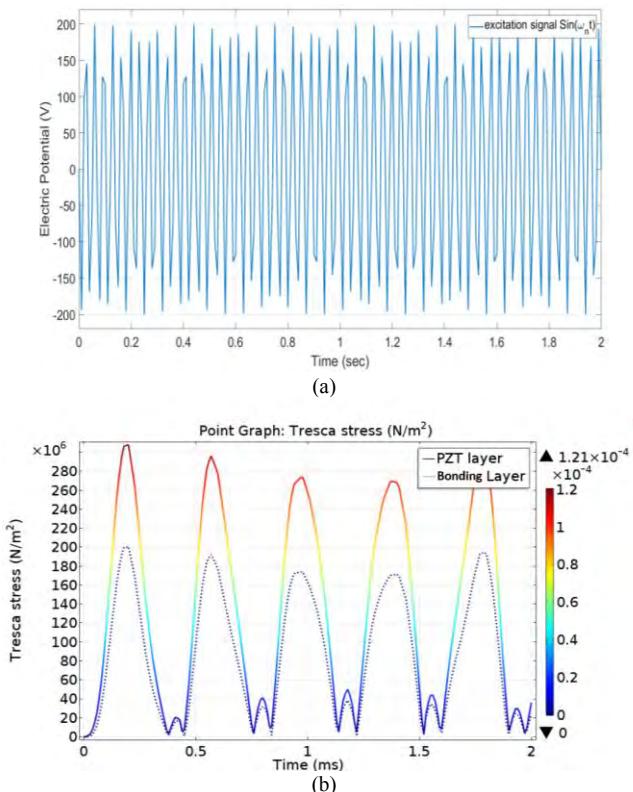

Figure 4. a) The excitation signal at the first natural frequency, b) The Tresca stress at the boundary and displacement profile.

For the experimental setup, the main instruments include a fixture, a high precision laser measurement sensor (LK-H022, resolution of  $0.02 \mu\text{m}$ ), a signal generator, a high-precision high voltage power amplifier (TEGAM-2350), and a data acquisition system.. The experimental setup is shown in Fig. 5. In order to verify the FEM simulation along with the experimental measurement results, an excitation signal the same as Fig. 4-a was applied to the system. Fig. 6 shows the center deflection of the double PZT layer. As can be seen in this figure, the maximum value for deflection is equal to  $117 \mu\text{m}$ , which is close to the FEM result with the error of 3.3%.

Figure 5. 1) Double PZT layer, 2) Fixture, 3) Vibration Shaker Systems, 4) a high precision laser measurement sensor (LK-H022, resolution of  $0.02 \mu\text{m}$ ), 5) Signal generator, 6) Precision power amplifier high voltage (TEGAM-2350), 7) Data acquisition system.

#### IV. APPLICATION OF DOUBLE PZT LAYER IN MICROPUMP

In this section, the double PZT actuator will be installed on a valveless micropump to see the effect of this proposed actuator on the flow rate of the valveless micropump. In the conventional mechanical micropump, the motion of one component such as gear or diaphragm can produce pressure difference, which is needed to move fluid sample. Mechanical micropumps can be classified into the following categories: rotary micropumps, moving diaphragm micropumps, and peristaltic micropumps. The actuation methods of the moving diaphragm micropumps include piezoelectric, electrostatic, thermopneumatic, shape memory alloys, and other novelties. In this research, we choose the double piezoelectric actuator to move the diaphragm of a valveless micropump. A typical configuration of the valveless micropump with the double piezoelectric actuator in COMSOL Multiphysics software is shown in Fig. 7. COMSOL Multiphysics is powerful software that can simulate the interface between solid structure, fluid environment, and electrical field.

In a typical valveless micropump, there is no moving part. It works base on geometry property of nozzle and diffuser. The purpose of this section is not focused on the principle of this type of micropumps. More detail about the micropump design can be found in Stemme's and Cui's papers [16,17]. Fig. 7-a

shows the micropump chamber in suction mode and Fig. 7-b shows the chamber of micropump in pump mode.

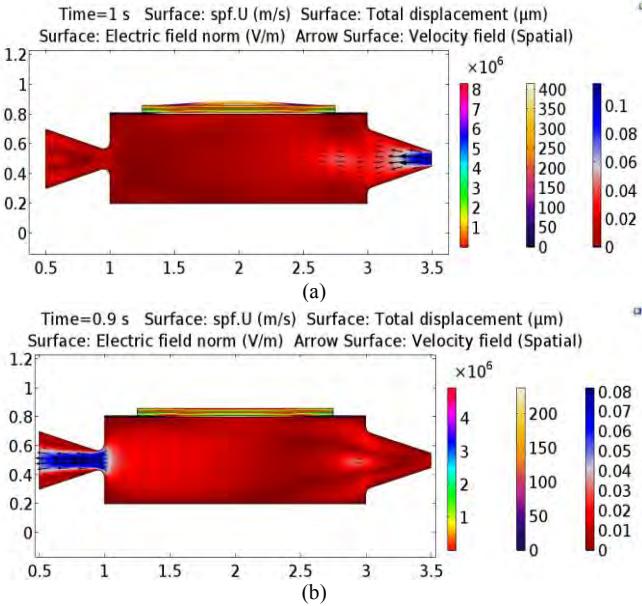

Figure 7. The FEM modeling of the valveless micropump with double PZT actuator a) The suction mode, b) The pump mode.

In order to investigate the effect of the double PZT actuator on the system, the flow rate of the system is calculated by FEM simulation. Fig. 8-a shows the flow rate of a valveless micropump with a regular single PZT actuator. As can be seen from this figure, the maximum flow rate reaches up to  $1.47 \times 10^{-5} \text{ m}^2/\text{s}$ . On the other hand, Fig. 8-b shows the flow rate of the same microvalve in the same condition, but with a double PZT actuator and a bonding layer. As can be seen from this figure the maximum flow rate would reach  $12.1 \times 10^{-5} \text{ m}^2/\text{s}$ , which is suitable for pumping biological samples such as blood. In other words, by utilizing our proposed double PZT actuator, the flow rate of a valveless micropump can increase up to 8.23 times.

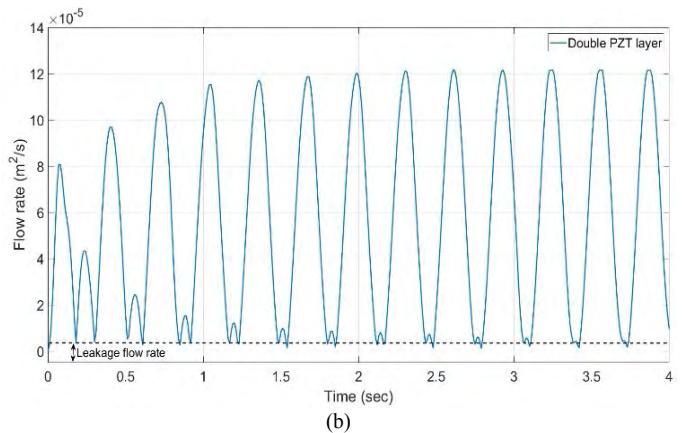

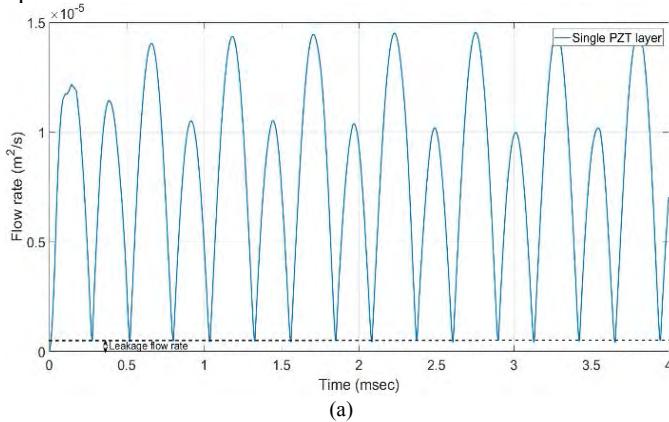

Figure 8. The output flow rate of the valveless micropump a) With a single PZT actuator, b) With a double PZT actuator.

## V. CONCLUSION

In this research, we designed a double PZT layer as an actuator for a valveless micropump. The analytic analysis of this newly proposed actuator was first conducted and then verified with FEM simulation. The comparison between COMSOL Multiphysics simulation and analytic computation reveals the high accuracy of our deducted analytic solution, whose error is less than 1%. This is valuable since the designer can estimate the natural frequency of a new double PZT layer quickly for different dimensions by using our analytic solution without depending on any expensive FEM simulation. Moreover, the experimental setup was established to measure the maximum displacement for a comparison with the FEM simulation. The result shows that the difference between FEM simulation and our experimental measurement is less than 4%. Furthermore, the proposed actuator was applied to a typical valveless micropump to evaluate the functionality of the actuator. The comparison between a regular valveless micropump with a single PZT actuator and the same micropump with a double PZT actuator reveals that the flow rate will increase up to 8.23 times.

**Abstract**— Crude oil spill is a significant threat to marine wildlife and human health. Understanding the interaction of oil-degrading bacteria at aqueous-oil interfaces at submillimeter scale is crucial to biodegradation and bioremediation. Here we present a microfluidic system that allows real-time and parallel observation of bacteria interaction with crude oil during biofilm formation and degradation of the oil. A simple and robust microfluidic platform is designed, fabricated and tested. Stable and controllable oil-bacterial solution interfaces are formed. The theory of the capillary valves used in the device and the microfabrication steps are presented. Experimental results show the accumulation of *Marinobacter hydrocarbonoclasticus* –an oil degrading bacteria– at the bacterial solution interface with paraffin oil. After ~3 hr of incubation, bacteria start to form microcolony at the oil interface. Results show that presented microfluidic device can be successfully used for research on bacteria-oil interactions and other applications requiring an interface formed by two immiscible liquids.

**Keywords-** *microfluidics; oil-degrading bacteria; biofilm; interfaces; capillary valve*

## I. INTRODUCTION

Crude oil spill is a significant threat to marine wildlife and human health. Each year, ~700 million tons of crude oil is introduced to aquatic ecosystem through human related activities and by natural seepage from reservoirs [1], [2]. This, therefore, has motivated more progress in marine oil spill remediation studies [3], [4]. Nature has evolved an effective way to rectify the problem using indigenous microorganisms to clean up the oil contaminants [5]. *Marinobacter hydrocarbonoclasticus* (MH) is an aquatic bacterium with the ability to form biofilms at the interface between water and oil [6]. MH uses this ability to increase the bioavailability of hydrocarbons, which serve as its main energy source, and further to degrade the oil. Biofilms have been previously studied using macroscopic approaches [7]. Analysis at microscales, however, can provide key information on the dynamics of biofilm formation and disruption [8], [9]. A central challenge for studying MH is to

form a stable and observable oil-bacterial solution interface that mimics those found in natural settings.

Over the last decade, the lab-on-a-chip technology and in particular microfluidics has been maturing, leading to tremendous applications in life science and engineering [10]. In general, microfluidics can help to overcome challenges and limitations of convectional assays, for example in biology and chemistry, and also allow development of approaches that can lead to better understanding of natural or engineered phenomenon at submillimeter scale [11]. Microfluidics offers unique advantages such as low sample and reagent volumes ( $\mu\text{L}$  to  $\text{pL}$ ), precise control of spatial and temporal factors with high sensitivity, low-cost, with simplified fabrication and operation steps [10], [12]. Moreover, the use of biocompatible and optically transparent materials such as Polydimethylsiloxane (PDMS) facilitates the culture of biological samples and image acquisition using conventional microscopy [13]. These advantages make microfluidics an ideal tool for studying the interaction of *Marinobacter hydrocarbonoclasticus* with oil.

Here we present a simple and versatile microfluidic device for studying bacteria with oil degrading ability as a model for marine bacteria interaction with crude oil during biofilm formation. Using capillary valves incorporated in the microfluidic device, the oil-bacterial solution interface is realized. The principle behind the capillary valves used in the microfluidic device is presented. Use of such microfluidic device with passive valves is advantageous because it does not require complex setup, thus increasing the simplicity of the fabrication and liquid handling in the device. The design of the device allows for experimental parallelization with different conditions at a time to investigate, for instance, the effects of two different oils or promoting/inhibitory reagents on the bacteria interaction with the oil.

## II. RESULTS AND DISCUSSION

### A. Microfluidic device

Fig. 1 shows the schematic representation of the microfluidic device for studying bacteria interaction with oil.

The device consists of three parallel channels that allow the formation of immiscible liquid-liquid interfaces. The middle and the two adjacent channels are interconnected through 100  $\mu\text{m}$  gaps between 20 trapezoidal posts located in series (Fig. 1). All channels have 40  $\mu\text{m}$  height. The abrupt angle of the posts geometry increases the physical contact angle between the solid-liquid interface, resulting in a capillary valve action [14], which consequently retains the meniscus between the microposts and prevents the liquid in the middle channel from flowing into the side channels. The middle channel can be filled with oil and side channels with bacteria solution to bring the two liquids into contact (Fig. 1). Fig. 2 shows the PDMS microfluidic device fabricated using photolithography and soft lithography techniques as described in the method section [15].

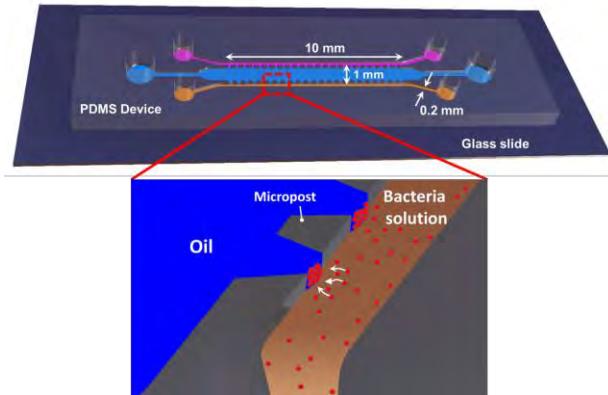

Figure 1. Architecture of the microfluidic device developed to study interaction of *Marinobacter hydrocarbonoclasticus* and oil. Liquid-liquid interfaces are achieved at the meniscuses formed as a result of the gaps between the microposts.

### B. Capillary valves

The capillary valves stop the liquid from flowing to a certain region of the microfluidic device using a capillary pressure barrier [14]–[16]. For this particular type of valve, the capillary pressure barrier develops when abrupt enlargement of the channel happens. The valve consists of a region of the channel that is necked down followed by a sharp expansion of the cross-section that locally increases of the static contact angle. In the proposed microfluidic device, the implemented microposts work as capillary valves (Fig. 2).

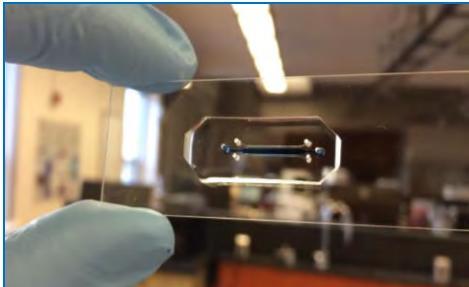

Figure 2. Image of fabricated PDMS microfluidic device. The loaded blue liquid is stopped from flowing to the side channels by the microposts acting as capillary valves.

The capillary valves stop the liquid from flowing to a certain region of the microfluidic device using a capillary

pressure barrier [14]–[16]. For this particular type of valve, the capillary pressure barrier develops when abrupt enlargement of the channel happens. The valve consists of a region of the channel that is necked down followed by a sharp expansion of the cross-section that locally increases of the static contact angle. The loaded liquid in the microfluidic device drives by the combination of the external pressure and capillary action in the channel and between microposts (necked regions, Fig. 3a). The abrupt enlargement of the edge of the microposts (145°) prevented the liquid from flooding to the side channel using the pressure barrier (Fig. 3b). This can be explained in terms of changes in the energy for the liquid-solid-air interface system. The total interfacial energy ( $U_T$ ) of capillary system can be presented by:

$$U_T = A_{SL}\gamma_{SL} + A_{SA}\gamma_{SA} + A_{LA}\gamma_{LA} \quad (1)$$

where  $A_{SL}$  and  $\gamma_{SL}$ ,  $A_{SA}$  and  $\gamma_{SA}$ ,  $A_{LA}$  and  $\gamma_{LA}$  are solid-liquid, solid-air, and liquid-air interface areas and surface energies per unit area, respectively [16], [17]. The relation between surface energies of triple interfaces and the contact angle of liquid  $\theta_C$  with the surface of microfluidic channel at the meniscus can be expressed by Young's equation:

$$\gamma_{SA} = \gamma_{SL} + \gamma_{LA} \cos \theta_C \quad (2)$$

The  $U_T$  of the system is a function of loaded volume liquid ( $V_L$ ) into the device as wetted surfaces change by increase of the  $V_L$ .

$$P = -\frac{dU_T}{dV_L} = \gamma_{LA} \left( \cos \theta_C \frac{dA_{SL}}{dV_L} - \frac{dA_{LA}}{dV_L} \right) \quad (3)$$

When liquid is loaded, it wets the surfaces of the channels which increases the liquid-solid interface and thus the positive pressure moves the liquid forward and fills the channel. In order to stop the liquid from going to the side channels, pressure as driving force should be controlled. This can be achieved by geometry change of the valve. The abrupt geometry change of valve results in an increase of liquid-air interface more than solid-liquid interface at the end of the tapered edge, which leads to opposite sign of the pressure at the meniscus. The negative pressure is a repulsive force and thus stops the filling front at the edge of the valve. When the liquid reaches the sharp edge of the valve, the filling front stops and meniscus remains at the edge unless higher pressure is applied to the liquid which breaks the pressure barrier and liquid flows to the side channels. The Young-Laplace equation expresses the inverse relation of pressure across the liquid-air interface and the radius of meniscus. According to the equation 4, the pressure at the liquid-air interface increases when the meniscus radius ( $r$ ) gets smaller or in other words when meniscus becomes more convex [16], [18].

$$\Delta p = p - p_n = \frac{2\gamma_{LA}}{r} \quad (4)$$

Depending on the difference between internal pressure ( $p$ ) of the liquid and normal pressure in the side channel ( $p_n$ ), the liquid-air interface bulges more or less. For a given volume, if further illiquid is gradually loaded to the channel, the liquid continues to move and meniscus shape changes from concave to flat and then to convex (Fig. 3). If the volume of the liquid decreases, the meniscus shape changes back to the concave.

This is a reversible action until the meniscus is pinned and valve is not open. Here we assume that all the surfaces in the microchannel for PDMS and glass are homogenous and have same surface properties (e.i. hydrophobic).

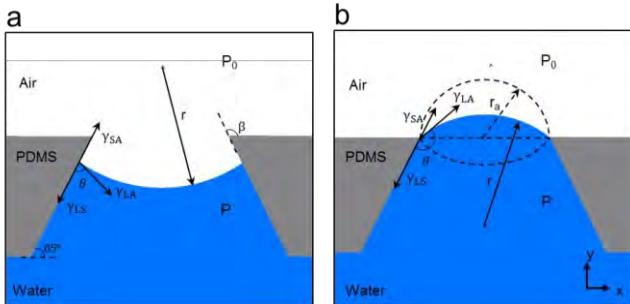

Figure 3. Principle of the capillary valves. (a) Filling front of the liquid while reaching the sharp edge of the valve and (b) the pinned meniscus due to the pressure barrier from the valve.

### C. Formation of liquid-liquid interface

To test the functionality of the device, first the middle channel was filled with the oil (colored in green in Fig. 4) and after the oil filling front between the microposts was stopped by the valves, the side channels were filled with the water (colored in pink in Fig. 4). Fig. 4 shows the well-defined oil-water interfaces formed between microposts. Similar interfaces achieved for all the 20 gaps between microposts. By modulating the volume of liquid loaded into the middle channel, meniscus shape can be altered and concave, flat, and convex meniscus can be achieved (Fig. 5).

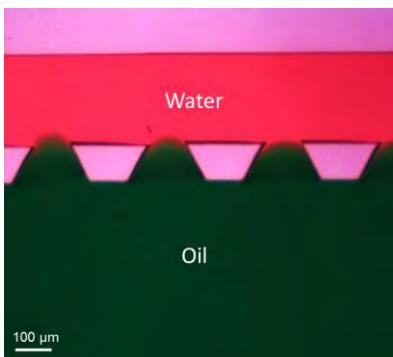

Figure 4. Stable and well-defined oil-water interfaces formed between microposts. Oil is colored in green and water in pink.

The effectiveness of the valves to pin and maintain the meniscus during the experiments were tested and results showed that oil-bacterial solution interfaces were stable over the course of the experiment for  $> 5$  hr. Using this approach, it is possible to bring two immiscible liquids into contact and form a liquid-liquid interface, such as oil-water, between the microposts.

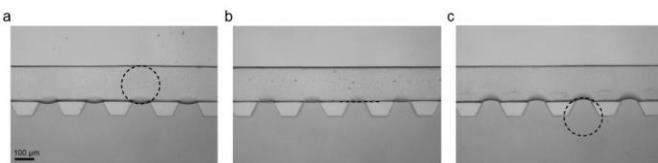

Figure 5. Zoomed view of the middle channel filled with water. By varying the volume of liquid loaded to the channel, the meniscus shape can be controlled to be a) convex, b) flat, and c) concave. Side channel was left empty. The dashed line and circles show the direction of the meniscus.

### D. Bacteria interaction with oil

In order to study biofilms formation at the oil-water interface, the middle channel was loaded with metabolisable hydrocarbon and the side channels were filled with highly concentrated salt solution containing FITC-labeled *M. hydrocarbonoclasticus*. The experimental results demonstrate observable oil-bacterial solution interfaces between all microposts and substantial bacteria accumulation at the oil interfaces (Fig. 6). Due to the migration of the bacteria towards the oil and their accumulation there, higher number of bacteria were found close to the oil interface (Fig. 6).

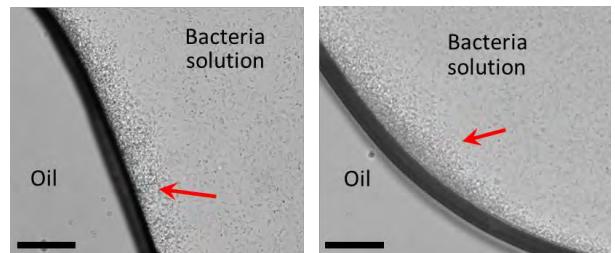

Figure 6. Accumulation of *Marinobacter hydrocarbonoclasticus* at the bacterial solution interface with paraffin oil. Scale bars, 50 μm. Red arrows show the area with bacteria accumulated at the oil interface.

Fig. 7 shows the images of the oil-bacteria interface at time zero (Fig. 7-left) and at time  $\sim 3$  hr (Fig. 7-right). The accumulation of the bacteria and formation of the microcolony in the microfluidic device was imaged over time. After 3 hours of incubation, marinobacter bacteria started to form biofilm/microcolony at the interface with the parafin oil. Results show the successful formation of stable and observable oil-bacterial solution interfaces that can mimics those found in natural settings. The possibility to have 20 interfaces at each side of the middle channel improves the number of data points and statistical analysis to support the observed phenomenons.

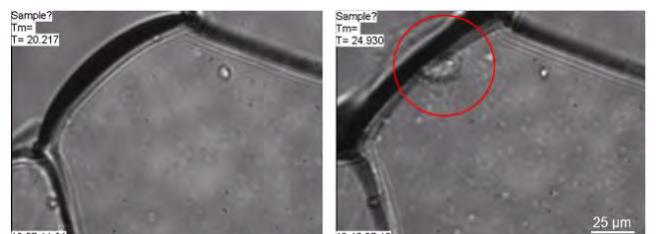

Figure 7. Formation of a biofilm/microcolony between marinobacter and parafin oil after  $\sim 3$  hours of incubation in 20 °C in the microfluidic device. The microcolony is shown by red circle.

### III. CONCLUSION

In summary, a simple and robust microfluidic device allowing the formation of oil-water interfaces was presented and used to study interaction of *Marinobacter hydrocarbonoclasticus* – an oil degrading bacteria – with parafine oil. The device utilized capillary valves formed by the sharp edges of 20 microposts that connect the two channels

together and allowed for controllable and observable interfaces between oil and bacterial solution. The proposed microfluidic device enabled experimental parallelization with different conditions at a time to investigate, for instance, the effects of two different oils or promoting/inhibitory reagents on the biofilm formation. In order to study biofilm formation at the oil-water interface, the middle channel can be loaded with a highly concentrated salt solution containing *Marinobacter hydrocarbonoclasticus*, while the side channels can be filled with a degradable and non-degradable oil such as Hexadecane and 1-Octanol, respectively. This versatile platform has great potential not only for studying oleolytic biofilms, but also for applications that require interfaces formed by two immiscible liquids.

#### IV. MATERIALS AND METHODS

##### A. Fabrication of microfluidic device

The microfluidic device was fabricated using photolithography and soft lithography techniques [19]. Microfluidic networks were designed in CATIA (Dassault Systems, V19). For maximum process reliability, the silicon wafer was cleaned with acetone and isopropanol, and then rinsed with water for 5 minutes. The wafer was then dried on a 100 °C hotplate. A 40 µm layer of SU-8 50 (MicroChem, USA) was spin-coated on a silicon wafer and selectively exposed to ultraviolet light using a maskless photolithography system (Intelligent Micro Patterning Co., USA). SU-8 cross-linking was obtained at near UV (350-400 nm) radiations for 3 s with ~35 mW/cm<sup>2</sup> exposure energy. The unexposed photoresist was developed in the SU-8 developer (MicroChem, USA) for 20 minutes. The exposure and development time were optimized to achieve sharp edges for the microposts. The developed SU-8 mold was silanized with (tridecafluoro-1,1,2,2-tetrahydrooctyl)-1-trichlorosilane (Sigma-Aldrich, Switzerland) to reduce adhesion between the SU-8 mold and PDMS. PDMS precursor and crosslinking agent (Sylgard 184 Silicone Elastomer, Dow Corning Corp., USA) were mixed at a ratio of 10 to 1, based on weight, and degassed in a vacuum chamber for 30 min. Then, the PDMS was poured on the mold, degassed, and cured at 80 °C for at least 1 hour. The cured PDMS layer was peeled off from the SU-8 mold and a hole puncher (1 mm in diameter) was used to punch the inlet and outlet ports. A microscope slide (Microscopes America, Inc., USA) was bonded to the PDMS layer using a plasma cleaner (Harrick Plasma Inc., USA) to complete the microfluidic device.

##### B. Experimental procedure and microscopy

Microchannel inlets were connected to syringes containing the oil and bacteria solutions using silicon tubes (TYGON R3607, Ismatec) and 21-gauge 90-degree-bent needle (APM Technica). *Marinobacter hydrocarbonoclasticus* culture of 2 days old was used for the experiments. Prior to the experiments, bacteria were centrifuged for 10 min at 2000 rpm and then resuspended in 200 µl of the culture medium. After loading the channels, microfluidic device was placed into the incubator stage of an inverted microscope for temperature and humidity control. An inverted microscope (Olympus IX83,

Germany) equipped with a CMOS camera (Zyla-4.2-CL10, ANDOR, Ireland) was used to capture 10x (numerical aperture (NA)=0.13, UPLanFL N) and 40x (NA 0.6, LUCPlanFL N) magnification bright-field image sequences of bacteria interacting with the oil in the microfluidic device. Freely available image processing software ImageJ (US National Institutes of Health) [20] was used to perform image analysis.

# Pneumatic Pressure Control: An Open-Source Droplet Microfluidic System

Run Ze Gao, Marie Hébert, and Carolyn L. Ren

Mechanical and Mechatronics Engineering

University of Waterloo

Waterloo, Canada

c3ren@uwaterloo.ca

**Abstract**— Open-source droplet microfluidic systems are envisioned to decrease the barriers to entry for exploration in new microfluidic research areas and increase adoptions in existing areas such as micro total analysis systems. At the heart of droplet microfluidics systems is a pneumatic pressure control system, which produces pulseless pressure-driven flow to manipulate nanoliter-sized droplet movement in microfluidic environments. Currently, this device remains a barrier regarding cost and performance. Commercially available off-the-shelf and customized systems offer high performance at a premium price and are proprietary which cannot be upgraded or modified. In-house built systems often do not exist due to long development cycles from the ground up. Hence, other than dedicated droplet microfluidics groups, compromises regarding the cost to performance ratio and development flexibility are taken by most.

This project presents a pneumatic pressure control system based on open-source hardware and software at a fraction of the cost and similar performance compared to premium commercial systems. All components are widely available through online suppliers. The code, design, and bill of material are made available for everyone on GitHub. The open-source nature of this project provides a gateway for many on a tight budget to tryout droplet microfluidics with the pulseless flow. This project is a small step in creating an open ecosystem for droplet microfluidics. Nonetheless, it enables an alternative to the rigid and non-standardized methodology that exists in the overarching microfluidics and lab on chip community today.

**Keywords - Microfluidics, pneumatic control, open-source**

## I. INTRODUCTION

Fluigent [1], Elveflow [2] and Dolomite [3] produces premium pneumatic controlled actuators commercially. These systems have high performance but lack flexibility due to

proprietary and closed-source nature of commercial products. The cost is also much higher than the open-source pneumatic pressure control system introduced here. This prevents the adoption of precision microfluidic control which is one the key area that must be developed for broad adoption of microfluidic and lab-on-chip technology.

## II. METHODOLOGY

The making of the open-source pneumatic control system for microfluidics involves two critical factors, component selection and procedure for assembly and testing as it must be reproducible by others. Fig. 1 shows the open-source system development steps.

Component selection is crucial due to the very nature of open-source projects. All parts are selected to be easily obtainable and widely available via reputable online sellers. The procedure for assembly and performance testing are streamlined.

### A. Materials

The components are purchased from online sellers, which are DigiKey, McMaster Carr, and Amazon. The pressure actuator is purchased from ControlAir. All components can be acquired worldwide.

### B. Procedure

The building procedure will be outlined in the standard operating procedure available on GitHub. The complete bill of material, software code, printed circuit board/soldered breadboard design, housing design and performance testing procedure will be available on GitHub as well. All resources available on GitHub for this pneumatic pressure control

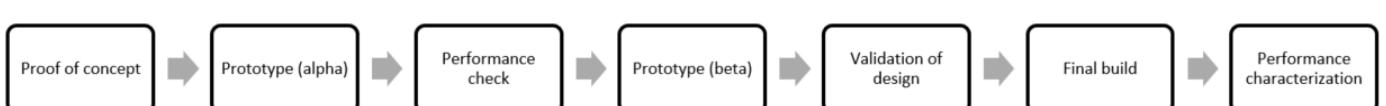

Figure 1. Open-source pneumatic pressure control system development process

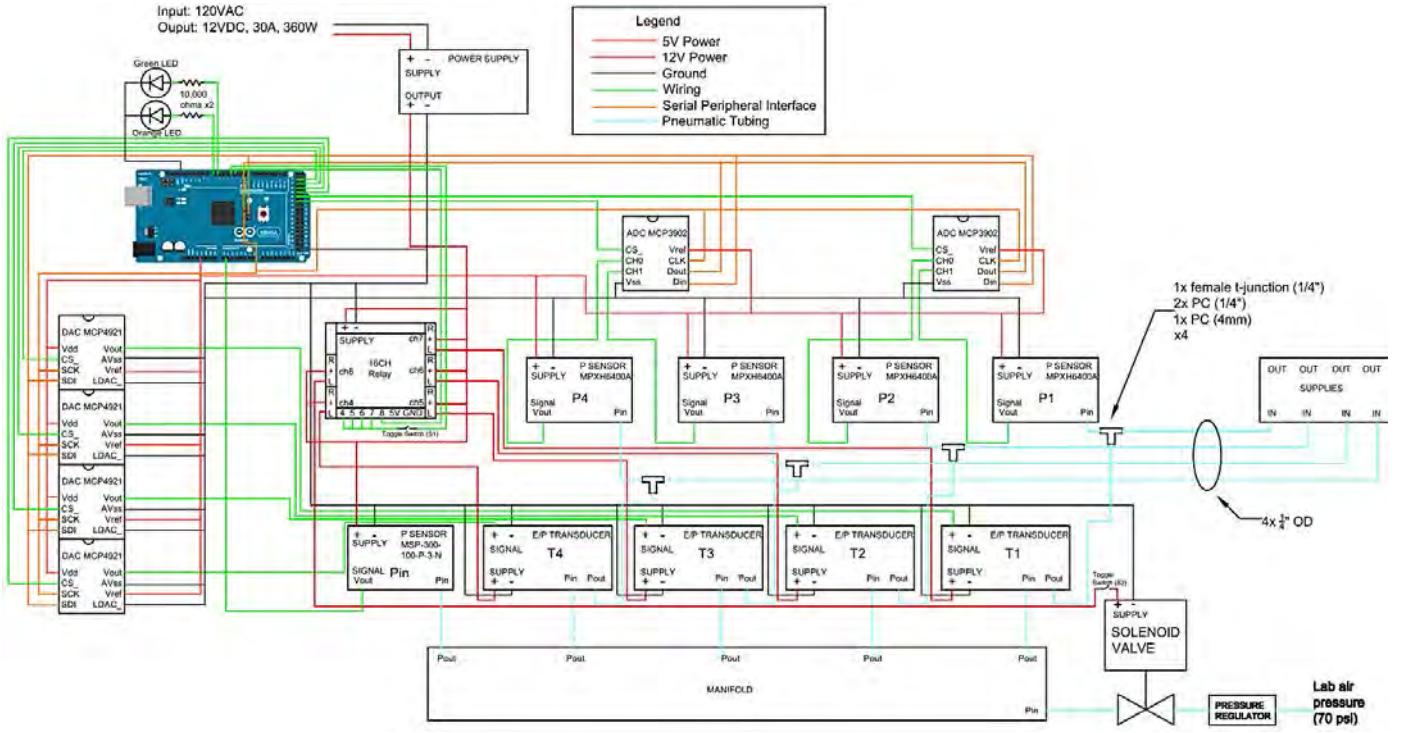

Figure 2. Open-source pneumatic pressure control system schematic

system will be open to everyone with General Public License.

The building procedure consists of populating the soldered breadboard or printed circuit board with electronic components, and system integration.

The performance and criteria validation procedure includes a signal to noise ratio testing, response testing, stability testing, and real-world performance testing.

### III. DESIGN

Due to the open-source nature of the project, the performance to cost ratio is crucial. Ideally, the performance should be on par with the premium commercial systems while being much cheaper than commercial units. Table 1 and Table 2 shows the design constraints and criteria. Fig. 1 shows the design schematic.

Table 1. Pneumatic pressure control system design constraints

Design Constraint	Constraint Value/Range	Description/Reasoning
Pressure range	0 to 2000mbar	Most microfluidics operates within this range.
Resolution	$\leq 0.5\text{mbar}$	For most application's sensitivity requirement, this resolution is sufficient.
Accuracy	$\pm 5\text{mbar}$	Physical flow is not affected by accuracy smaller than this (hypothesis).
Precision	$\pm 5\text{mbar}$	Physical flow is not affected by precision smaller than this (hypothesis).
Response time	$\leq 1\text{ second}$	Passive microfluidics does not require stringent response time as it operates mostly based on steady state pressure per

channel. Active-control systems are the same as it operates based on closed-loop feedback control of droplet position.

Settling time	$\leq 1\text{ second}$	Passive microfluidics does not require stringent settling time for the same reason as response time. Active-control systems operate based on droplet location rather than droplet velocity/acceleration, thus settling time is determined to be sufficient at this constraint.
---------------	------------------------	--

Table 2. Pneumatic pressure control system design criteria

Design Criteria	Description/Reasoning
Safe to operate	The system must have redundancy built-in to ensure electrical safety and pneumatic pressure safety for users.
Pulseless	The control system must produce pulseless flow during real-world operations in any microfluidics systems with any fluid.
Modular hardware design	Allow the user to build the system, change components, and upgrade hardware with ease.
Open source software	The open source software allows the user to continuously improve the software, and use any suitable control algorithm, and integrate with their system seamlessly.
Ease of maintenance	The user has the flexibility to carry out maintenance of any hardware by themselves with no patent or proprietary restrictions.

#### A. Control System and Data Acquisition

The control system consists of an Arduino Mega, which is open-source electronic incorporating a microcontroller ATmega 2560, and four MCP 4921 which are single channel 12-bit digital to analog converters (DAC). The DAC converts

digital control signals to analog signals for pneumatic pressure actuation through ControlAir T900.

The data acquisition system consists of two MCP 3202, which are two channel analog to digital converter (ADC) that converts analog signals from the external pressure sensor, MPX4250D, to digital signals feed into Arduino microcontroller used in feedback in the active-controlled microfluidic system, and user interface display in both passive and active-controlled microfluidic systems. Fig. 2 shows the full schematic of the four channel open-source pneumatic pressure control system.

### B. Pneumatic System

The pneumatic system consists four pressure actuators, ControlAir T900, which has a range of 0 to 2000mbar, with  $\pm 2$ mbar accuracy. Four pressure sensors, MPX4250D, are used to measure the pressure provided by the actuators, one sensor for each actuator. MPX4250D has a range of 0 to 2500 mbar, with an overall minimum accuracy of  $\pm 34.5$  mbar. Various tubing is used to deliver pneumatic pressure to fluid reservoirs, which will be included in the bill of material on GitHub.

### C. Software and User Interface

The software is written in C++. Arduino IDE is used for the control and operation algorithm of the open-source pneumatic pressure control system. This includes the system start-up sequence, system calibration sequence, a signal converting algorithm, serial peripheral interfacing, pressure command code for the pressure actuators, and pressure read code for the pressure sensors.

The graphical user interface (GUI) and computer-to-microcontroller communication are coded using MS Visual Studios based on QT framework. The design of the GUI is based on end-user suggestion as well as emulating premium commercial unit's GUI. GUI is designed to be minimalist to streamline the user experience. However, due to the open-source nature of the software, the GUI can be modified with additional or fewer functions, and the GUI can be integrated with other Windows-based operating system GUI. Fig.3 shows the graphical user interface.

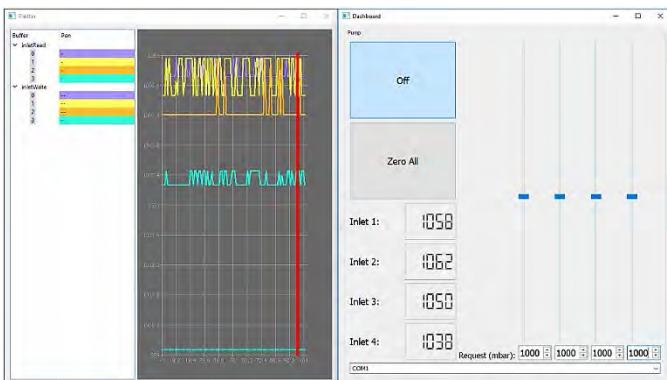

Figure 3. Open-source pneumatic pressure control system graphic user interface

## IV. TESTING AND VALIDATION

The signal testing is done using digital phosphor oscilloscope. The pressure performance testing and benchmarking is done using the prototype setup. Two different types of pressure sensors, MPX4250DP and MPXV5004 are used to conduct performance testing. A flow sensor, Sensirion SLG1430-480 is used to conduct real-world performance testing and benchmarking.

### A. Signal Noise Ratio

Noise is minimized by using eighth-order Butterworth, low pass filters, MAX7480, which provides ADC anti-aliasing and post-DAC filtering. Also, noise is further reduced by using precision 5V voltage reference, LM4040, which has an accuracy of 5mV. The result of which is that the pressure sensors and pressure actuators are operating within their manufacturer's specifications.

### B. Response Time

Fig. 4 shows the step response time of all four transducers increasing from 1000mbar to 2000mbar. The response time for each of the four transducers over this range is less than one second, which satisfies the response time and settling time constraints.

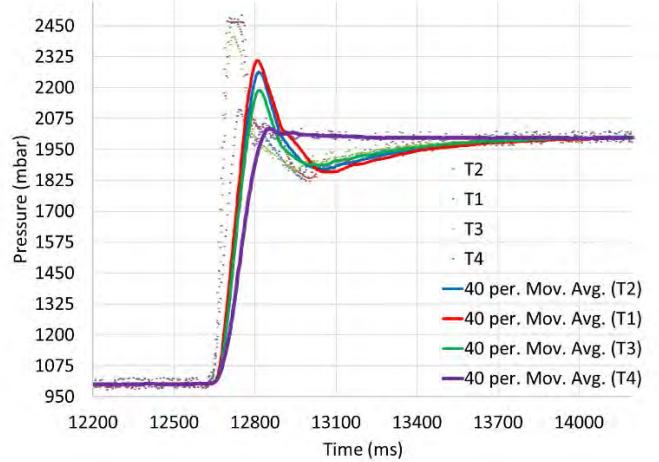

Figure 4. Response time and settling time of all four channels of the open-source pneumatic pressure control system

### C. Pressure Stability

Fig. 5 shows the pressure stability comparison between one of pneumatic pressure control system's channels and one of Fluigent MFCS EZ's channels. The data is taken at 20mbar. The two systems have similar performance regarding pressure stability. The accuracy and precision design constraints for pneumatic pressure control system are achieved.

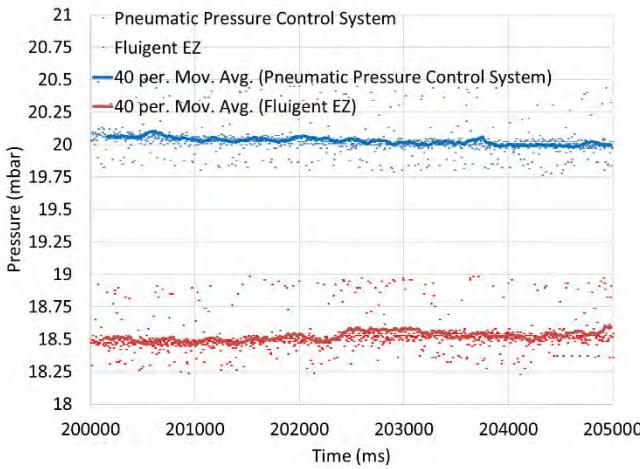

Figure 5. Pressure stability comparison between open-source pneumatic pressure control system and Fluigent MFCS EZ

#### D. Flow Rate Stability

Fig. 6 shows the flow rate stability comparison between one of pneumatic pressure control system's channels and one of Fluigent MFCS EZ's channels. The flow rate data are taken at 300mbar. Both systems display similar flow rate stability.

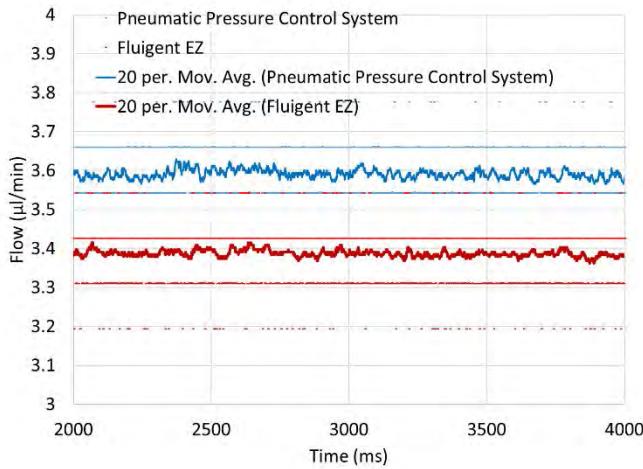

Figure 6. Flow Rate stability comparison between open-source pneumatic pressure control system and Fluigent MFCS EZ

## V. DISCUSSION

Safety features are built into the design. Soft stops are incorporated into the code which stops the communication when the pressure sensor reads sudden unexpected pressure spikes or drops or higher than operating limit pressure levels. Hard stops include physical toggle switches that shut the

supply power to the pneumatic solenoid and pressure actuators.

The testing and validations results show that the open-source pneumatic pressure control system can take full advantage of pressure actuator performance without sacrifice or compromise due to an analog signal to noise ratio. In other words, the precision and accuracy are limited by the pressure actuator. Also, precision is determined to be more important than accuracy as pulseless criteria is mostly concerned with precision. Overall, all of the design constraints and criteria are met.

The pressure stability test and flow rate stability test show that the open-source pneumatic pressure control system can achieve the same performance as Fluigent MFCS EZ. The difference between the two systems lies in the consistency in performance between channels/pressure actuators.

## VI. CONCLUSION

Safety features regarding pneumatic pressure and electricity have been incorporated into the design and build of the open-source pneumatic pressure control system. The testing and validation results show that the open-source pneumatic pressure control system can take full advantage of pressure actuator performance. Overall, all of the design constraints and criteria are met. The benchmarking shows that open-source pneumatic pressure control system has similar performance compared to Fluigent MFCS EZ while costing much less than a commercial system.

## ACKNOWLEDGMENT

The authors would like to thank Natural Science and Engineering Research Council, Canada, and Ontario Center of Excellence for the grants awarded to Professor Carolyn Ren.

# Drag Reduction and Heating

J.M. Floryan, S. Shadman, M.Z. Hossain  
 Department of Mechanical and Materials Engineering  
 Western University  
 London, Ontario, N6A5B9, Canada

**Abstract** - An external force is required to maintain the relative movement of horizontal plates. It is shown that this force is reduced when the plates are subject to a spatially distributed heating. The largest reduction occurs for heating wavelengths of the order of distance between the plates with its magnitude increasing proportionally to the second power of the relevant Rayleigh number. It is shown that a sufficiently strong heating eliminates the need for the driving force altogether. The effect is active only in small Reynolds number flows.

**Keywords** - drag reduction; heating

## I. INTRODUCTION

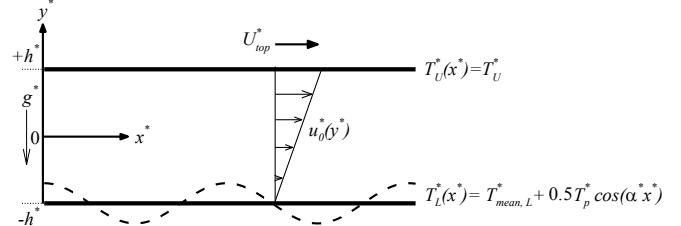

Friction between moving shafts found in numerous machines contributes to the energy cost of operating these devices. This cost may be estimated by determining force required to maintain the relative motion between these parts. Similar processes can be found in other applications, e.g. towing of a free-floating body in a shallow basin. In general flows which form in the space between two infinite plates, relative motion are well approximated by the Couette flow model, which is one of the family of simple flows frequently used in analyses.

Couette flow is characterized by the absence of streamwise pressure gradient, a linear velocity distribution across the fluid layer and the lack of the linear stability limit [1]. The nonlinear stability analyses are well reviewed in and demonstrate various routes to secondary finite-amplitude states as well as to turbulence. Surface modifications either in the form of transverse grooves [3], longitudinal grooves [4] or wall transpiration [5] can lead to centrifugal instabilities. Replacing the plane Couette flow with the annular Couette flow leads to shear instabilities [6]. Transition to secondary states leads to an increase in the wall shear and the need to increase the externally-imposed driving force. Such states should be avoided if minimization of energy cost is of interest.

Analyses of non-isothermal Couette flows are rather limited. They typically involve fluids with temperature-dependent material properties in a flow system exposed to a spatially uniform heating [7]. The addition of gravity brings in buoyancy effects which may generate secondary flows through the Rayleigh-Bénard (RB) instability [8,9] if the relevant critical conditions are met. Analyses of the resulting mixed

convection are well reviewed in [10]. The use of spatially non-uniform heating leads to structured convection which occurs regardless of the heating intensity, but which is yet to be studied in the case of Couette flow. It is known that such heating leads to the reduction of pressure losses in pressure-gradient driven flows [11-13].

The present work is part of a wider search for drag reducing methods which, in the present case, manifests itself in the form of reduction of the external force required to maintain the relative plate movement. One of the approaches is to assure stability of the flow so that transition to secondary states is avoided. Another approach, which is followed here, is to create spatial flow modulations which could lead to the reduction of shear and, thus, reduction of the driving force. The use of grooves for this purpose has been explored in [14-16]. This paper explores modulations created by spatially distributed heating.

dynamic viscosity  $\mu^*$ , thermal expansion coefficient  $\beta^*$  and with variations of density  $\rho^*$  described by the Boussinesq approximation. The gravitational acceleration  $g^*$  acts in the negative  $y$ -direction. The upper plate is pulled in the positive  $x$ -direction with a constant velocity  $U_{top}^*$  while the lower plate is stationary. When the system is isothermal, the drag force and the resulting flow field can be easily determined:

$$\mathbf{v}_0(x, y) = [u_0(y), 0] = \left[\frac{(1+y)}{2}, 0\right], p_0(x, y) = C, F_0 = 0.5 \quad (1)$$

where velocity has been scaled with  $U_{top}^*$  as the velocity scale,  $Q_0$  stands for the flow rate scaled with the same velocity scale,  $\tau_0$  stands for the shear acting on the upper plate scaled with  $U_{top}^* \mu^* / h^*$ ,  $F_0$  denotes the force per unit length and width required to drag the upper plate scaled with  $U_{top}^* \mu^* / h^*$  and the relevant Reynolds number is defined as  $Re = U_{top}^* h / \nu$ .

Introduce an external heating resulting in sinusoidal temperature variations along the lower plate,

$$T_L^*(x^*) = T_{mean,L}^* + 0.5 T_p^* \cos(\alpha^* x^*), \quad T_U^*(x^*) = T_U^*, \quad (2)$$

where the subscripts “mean” and “ $p$ ” refer to the mean and periodic parts, respectively,  $T_p^*$  is the peak-to-peak amplitude of the periodic component, and subscripts  $L$  and  $U$  refer to the lower and upper plates, respectively. Using the upper plate’s temperature for reference and introducing the relative temperature  $\theta^* = T^* - T_U^*$  lead to plates’ temperatures of the form

$$\theta_L^*(x) = \theta_{uni}^* + 0.5 \theta_p^* \cos(\alpha^* x^*), \quad \theta_U^*(x) = 0, \quad (3)$$

where  $\theta_{uni}^* = T_{mean,L}^* - T_U^*$ ,  $\theta_p^* = T_p^*$ . Using half of the gap height  $h^*$  as the length scale and  $\kappa^* \nu^* / (g^* \Gamma^* h^3)$  as the temperature scale results in the temperature boundary conditions of the form

$$\theta_L(x) = Ra_{uni} + 0.5 Ra_p \cos(\alpha x), \quad \theta_U(x) = 0, \quad (4)$$

where  $Ra_{uni} = g^* \Gamma^* h^3 T_{uni}^* / (\kappa^* \nu^*)$  is the uniform Rayleigh number measuring the intensity of the uniform heating,  $Ra_p = g^* \Gamma^* h^3 T_p^* / (\kappa^* \nu^*)$  is the periodic Rayleigh number measuring the intensity of the periodic heating, and all material properties are evaluated at the reference temperature  $T_U^*$ .

The field equations take the form

$$\begin{aligned} \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} &= 0, & u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} &= -\frac{\partial p}{\partial x} + \nabla^2 u, \\ u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} &= -\frac{\partial p}{\partial y} + \nabla^2 v + Pr^{-1} \theta, & u \frac{\partial \theta}{\partial x} + v \frac{\partial \theta}{\partial y} &= Pr^{-1} \nabla^2 \theta, \end{aligned} \quad (5)$$

where  $(u, v)$  are the velocity components in the  $(x, y)$  directions, respectively, scaled with  $U_v^* = \nu^* / h^*$  as the velocity scale,  $p$  stands for the pressure scaled with  $\rho^* U_v^{*2}$  as the pressure scale and  $Pr = \nu^* / \kappa^*$  is the Prandtl number. These equations are subject to boundary conditions (2.4) combined with

$$u(-1) = 0, \quad u(1) = Re, \quad v(-1) = 0, \quad v(1) = 0, \quad (6)$$

where  $U_{top}^* / U_v^* = Re$ . As the flow is driven by the movement of the upper plate, any effects associated with the mean pressure gradient are eliminated through imposition of constraint of the form

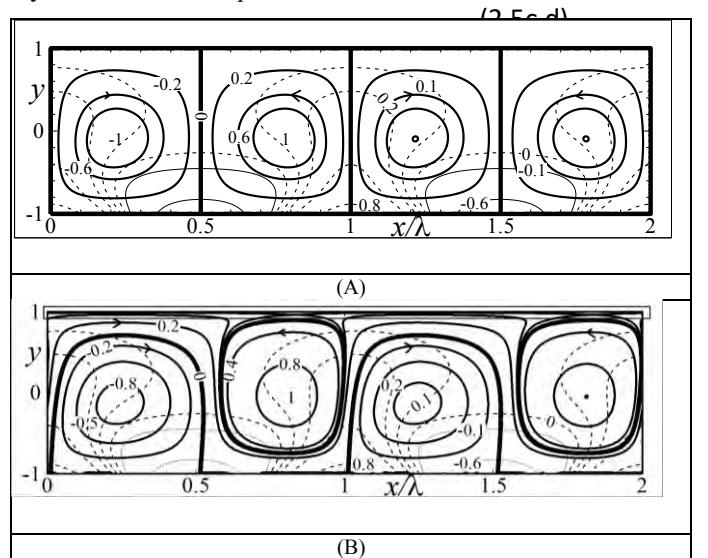

$$\left. \frac{\partial p}{\partial x} \right|_{mean} = 0. \quad (7)$$

Heating alters the flow resulting in the change of the driving force,  $\Delta F^* = F_0^* - F^*$ , which, when scaled with  $\rho^* U_v^{*2}$ , can be evaluated using the following relation

$$\Delta F = F_0 - F = Re \left( \frac{1}{2} - Re^{-1} \lambda^{-1} \int_0^\lambda \left. \frac{du}{dy} \right|_{y=1} dx \right). \quad (8)$$

### III. DISCUSSION OF RESULTS

Identical mean temperatures of both plates correspond to  $Ra_{uni} = 0$ . When the upper plate is stationary ( $Re = 0$ ), a purely periodic heating results in the formation of convective counter-rotating rolls with the fluid moving upwards above the hot spots and downwards above the cold spots, as illustrated in Fig.2a, and its temperature rising above the mean in most of the fluid volume. Slow movement of the upper plate ( $Re = 1$ ) results in a competition between the plate-driven and the buoyancy-driven motions. The flow topology is simple in the zones with the clockwise-rotating rolls as the roll movement is kinematically consistent with the plate movement, resulting in the formation of a single stream of fluid moving in the positive  $x$ -direction located in the immediate vicinity of the moving plate. A complex flow topology forms in the zones with the counterclockwise-rotating rolls as the fluid stream splits into two branches, one flowing above the rolls and one flowing beneath them. The upper branch is dominated by the plate effect, and the lower branch is dominated by the roll effect (see Fig.2b). Most of the fluid remains trapped in the rolls, i.e. either in the clockwise rolls attached to the lower plate or in the counter-clockwise rolls bounded by the two branches of the stream moving to the right. A further increase of the plate velocity ( $Re = 5$ ) results in the dominance of the plate-driven movement with most of the fluid moving to the right, the elimination of the counterclockwise rolls and the reduction of the size of the clockwise rolls (see Fig.2c) but with the buoyancy effects still providing a significant contribution to the overall flow dynamics. A further increase of  $Re$  results in the eventual elimination of the rolls (see topology for  $Re = 50$  in Fig.2D). The sequence of plots displayed in Fig.2 illustrates the process of formation of both the flow and boundary layers near the lower plate as  $Re$  increases.

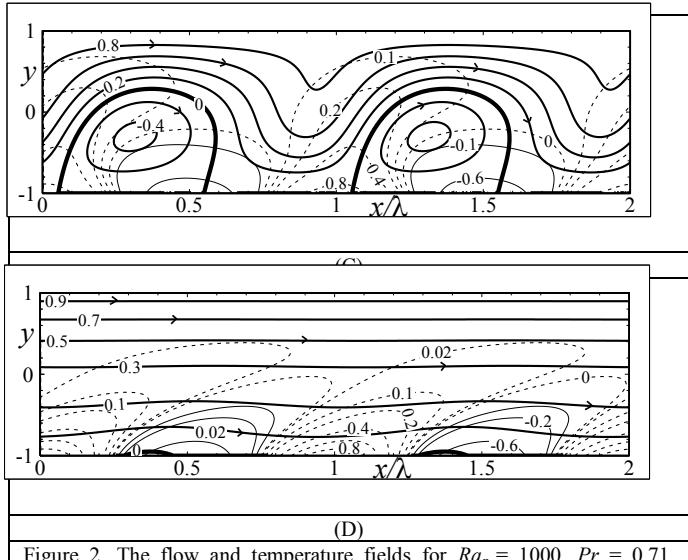

Figure 2. The flow and temperature fields for  $Ra_p = 1000$ ,  $Pr = 0.71$ ,  $Ra_{uni} = 0$ ,  $\alpha = 2$  and (A)  $Re = 0$ , (B)  $Re = 1$ , (C)  $Re = 5$ , (D)  $Re = 50$ . Thick solid lines identify streamlines, thin solid lines identify negative isotherms while thin dashed lines identify positive isotherms. Thick streamlines mark borders of bubbles trapping the fluid.

The results presented in Fig.3 demonstrate that all heating wave numbers lead to a decrease of the driving force with the magnitude of this reduction being a strong function of  $\alpha$ . The largest reduction occurs for  $\alpha \approx 1-2$  with its magnitude decreasing proportionally to  $\alpha^4$  if an excessively small  $\alpha$  is used. The flow and temperature fields (not shown) are qualitatively similar to those displayed in Fig. 2. The use of an excessively large  $\alpha$  also results in a reduction of  $\Delta F$  but at a much higher rate, i.e. proportionally to  $\alpha^{-7}$ .

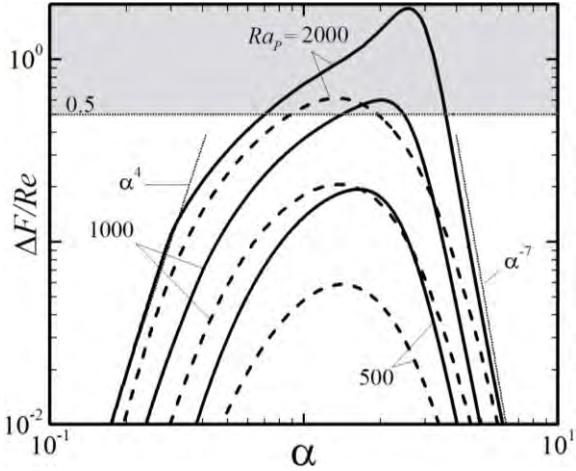

Figure 3. Variations of  $\Delta F/Re$  as a function of  $\alpha$  for  $Pr = 0.71$ ,  $Ra_{uni} = 0$ ,  $Re = 1$  (solid lines) and  $Re = 10$  (dashed lines). Thin dotted lines identify asymptotes. The shaded area identifies conditions where the driving force must change direction and becomes a braking force.

The force-reducing effect is a strong function of  $Re$  (see Fig.4). The magnitude of  $\Delta F$  increases proportionally to  $Re$  for small  $Re$ 's, reaches a maximum at  $Re \sim 5-6$  and then decreases at a rate proportional to  $Re^{-2}$ . The flow topologies displayed in Fig.2 show that the elimination of  $\Delta F$  is associated with the

reduction of convection bubbles and confinement of convection effects to a thin boundary layer near the lower plate.

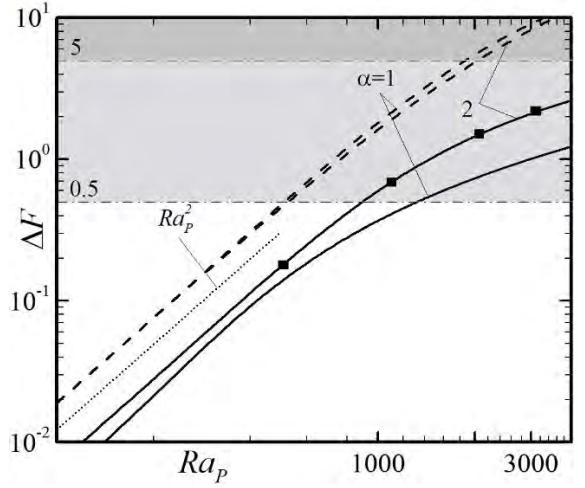

Figure 4. Variations of  $\Delta F$  as a function of  $Ra_p$  for  $Pr = 0.71$ ,  $Ra_{uni} = 0$ ,  $Re = 1$  (solid lines) and  $Re = 10$  (dashed lines). The shaded area identifies conditions where the driving force must change direction and becomes a braking force when  $Re = 1$  and the double shaded area identifies such conditions for  $Re = 10$ .

As it is unlikely that the mean temperatures of both plates can be kept equal, it is of interest to determine how their difference may affect the system response. This difference is expressed in the analysis as the uniform Rayleigh number  $Ra_{uni}$  whose positive (negative) values correspond to the lower plate being hotter (cooler). The results displayed in Fig.5 demonstrate that the uniform heating increases  $\Delta F$  while cooling decreases it, and the change is approximately linear with  $Ra_{uni}$ .

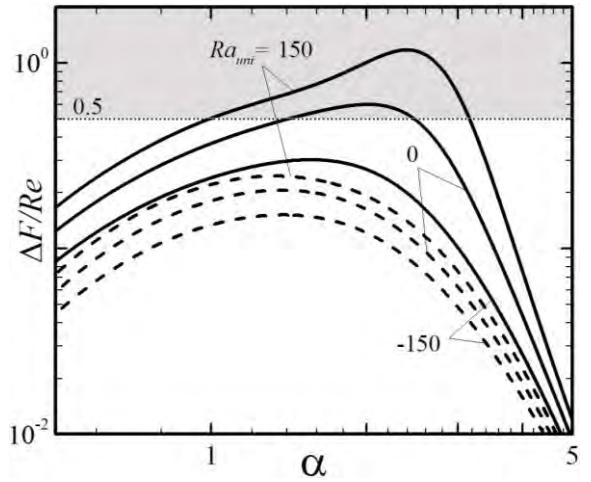

Figure 5. Variations of  $\Delta F/Re$  as a function of  $\alpha$  for  $Re = 1$  (solid lines) and  $Re = 10$  (dashed lines),  $Ra_p = 1000$ ,  $Pr = 0.71$ . The shaded area identifies conditions where the driving force changes direction and becomes a braking force.

#### IV. SUMMARY

An external force is required to generate a relative motion between horizontal plates with the rate of this motion expressed in terms of the Reynolds number  $Re$ . The effects of spatially distributed heating on the magnitude of this force have been analyzed. Heating resulting in the lower plate temperature varying sinusoidally in the horizontal direction, with its amplitude expressed in terms of a periodic Rayleigh number  $Ra_p$  and the spatial distribution described by the wave number  $\alpha$ , has been considered. The analysis has been limited to  $Ra_p < 3000$  to avoid condition leading to a potential formation of secondary flows. The difference between the mean plates' temperatures has been expressed in terms of the uniform Rayleigh number  $Ra_{uni}$  with positive values corresponding to a warmer lower plate. The fluid motion results from a competition between the buoyancy-driven effects and the plate-driven movement. The former has the form of counter-rotating rolls whose distribution is dictated by the heating pattern. The latter one adds a rectilinear motion which leads to the reduction and eventual elimination of the rolls if  $Re$  is large enough.

It has been shown that periodic heating always reduces the driving force, regardless of whether the heating is applied to the lower or upper plate, but the magnitude of this reduction is a strong function of the heating wave number. The largest reduction is achieved for  $\alpha = 1\text{--}2$  with a rapid decrease of this effect when either too small or too large  $\alpha$ 's are used. An increase in  $Ra_{uni}$  magnifies this effect. An increase in  $Re$  eliminates the rolls and reduces this effect, leading to its practical elimination for  $Re > 30\text{--}50$  depending on the heating intensity. The use of proper heating intensity and distribution results in the complete elimination of the driving force as the plate movement can be supported by the buoyancy effects only. Conditions where an external braking force needs to be used to prevent the plate from accelerating have also been identified.

**Abstract**—This paper provides a comparison between the separation efficiency in cyclones separators using two optimization techniques. Separation optimizations using ferrous powder, and additional tangential chamber were investigated. The proposed techniques show separation efficiency enhancements compared to the basic cyclone separator design. The separation ratio efficiency,  $\varepsilon_{sp}$ , is evaluated by calculating the outlet to inlet count ratio. Similar to experimental studies in the literature, the inlet and outlet particle counts were evaluated using discretization techniques with the help of a microscope and a membrane collecting the dust at the outlet. It is observed from the two optimization techniques that the addition of ferrous powder while attracting it through magnetic forces provides an additional separation enhancement by 2% for 11  $\mu\text{m}$  particles sizes. This advantage comes with a total of 25% efficiency enhancement for 4  $\mu\text{m}$  particles compared to conventional designs. This study gives an insight on the different approaches proposed.

**Keywords-component;** cyclone separators; efficiency; ferrous powder; tangential chambers

## I. INTRODUCTION

There has been an increasing demand for natural gas extraction in the last 50 years [1]. To meet this demand efficiently, there have been advances in all the natural gas processes. A special attention had been given to natural gas treatment process by which the natural gas is cleaned from residues and unwanted particles [2]. The efficiency enhancement in gas treatment leads to reduction in energy consumption, which in turns reduces the overall CO<sub>2</sub> emissions into the environment.

The removal of solid and liquid particles is among the most important processes in natural gas treatment [2]. It is essential to remove the solid particles from the gas stream as they are considered to be the main reason in damaging the downstream equipment such as compressors, pressure vessels and heat exchangers. Many techniques have been innovated to remove these particles from the natural gas stream. Among the evolving technologies used to remove solid particles are the cyclone separators. Cyclone separators consist of a major barrel

and a conical chamber by which the solid particles are separated from the main stream by centrifugal forces [3]. Compared to other solid-gas separators, the main drawback of cyclone separators would be its inability to separate small sized particles (i.e. particles smaller than 3  $\mu\text{m}$  at efficiencies higher than 75%). On the other hand, cyclone separators have an advantage among other types of solid-gas separators (such as cartridge filters) and that is its low operating cost as well as its simple design [3].

Many researchers have focused on enhancing the cyclone separator efficiency. Among those, Kim et al. [4] proposed the introduction of guiding vanes to enhance the separation efficiency. Their results indicate an increase by 27% in separation efficiency for 4  $\mu\text{m}$  particles. Another study conducted by Lim et al. [5] investigated splitting the inlet of the cyclone separators into two parts. Their results showed a separation efficiency increase by 15% as compared to the conventional one inlet cyclone separator. In a similar study, Xiong et al. [6] attached vortex finders at the inlet of the cyclone separator. Their analysis showed that helical profile vortex finders could enhance the separation efficiency by 9% compared the straight profile vortex finders. Xiang et al. [7] also studied the effect of the conical chamber dimensions on the separation efficiency. Their study findings indicate that a decrease in the bottom radius of the cone from 19.4 mm to 11.6 mm would enhance the separation efficiency by 16%. Yoshida et al. [8] suggested the study of the conical length effect on the separation efficiency. Their analysis showed that the 50% cut size was reduced. Park et al. [9] also investigated the effect of allocating cyclone separators in series with step-up cyclone chamber diameters. The first cyclone could segregate particle sizes ranging from 4.5 – 11  $\mu\text{m}$ , the second cyclone could segregate particle sizes ranging from 3.4 – 7.9  $\mu\text{m}$ , and the third cyclone could segregate particle sizes ranging from 1.8 – 4.3  $\mu\text{m}$ . The injection of mist was another proposed study analyzed by Yang and Yoshida [10]. In their analysis, they were able to achieve a 20% efficiency enhancement for 1  $\mu\text{m}$  particle size capturing at 20 m/s inlet velocity.

Although many investigators have reached an enhancement in the separation efficiency, this study compares between two novel and simple techniques for separation efficiency enhancement.

## II. METHODOLOGY

In this study, a conventional cyclone separator based on Stairmand's design [11] was modified. Two modification techniques were applied. The first method studies the effect of adding ferrous powder along with magnets to enhance the separation efficiency. The magnetic force will act in the direction of the centrifugal force, and hence, separation efficiency will be enhanced. The second method studies the effect of adding a tangential collecting chamber at the conical section of the separator. As particle velocities increase in this section of the cyclone separator, the tangential collecting chamber will increase the tendency of capturing smaller solid particles at a higher rate, and hence, separation efficiency will be enhanced.

### A. Ferrous Powder Addition

This novel technique involves mixing the gas-solid inlet mixture with adhesive ferrous powder. Particles entering with the gas flow get attached to ferrous powder through a helical mixing chamber. The solid particles will stick to the adhesive ferrous powder and then get attracted by permanent magnets attached to the walls of the cyclone separator in the major barrel [12]. The additional magnetic force is applied radially in the same direction as the centrifugal force; therefore, separation forces would increase and increase the separation efficiency. Figure 1 shows a schematic of the attraction process.

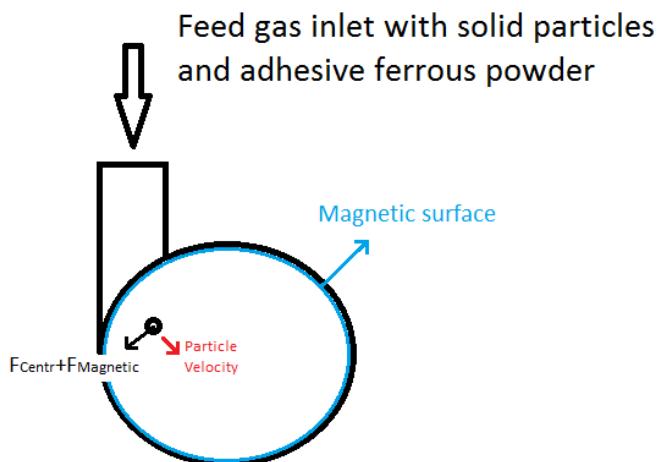

Figure 1: Schematic of ferrous powder addition

### B. Additional Tangential Chamber

This novel technique suggests the use of an additional opening (collecting chamber) located at the conical section of the cyclone separator. The aim of the additional chamber is to collect particles at their highest angular velocities. Higher velocities conclude that the particles have higher tendency to reach outer walls of the conical section [13]. The additional collecting chamber at the conical section would increase the chances of collecting more particles reaching the walls of the conical chamber. This approach will reduce the possibility of escaping particles after bouncing off the conical chamber walls and escape with clean gas. Figure 2 shows an image of the additional tangential chamber located at the conical part of the cyclone separator.

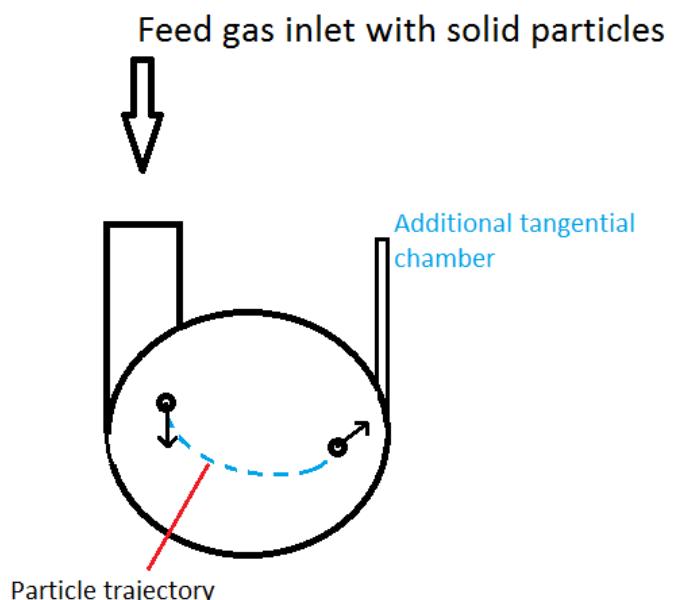

Figure 2: Additional conical tangential chamber

In both setups, the escaped solid particles are captured on a Whatman GE Healthcare membrane at the outlet stream. The exit outlet particles are also analyzed using the Qualitest Digital Microscope.

## III. RESULTS AND DISCUSSIONS

The separation efficiency evaluated in this study ( $\varepsilon_{sp}$ ) is an indication of the cyclone separator performance. Therefore, higher values of the separation efficiencies indicate an enhanced cyclone separator and vice versa.

### A. The Effect of Ferrous Powder Addition

Adding ferrous powder to the solid particles stream and recapturing the mixed (ferrous-solid) combination adds to the centrifugal force behaving on the solid particles in traditional cyclone separators. The additional force increases the chances of solid particles to reach the outer walls and get separated. Thus, the separation efficiency enhancement shown in Figure 3 explains the effect of the additional magnetic force compared to tradition cyclone separator performance.

### B. The effect of adding a tangential chamber

Adding a tangential collection chamber at the conical section of the cyclone separator plays the role of capturing particles which reach the walls of the cone. This method raises the opportunity of capturing these particles while reducing the percentage of escaping particles with the fluid flow after hitting the walls. Thus, the separation efficiency enhancement shown in Figure 3 explains the effect of the additional tangential chamber compared to tradition cyclone separator performance

The separation efficiency results of both proposed techniques are shown in Figure 3. It is very clear that both techniques add to the separation efficiency. The minimum enhancement that both techniques provide is 25% at 4  $\mu\text{m}$

particles and 3% at 11  $\mu\text{m}$  particle sizes. Moreover, the separation efficiency enhancement using ferrous powder show better performance as compared to tangential chamber performance (i.e. ferrous powder technique shows a 2% higher separation performance compared to the tangential chamber addition). This enhancement could be due to a consistent force applied to all particles via the magnetic field. However, in the additional chamber process, not all particles will reach the outer walls of the cone at the chamber's opening. Therefore, the reduction of the tangential chamber performance compared to the ferrous powder is explained.

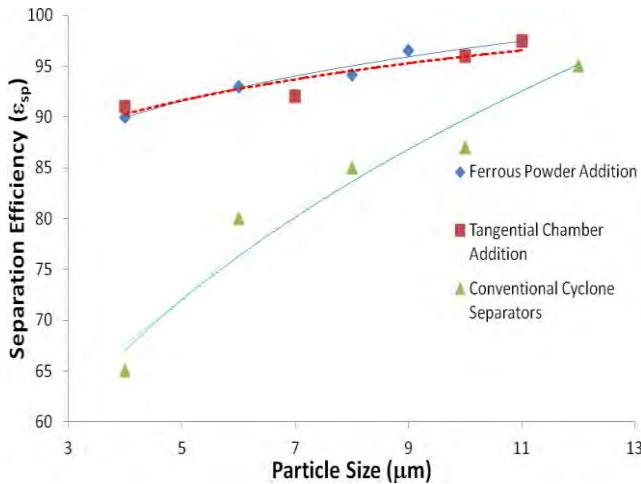

Figure 3: Comparison between proposed novel methods

#### IV. CONCLUSIONS

The comparison between two novel techniques was investigated in this paper. Results show that these techniques, the ferrous powder addition and the tangential chamber addition enhance the separation efficiency of solid particles. On the other hand, the ferrous powder addition shows a better performance for larger particles as compared to the tangential chamber addition. Ferrous powder addition shows a 2% enhanced efficiency over the addition of the tangential chamber. This could represent the nature of the continuous attraction force exerted by the magnets on solid-ferrous particles combination. None the less, both approaches provide a minimum enhancement of at least 25% for 4  $\mu\text{m}$  particles. Thus, further research in the future could allow cyclone

separators to have higher separation efficiencies and could allow cyclones separators to replace cartridge filters. Therefore, lower maintenance time and cost would be saved in the filtration industry.

**Abstract**—The impact and evaporation of droplets impinging on a heated porous substrate is relevant to applications such as fire suppression by sprinkler systems, spray cooling of heated surfaces, and the deposition of fuel droplets on combustor walls. Design involving these sub systems requires an understanding of the heat and mass transfer between the droplet and porous surface. An experimental study was done in which pure water and n-heptane droplets were deposited onto porous, stainless steel surfaces made from sintered powders with varying pore size (5  $\mu\text{m}$  and 100  $\mu\text{m}$ ). n-Heptane was chosen to compare the effects of surface tension on the evaporation process. Initial surface temperatures were varied from 60°C to 300°C. Results were compared with those for droplet evaporation on a solid, impermeable stainless steel surface. On porous surfaces, it is difficult to determine when a droplet has completely evaporated from video images, since liquid penetrates into the surface pores. At low wall temperatures (60°C to 120°C), droplet evaporation was measured by placing the heated surface on a digital scale and recording the weight decrease as a function of time. At high wall temperatures (above 120°C), video techniques were employed to capture evaporation times. At high wall temperatures, the porous surfaces were the most effective at vaporizing both the pure water, and n-heptane droplets, resulting in the lowest evaporation times. At low wall temperatures the porous surfaces became less effective at transferring heat to both the water and n-heptane. For n-heptane the evaporation times increased on the porous surfaces as compared to the impermeable surface. Similar results could be seen with the water on the 100  $\mu\text{m}$  surface. The Leidenfrost transition point was shown to increase with porosity. Droplet levitation was not achieved with the water on the porous surfaces, however due to the lower heat of vaporization of n-heptane it was achieved on the 5  $\mu\text{m}$  and 100  $\mu\text{m}$  substrates at surface temperatures of 225°C and 285°C respectively.

**Keywords:** *Porous media, Evaporation, Stainless steel, Water, n-Heptane, Pore size, Leidenfrost point*

Liquid droplet impact on hot porous surfaces is studied due to its significance in a wide variety of spray cooling applications. These include, cooling of reactors in nuclear power plants; fire suppression by sprinkler systems; and the deposition of fuel droplets on combustion chamber walls. In the fire extinguishment process, water can be used to both extinguish flames, and prevent the flame spread by cooling surfaces that have not yet been ignited. However, the use of large amounts of water can cause secondary fire damage encouraging research into this area to reduce the amount of water used. As fires can involve the burning of porous materials (e.g. wood, fabrics, papers), understanding the thermal effects of droplet impingement on hot porous surfaces will assist in predicting the quantity of water needed for sufficient cooling of the surface while minimizing secondary damage. In addition to fire suppression systems, the evaporation of fuel droplets on heated surfaces is of critical importance in the design of combustion devices. Optimizing droplet evaporation times is important in ensuring improved combustion efficiencies, and reducing gaseous emissions during the combustion process.

The total evaporation time of a droplet is dependent on several key parameters. Reference [1] stated that the heat transfer rate to the droplet is governed by the fluid and solid thermal properties, as well as the surface roughness and temperature. The surface temperature was described as the most significant parameter as it is used to define the heat transfer regime the droplet resides in (i.e. single phase evaporation, nucleate boiling, and film boiling). However, porous surfaces substantially alter the impact dynamics and heat transfer to the droplet. A droplet impinged on a porous substrate will not only spread over the surface, but penetrate into the surface pores. This pore penetration can enhance the heat transfer to the fluid and is known to depend on the properties of both the liquid and the porous substrate (i.e. pore size, porosity, wettability) [2]. The critical parameter influencing the impact behavior of the droplet is the Weber number. The Weber number,  $We$ , is defined as the ratio of the droplets inertial to surface tension forces.

$$We = \frac{\rho_f u_o^2 d_o}{\sigma} \quad (1)$$

The present work reports the results of an experimental study involving the evaporation of pure water and n-heptane ( $C_7H_{16}$ ) droplets deposited on hot porous substrates with different pore sizes, and varying surface temperatures. n-Heptane was chosen since it has lower surface tension and higher wettability compared to water and penetrated more easily into surface pores. A digital scale was the measurement technique used at low wall temperatures, where the evaporation times were captured from weight decrease as a function of time plots. There were two main objectives for this work: (1) measure droplet evaporation times using a weight-time approach at low wall temperatures to remove the uncertainty associated when using imaging techniques, and (2) to compare the effects of fluid surface tension on the impact and evaporation of a droplet when impinged on a porous substrate with different surface temperatures.

## II. EXPERIMENTAL METHOD AND CONDITIONS

Fig. 1 shows a schematic of the experimental setup employed to observe the droplet evaporation of a pure water and n-heptane droplet on a heated sintered 316 stainless steel porous substrate (5  $\mu m$  and 100  $\mu m$  average pore size, see Fig. 2). The results were compared with those for droplet evaporation on a solid, impermeable 316 stainless steel substrate. The arithmetic average surface roughness  $R_a$  for the impermeable, 5  $\mu m$  and 100  $\mu m$  surfaces are  $0.100 \pm 0.004 \mu m$ ,  $4.7 \pm 0.1 \mu m$  and  $12.2 \pm 1.6 \mu m$  respectively. All surfaces were square, 45 mm x 45 mm in size and 1.5 mm thick. Surface temperatures were varied from 60°C to 300°C. A gauge 24 K-type thermocouple was fixed using Omega CC high temperature cement to the surface of each of the substrates. The surface temperatures were monitored using a wireless thermocouple connector (MWTC-D-K-915, Omega Engineering, Laval, Quebec, Canada) and droplet evaporation was experimentally observed in the evaporative, nucleate boiling, and film boiling regimes.

Using a syringe pump (NE-1000, New Era Pump Systems, Farmingdale, New York, United States), 2.5 mm diameter droplets were formed with a gauge 26 blunt hypodermic needle for pure water, and a gauge 16 blunt needle for n-heptane. A larger needle was used for n-heptane due to its lower surface tension. Measurements of the droplet weight showed a drop-to-drop variation of less than  $\pm 2\%$ . The droplets formed on the needle tip, and once large enough would detach under their own weight. Due to n-heptane's solvent characteristics, a glass syringe, along with stainless steel fittings and chemical resistant PVC tubing were used to prevent contamination of the working fluid.

The impact velocity was controlled by adjusting the vertical distance from the tip of the needle to the top of the substrate, and was fixed at  $50 \pm 1$  mm for the experiments. The impact velocities for the pure water and n-heptane droplets at the time of impact were 0.9 m/s. The velocity measurements were determined from high speed imaging where they varied by  $\pm 5\%$

for the water and  $\pm 9\%$  for the n-heptane. The Weber numbers associated with these drop velocities are 29 and 65 respectively.

At surface temperatures ranging from 60°C to 120°C, setup Fig. 1a was employed to capture droplet evaporation. A 3D printed plastic holder was created to hold an aluminum thermal mass (45 mm x 45 mm x 20 mm thick) in which the substrate would sit, and was heated using a single 100W cartridge heater. The voltage applied to the heaters was adjusted with a 120V variac and the substrate surface temperature was regulated using a temperature controller (CN9000A, Omega Engineering, Laval, Quebec, Canada) and could be controlled to  $\pm 0.1^\circ C$ . Droplet evaporation was measured by placing the heated apparatus equipped with the surface on a digital scale (AG245, Mettler Toledo, Mississauga, Ontario, Canada) and recording the weight decrease as a function of time as the droplet evaporated.

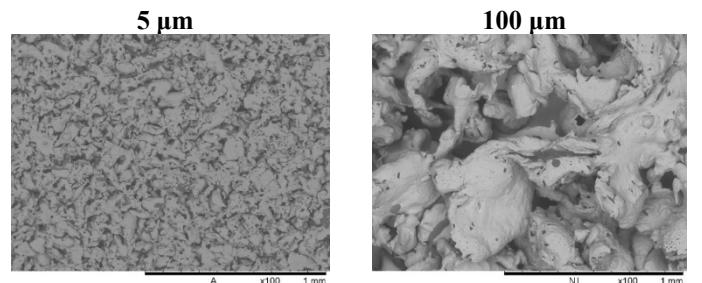

Figure 2. SEM images of the sintered porous stainless steel samples (5  $\mu m$  and 100  $\mu m$  average pore size) used during experimentation. Substrate dimensions: 45 mm x 45 mm by 1.5 mm thick.

With surface temperatures above 120°C, due to limitations with the 3D printed polylactic acid (PLA) substrate holder having a maximum operating temperature of approximately 150°C [9], and the scale having a maximum sample rate of 3Hz, setup Fig. 1b was employed. This setup used a larger aluminum thermal mass (70 mm wide x 75 mm long x 40 mm thick) equipped with two, 200W cartridge heaters wired in parallel and powered by a 120V variac used to regulate the heater output. The high-speed camera (Fastcam SA5, Photron, Tokyo, Japan) equipped with a bellows and 105 mm lens, was used to capture evaporation times at frame rates of 1000 to 5000 fps.

Surface temperatures of 150°C and above were in the nucleate boiling regime for both water and n-heptane, and evaporation was fast enough to prevent significant spreading of the absorbed liquid. As a result, the evaporation time of the deposited liquid coincided with the disappearance of the dry out front. All experiments were performed at an ambient room temperature of 23°C ±3°C.

### III. RESULTS AND DISCUSSION

The difference in evaporation times observed between the pure water and n-heptane are closely tied to the differences in fluid properties and how that affects the behavior of the droplet as it impacts on the porous surfaces. Figs. 3 and 4 show image sequences of the first 25 milliseconds immediately after impact of pure water (Fig. 3) and n-heptane (Fig. 4) droplets impinging on (a) an impervious surface, (b) a surface with 5 µm pores and (c) a surface with 100 µm pores. The initial surface temperature in all cases was 250°C. Droplets were deposited from a 50 mm drop height. The water and n-heptane droplets evolution on all three surfaces starts off similar during the first 2.4 ms except for the spread factor which is larger with the n-heptane as compared to the water on the same surface due to n-heptane's lower surface tension. The spread factor ( $\beta$ ) is the dynamic spread diameter of the droplet after impact normalized by the initial droplet diameter ( $\beta_{\text{film}} = D_{\text{film}}/d_0$ ). The lower surface tension allows inertial forces to play the dominant role during droplet impact where the formation of the liquid jet can span a larger distance before viscous dissipation, surface tension and surface roughness effects dissipate the kinetic energy and bring the droplet to a stop. The surface roughness can be seen impeding the droplet spread as porosity is increased with both water and n-heptane. The water droplet begins its upwards levitation at 10 ms on the impervious surface (see Fig. 3a) while this process is observed to be delayed with the n-heptane (see Fig. 4a). This appears to be due to n-heptane's larger contact area, where the droplet has a longer distance to recoil before levitation of the bulk fluid occurs. Similarly, instability at the rim of the lamella for n-heptane takes effect early in the spreading process at 1 ms for all three surfaces. The fingering is a source for satellite droplets which can be seen being ejected from the bulk of the fluid at 10 to 25 ms. The Leidenfrost point (LP) was achieved with the water on the impervious surface only, and with the n-heptane on all surfaces, porous and impervious. The delayed

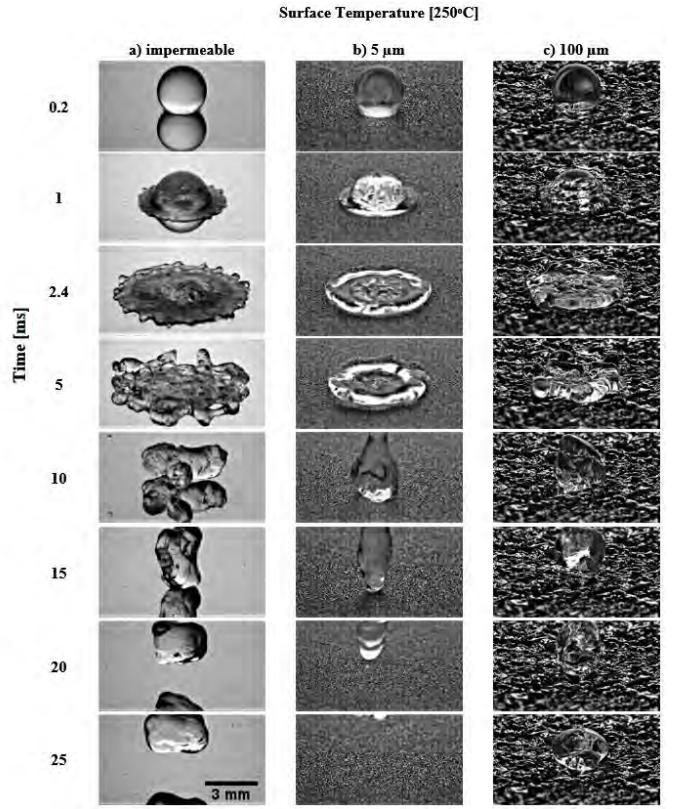

Figure 3. Water droplet impact on the (a) impermeable, (b) 5 µm and (c) 100 µm surfaces. Surface temperature  $T_w = 250^\circ\text{C}$  (film boiling regime),  $V_i = 0.9 \text{ m/s} \pm 5\%$ ,  $d_0 = 2.5 \text{ mm} \pm 2\%$ ,  $We = 29$ .

onset of the LP is due to the vapors produced during evaporation being able to permeate through the porous structure preventing vapor pressures from building between the solid-liquid interface, and allowing the fluid to remain in contact with the surface at increased temperatures. Direct contact heat transfer across a solid-liquid interface is higher than across a vapor gap improving the evaporation times in the film boiling regime. Droplet levitation occurred with the n-heptane on the porous surfaces due to its lower heat of vaporization. It takes less energy to cause a phase change, where the rate of vapor production as a result would increase. The pressures build underneath the droplet providing the necessary forces required for levitation.

Curves of the droplet lifetime as a function of surface temperature can be used to determine when changes occur during the evaporation and impact process [4]. For both pure water and n-heptane, the droplet lifetime curves as a function of surface temperature followed similar trends and are shown in Figs. 5 and 6 respectively. A graph insert is shown in each of the plots, utilizing a log time scale to clearly illustrate the difference in evaporation times between the three surfaces at temperatures ranging from 150°C to 300°C. As the surface temperature was raised, evaporation times decreased until a minimum was reached, corresponding to the critical heat flux (CHF) point. For pure water on the impervious and the 100 µm surfaces, the CHF occurred at approximately 200°C. The CHF for the 5 µm surface occurred at 150°C. Similarly, for the n-heptane the CHF for all

Surface Temperature [250°C]

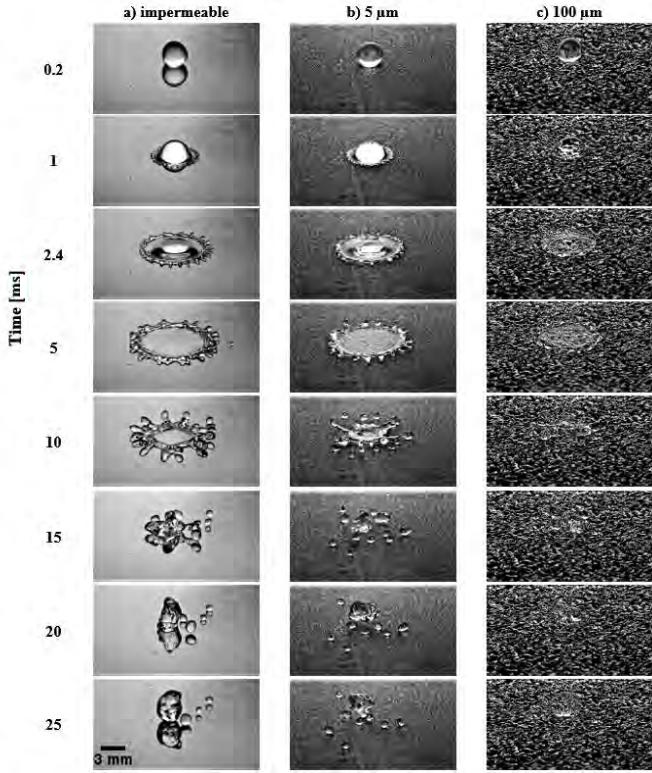

Figure 4. n-Heptane droplet impact on the (a) impermeable, (b) 5  $\mu\text{m}$  and (c) 100  $\mu\text{m}$  surfaces. Surface temperature  $T_w = 250^\circ\text{C}$  (film boiling regime),  $V_i = 0.9 \text{ m/s} \pm 9\%$ ,  $d_o = 2.5 \text{ mm} \pm 2\%$ ,  $We = 65$ .

three surfaces happened at approximately 150°C. At low wall temperatures ranging between 60°C to 120°C the ability of the porous substrates to effectively vaporize the water and n-heptane droplets displayed significantly different results. The water droplet evaporated the fastest on the 5  $\mu\text{m}$  surface while the n-heptane droplet on average evaporated the slowest as compared with the impervious and 100  $\mu\text{m}$  surfaces. The reduced times

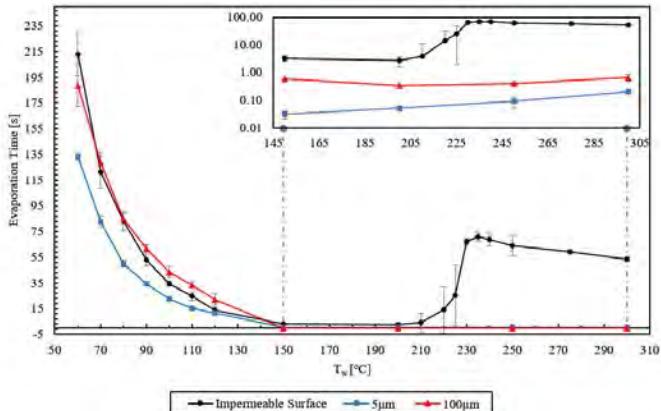

Figure 5. Evaporation time as a function of the surface temperature for the (a) impermeable, (b) 5  $\mu\text{m}$  and (c) 100  $\mu\text{m}$  surfaces using pure water as the working fluid. A graph insert is shown at surface temperatures ranging from 150°C to 300°C using a log time scale to show evaporation time differences between the surfaces.

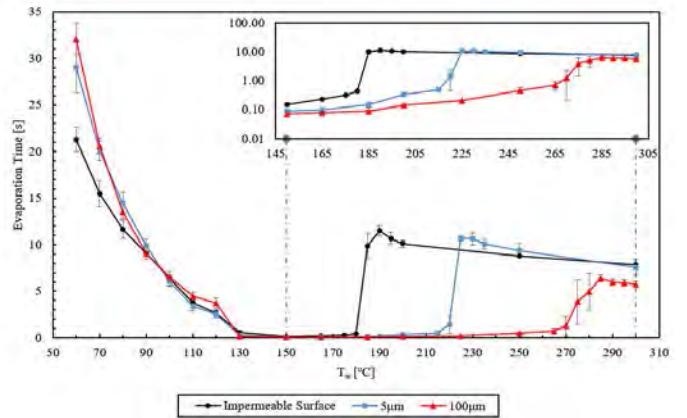

Figure 6. Evaporation time as a function of the surface temperature for the (a) impermeable, (b) 5  $\mu\text{m}$  and (c) 100  $\mu\text{m}$  surfaces using n-heptane as the working fluid. A graph insert is shown at surface temperatures ranging from 150°C to 300°C using a log time scale to show evaporation time differences between the surfaces.

with the water is attributed to an increase in the total contact area that can be achieved as the water permeates into the porous structure. As the primary mode of heat transfer within this temperature range is heat conduction, this would increase the rate of heat transfer to the fluid reducing overall evaporation times. Moreover, the increased evaporation times observed with the n-heptane can be attributed to the fluids lower surface tension. The reduction in surface tension substantially improves the rate at which n-heptane penetrates the surface pores causing the fluid to pool at the bottom of the substrate before fully evaporating. Due to n-heptane's low heat of vaporization and the lower permeability of the 5  $\mu\text{m}$  surface, vapor pressures build up more rapidly within the substrate, reducing heat transfer and increasing the time required for complete evaporation. Similar behavior can be observed with the water and n-heptane on the 100  $\mu\text{m}$  surface within this temperature range. As wall temperatures were raised, ranging from 150°C to 300°C, the porous substrates were the most effective at vaporizing both the water and n-heptane droplets before the LP was reached. This behavior suggests that the substrate structure plays a critical role in droplet evaporation. Water droplets evaporated the quickest on the 5  $\mu\text{m}$  surface due again to an increased contact area that can be achieved as the vapors permeate away from the solid-liquid interface allowing the droplet to remain in contact with the surface at the increased temperatures. Additionally, the n-heptane evaporated the fastest on the 100  $\mu\text{m}$  surface. Due to the low heat of vaporization of n-heptane, and the higher porosity, and permeability of the 100  $\mu\text{m}$  surface compared to the 5  $\mu\text{m}$  surface meant a larger quantity of vapor could flow into the porous structure. As a result, less vapor will build up within the porous cavities hindering the rate of evaporation. The LP was reached with the water droplet on the impervious surface at 235°C. Similarly, the LP was successfully reached with the n-heptane at surface temperatures of 190°C (impervious surface), 225°C (5  $\mu\text{m}$  surface), and 285°C (100  $\mu\text{m}$  surface) respectively.

**Abstract**—The objective of this work is to report a computational fluid dynamics study assessing the hemodynamic effects of fenestration misalignment, towards understanding post-surgical complications of fenestrated endovascular aneurysm repair for abdominal aortic aneurysms. Idealized models were constructed based on geometries from a patient with an infrarenal aortic aneurysm. Fenestrated stent grafts were simulated in the models, with combinations of different fenestration misalignments and takeoff angles. Computational fluid dynamics simulations were performed by solving the governing equations for blood flow under physiologically realistic boundary conditions. Hemodynamic results of renal artery flow rate and time-averaged wall shear stresses were analyzed to build connections between the degree of fenestration misalignment, the takeoff angle, and changes in flow dynamics.

**Keywords**—abdominal aortic aneurysms; computational fluid dynamics; fenestrated endovascular aneurysm repair; hemodynamics; time-averaged wall shear stress

## I. INTRODUCTION

An abdominal aortic aneurysm (AAA) is a weakening and progressive enlargement of the aorta, which is the body's main artery. If left untreated, AAAs will continue to grow and potentially rupture, leading to death in 80% to 90% of cases [1]. Fenestrated endovascular aneurysm repair (FEVAR) is a minimally invasive treatment option for AAAs that involve the branch vessels such as the renal arteries. FEVAR involves inserting a fenestrated stent graft into the aorta at the site of the aneurysm and can include additional stenting of the branch vessels. FEVAR has been continuously evolving over the past two decades [2]; however, post-surgical complications including acute kidney injury (AKI) and renal artery thrombosis [3] were reported, and in some cases, at greater rates than for open aneurysm repair [3], leading to secondary interventions and renal function deterioration [4]. Some cases of post-surgical renal dysfunction were associated with aortic stent graft misalignment [4], where the fenestration was not aligned with the renal artery ostium; however, associations between fenestration misalignment and post-surgical complications have not been investigated *in vivo* due to difficulties with data acquisition [5].

As a first step towards understanding post-surgical complications of FEVAR, including AKI and renal artery thrombosis, this study aims to use computational fluid dynamics (CFD) to determine how fenestration misalignment impacts renal artery hemodynamics. Two factors, renal artery flow rate and renal artery time-averaged wall shear stress (TAWSS) were adopted as hemodynamics indices [6-10] to indicate the risks of AKI and renal thrombosis.

## II. METHODS

### A. Geometry

An idealized 3-D computational model of a post-surgical AAA was built using ANSYS DesignModeler (ANSYS Inc., Canonsburg, PA, USA). The lengths and diameters of the vessels were taken from the geometry of a patient with an infrarenal aortic aneurysm [11]. The patient was treated with endovascular aneurysm repair instead of FEVAR. However, this prototype was chosen due to availability of both the AAA geometry and physiological boundary conditions. It is assumed that neither the post-surgical model boundary conditions nor the post-surgical geometry changes with aortic aneurysm type. Taking advantage of the assumed symmetry between the left and right sides of the model, a half-symmetric geometry was adopted, including half of the aorta, one renal artery, and one iliac artery (Fig. 1). A fenestrated stent graft was then simulated in the model, with a flared renal stent that opens in the renal artery.

Both a reduction of the effective area of the renal artery orifice and the takeoff angle (TOA) between the aorta and the renal artery were considered in our model. Reduction of effective area on the proximal end of renal artery is caused by fenestration misalignment [4]. TOA is defined as the angle between the centreline of the renal stent and centreline axis of aorta [4].

A total of 15 cases were simulated, consisting of all combinations of five different fenestration alignments and three different TOAs. A fully aligned case, along with four cases of misalignment were considered. For the misaligned cases, the fenestration was positioned either 2.8 mm above or 2.8 mm below the proximal end of the renal artery, referred to as ‘vertical misalignment’, or rotated relative to the proximal end of the renal artery by either 17.5° clockwise or 17.5° counterclockwise, referred to as ‘horizontal misalignment’.

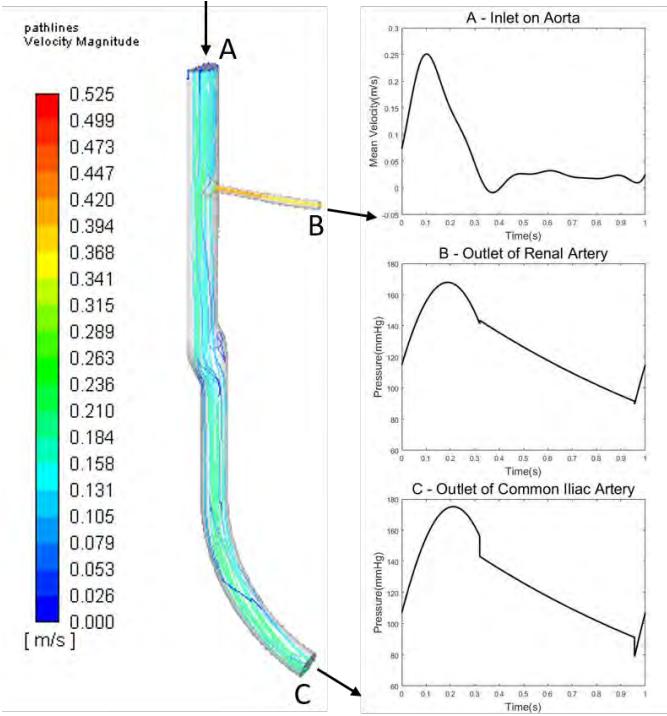

Figure 1. Post-surgical model with boundary conditions and velocity pathlines

(Fig. 2). These four misalignment cases were designed to have the equivalent of 45% effective area reduction in the proximal end of renal artery.

For the aligned case and each misaligned case, three different TOA were considered: 87.25° to model the average TOA, and 60.95° and 113.55° to model the maximum and minimum TOAs (Fig. 3), as reported by Jiale et al. [4].

#### B. Boundary Conditions

Patient-specific flow data were considered to define the inlet and outlet boundary conditions. Supraceliac-level flow rates, acquired from cine phase-contrast magnetic resonance imaging (PC-MRI) [11], were adapted to a Womersley velocity profile [12] applied at the inlet.

For the outlets of the renal and iliac arteries, 2-element Windkessel models [13] were used. These models account for arterial compliance and total peripheral resistance through analogies between fluid flow and electric circuits. The parameters for these models were fit to pressure data for the renal and iliac artery, approximated from brachial pressure cuff measurements immediately after the PC-MRI scan (Fig. 4) [11].

No-slip boundary conditions were specified for all vessel and stent graft walls, which were assumed to be rigid. A symmetry boundary condition was applied to the centre of the aorta. To delineate the effects of fenestration misalignment on renal artery flow, identical boundary conditions were defined for all simulations. Blood was assumed to be non-Newtonian fluid based on Quesmada viscosity model.

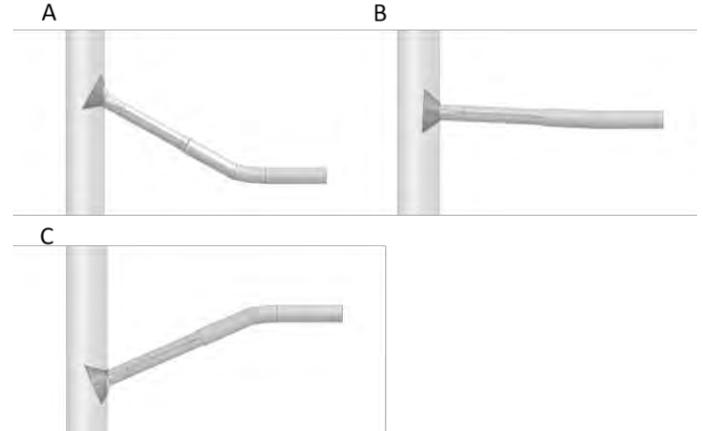

Figure 3. (A) Minimum (60.95°), (B) mean (87.25°), and (C) maximum (113.55°) takeoff angles

#### C. Numerical Analysis

Simulation of pulsatile flow in this 3-D post-surgical geometry were performed by solving the continuity and momentum equations using a finite volume approach in ANSYS FLUENT v. 18.

The computational geometries were discretized by tetrahedral patch-conforming methods with advanced functions of proximity and curvature in ANSYS ICEM CFD. Mesh layers were refined on the walls of the renal arteries to accurately resolve the renal artery WSS.

Mesh independence studies were carried out for two steady state simulations, conducted at  $t = 0.1$  s, corresponding to the maximum inlet velocity, and  $t = 0.5$  s, corresponding to a low inlet velocity and high outlet pressure. With the number of elements increasing by 50% for each refinement, 6 different mesh sizes were applied on each geometry, and grid independence was deemed to be reached when both the change of renal artery flow rate and the change of renal artery WSS were within  $\pm 5\%$  between two successive meshes. Among the 15 studied geometries, element numbers required to achieve grid independence varied from 199,708 to 450,033.

Relative residuals of continuity and velocities in the  $x$ ,  $y$ , and  $z$  coordinates were set to  $1 \times 10^{-4}$ . Based on monitoring the Courant number in pulsatile flow simulations, a uniform 0.02 s time-step was adopted. As suggested by Kandail et al. [7], simulations for all geometries were performed for four cardiac cycles to achieve periodic results.

### III. RESULTS AND DISCUSSIONS

Renal artery flow rate and renal artery TAWSS were used in our study as indices of risks of AKI and renal thrombosis, respectively. A decrease of renal artery flow rate leads to a decrease in kidney blood supply; hence it is an indicator of potential AKI. A decrease in renal TAWSS is suggestive of increased chance of renal thrombosis according to the Low Shear Theory [6].

#### A. Comparison of Renal Artery Flow Rate between Misaligned and Aligned Cases

Renal artery flow rates between cases with aligned and misaligned fenestrations were compared to determine the influence of fenestration misalignment on the amount of blood flow to the kidney. As is summarized in Table 1 and Fig. 4, a decrease of renal artery flow rate was observed by comparing flow rates in the misaligned models and the aligned model with the same TOA. The maximum decrease was found in the case where the fenestration was 2.8 mm below the proximal renal artery with a TOA of 60.95° (11.0%), while the minimum was found where the fenestration was 2.8 mm above the renal artery with a TOA of 113.55° (7.1%). Fenestration misalignment caused a decrease of renal artery flow rate in all studied renal TOAs, hence an increased opportunity for post-surgical renal AKI.

#### B. Comparison of Renal Flow Rate between Different TOAs

Results of renal flow rates for different TOAs were studied to determine the influence of renal artery position on renal flow rate. As shown in Fig. 4, for each group with the same alignment, the case with the 60.95° TOA had a higher renal flow rate than the case with the 87.25° TOA; while the case with the 113.55° TOA had the lowest renal artery flow rate. Within misaligned cases, by comparing renal flow rates of cases with 133.55° TOAs to cases with 60.95° TOAs, the maximum decrease of flow rate was found in the case where the fenestration was rotated 17.5° clockwise (18.0%), while the minimum was found where the fenestration was 2.8 mm below the renal artery (17.4%). Comparing to the percentage changes due to misalignment effects on renal flow rate (maximum of 11.0%), change of TOA had a larger effect on the decrease of renal flow rate.

#### C. Comparison of Renal TAWSS between Misaligned and Aligned Cases

Renal artery TAWSS between cases with aligned and misaligned fenestrations were compared to delineate the influence of fenestration misalignment on TAWSS. As is summarized in Table 2 and Fig. 5, decrease of renal artery TAWSS was observed by comparing cases of the misalignment models against the aligned models with constant TOAs. The maximum percentage decrease was found in the case where the fenestration was 2.8 mm below the renal artery with a TOA of 87.25° (21.0%), while the minimum was found where the fenestration was rotated 17.5° counterclockwise with a TOA of 60.95° (17.7%).

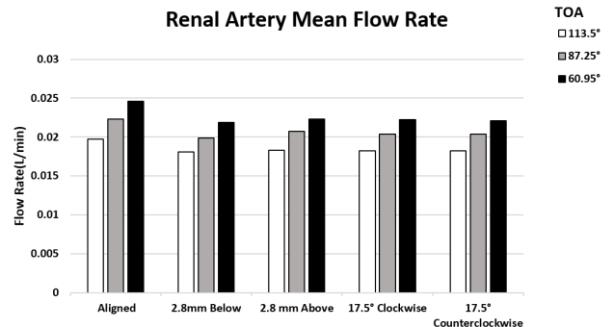

Figure 4. Renal artery flow rate (L/min) in different misalignment cases.

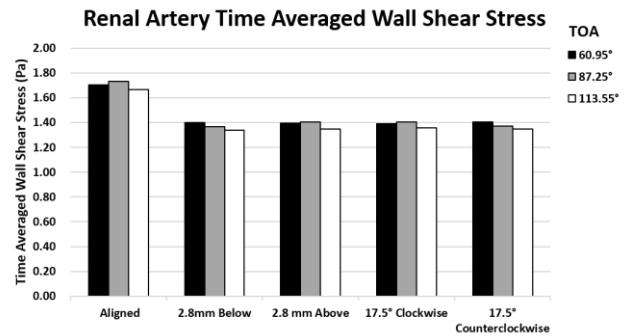

Figure 5 Renal artery time averaged wall shear stress in different misalignment cases.

In our study, we showed that fenestration misalignment and changes in TOA cause changes in renal hemodynamics, including the decrease of renal flow rate and renal TAWSS, which are suggestive of increased risk for post-surgical complications, including AKI and renal thrombosis.

Georgakarakos et al. [14] studied the impact of fenestration misalignment on renal WSS, but without considering the flaring of the renal stents or the reduction of the effective area of the proximal renal stent. In our institution, flaring of the renal stent is standard practice during FEVAR. Kandail et al. [7, 15] simulated blood flow with different TOAs and studied effects of flaring stent graft, but without considering either reduction of effective area or its combined effect with changes in TOA.

We were surprised to find that misalignment cases with constant reduction of effective renal artery area had different reductions in renal artery flow compared to the aligned case. Within the 2 cases of vertical misalignment (the fenestration above or below the renal artery) and the 2 cases of horizontal misalignment (the fenestration rotated either clockwise or counterclockwise), the case with the fenestration below the renal artery caused the largest decrease in renal artery flow, while the case with the fenestration above the renal artery caused the smallest decrease. A major limitation of our research is the lack of patient-specific geometries. Although we have previously validated our idealized model by comparing renal artery flow rates in our model with data reported in literature by Figueroa et al. [11], a more precise hemodynamic result would be obtained by studying models with patient-specific geometries applied with the same boundary conditions.

TABLE I. MEAN FLOW RATE OF DIFFERENT TAKEOFF ANGLES AND ALIGNMENT CASES

Takeoff Angle (°)	Mean Flow Rate (L/min)				
	Aligned	Vertical Misalignments		Horizontal Misalignments	
		2.8 mm Above	2.8 mm Below	17.5° Clockwise	17.5° Counterclockwise
60.95	0.0246	0.0219	0.0223	0.0222	0.0221
87.25	0.0223	0.0199	0.0207	0.0204	0.0204
113.55	0.0197	0.0181	0.0183	0.0182	0.0182

TABLE II. TIME AVERAGED WALL SHEAR STRESS IN DIFFERENT TAKEOFF ANGLE AND ALIGNMENT CASES

Takeoff Angle (°)	Time Averaged Wall Shear Stress (Pa)				
	Aligned	Vertical Misalignments		Horizontal Misalignments	
		2.8 mm Above	2.8 mm Below	17.5° Clockwise	17.5° Counterclockwise
60.95	1.7043	1.3993	1.3964	1.3931	1.4034
87.25	1.7305	1.3669	1.4041	1.4051	1.3706
113.55	1.6667	1.3396	1.3465	1.3556	1.3483

The study has built connection between fenestration misalignments and changes in hemodynamics, indicating that FEVAR with misalignment occurring could cause further renal dysfunction and possible post-operative impairment [4]. At the clinical level, it is suggested that closer attention should be put on possible fenestration misalignments when determining therapeutic strategies, and at the same time, more attention should be placed on studies to reduce misalignments.

#### IV. CONCLUSIONS

Our study clearly showed that fenestration misalignments caused decreases of hemodynamic indices including renal artery flow rate and renal TAWSS. In the perspective of renal artery flow rate, among misalignments with same reduction of effective area, the case with the fenestration 2.8 mm below the renal artery caused the highest decrease in renal flow rate, while the case with the fenestration 2.8 mm above caused the lowest decrease of the index. The TOA also affects indices of renal artery flow rate. Cases with TOAs of 113.55° had the lowest renal flow rate while cases with TOAs of 60.95° had the highest. TOA has larger effects than misalignments on renal artery flow rate.

## ABSTRACT

Flaring in oil and gas production is the controlled burning of unwanted exhaust gases to enhance safety. Obtaining complete combustion and thus eliminating or reducing smoke is critical to meet increasingly strict environmental regulations. To improve flare combustion, gas flares are equipped with air nozzles that introduce extra oxygen and improve mixing in the combustion zone. These nozzles are operated in the subsonic, sonic, or supersonic regimes. In this paper we are concerned with turbulence modeling of the jet flow exiting from a particular convergent-divergent nozzle used in flare systems. The Realizable  $k - \varepsilon$  and SST  $k - \omega$  models are used to study the compressible flow within that specific nozzle, which has an exit diameter of 3.38 mm and has convergent and divergent sections that are connected via a throat section with a finite length and constant diameter. The velocity profiles and turbulent kinetic energy predicted by both turbulence models, in the vicinity of the nozzle outlet and along the symmetry axis of the nozzle, are compared for nozzle pressure ratios in the range  $1.18 \leq \text{NPR} \leq 1.78$ . It is shown that for  $Ma \leq 1$ , both turbulence models predict nearly identical flow evolution along the nozzle. When the flow becomes supersonic, the shock surface, and consequently nozzle outlet velocity profiles, predicted by the SST  $k - \omega$  model deviates slightly from the other model. The differences, however, become negligible a couple of diameters downstream of the nozzle outlet. Computed entrainment rate coefficients vary slightly when changing the turbulence model, and this difference remains insignificant with increasing downstream distance.

**Keywords:** CD nozzle flow, compressible flow, turbulence models, entrainment rate, gas flaring

## 1. INTRODUCTION

Gas flaring is a technique used in several industries such as gas and oil separation plants (GOSPs), oil refineries, gas plants and other petrochemical plants in which unwanted or excess gases are burnt safely. Gas flares are also used to protect the plants against the danger of over pressurizing in case of emergency or critical equipment trip. The gas flaring system is very important and plants operations should cease if it is not working properly. While gas flaring is required for safety reasons, it has many drawbacks, including negative impacts on the environment (primarily due to incomplete combustion of the gas) and the waste of potentially useful resources. To mitigate these negative impacts, companies seek to eliminate or reduce gas flaring. In situations when flaring is unavoidable, it is desirable to have smokeless gas flaring (Figure 1). Saudi Aramco, the largest oil company in the world, has made a thorough analysis and study [1] to investigate a cost effective and efficient solution to retrofit its hundreds of gas flares in Saudi Arabia. Several options were explored such as Steam-Assisted Flare tips, sonic flare tips and Low-Pressure Air-Assist. However, none of these solutions was deemed to be cost effective and, therefore Saudi Aramco developed a new flare design named the High Pressure Air Assist System (HPAAS). Briefly, the system consists of convergent-divergent nozzles that surround the circumference of the flare exit tip. As these nozzles inject compressed air to the combustion zone, the resulting air entrainment from the atmosphere due to the high exit velocity provides the required air mass to yield smokeless flaring (Figure 1).

For a given nozzle shape, the flow controlling parameter is the nozzle pressure ratio (NPR). In converging nozzles (CN), as the NPR increases, the maximum flow rate is achieved when the flow speed at the nozzle exit is sonic, corresponding to the choked flow condition. A converging-diverging nozzle geometry (CDN) allows the flow to achieve supersonic speeds. For a CDN that undergoes an isentropic expansion the sonic condition is reached at the throat connecting an upstream subsonic condition to a downstream supersonic condition. In contrast, an isentropic compression within the nozzle connects an upstream supersonic condition to a downstream subsonic condition via a sonic throat [2]. If the flow is choked at the throat but the NPR differs from that required to yield isentropic flow, a combination of normal and oblique shocks is formed downstream of the throat [3]. Numerical predictions of the compressible flow within CDN, shocks behavior, and the compressible turbulent shear flow of supersonic jets has been subject of extensive studies in the last century.

Eggers [4] conducted an analytical and experimental investigation of a supersonic jet (Mach 2.22 nozzle) to understand turbulence quantities and jet entrainment. He concluded that an eddy viscosity formulation independent of the radial coordinate, employed by other researchers, for a compressible turbulent jet was not justified. Birch and Eggers [5] collated experimental data on developed free turbulent shear layers to facilitate the validation of the turbulence models and numerical predictions. They concluded that the available data were not sufficient to clearly establish the effect of density gradients on mixing rate. Lau et al. [6] conducted measurements of a 51mm diameter turbulent jet at Mach 0.28, 0.90, and 1.37 using a LDV and a hot-wire anemometer. Their data indicate a decrease in the spreading rate of the mixing layer with increasing Mach number. Seiner et al. [7] investigated the effect of jet temperature on the mixing rate, and concluded that high temperatures resulted in enhanced density fluctuations to increase the mixing rate.

Reynolds-averaged Navier–Stokes (RANS) solvers have been used by many researchers to simulate supersonic exhausts. A comprehensive review of various turbulence modelling, advantages and limitations of each approach is presented in [8]. Koch conducted a study on subsonic axisymmetric jets with flow separation using a two-equation  $k - \varepsilon$  turbulence model [9]. While the mean flow values showed a good agreement with experiment, the mixing rate predicted by the numerical modelling was lower than the experimental results, and so were the turbulent kinetic

energy levels. To incorporate compressibility effects in turbulence models, and consequently to better predict the decrease in the growth rate with increasing Mach number, an additional compressibility term should be included in the turbulence transport equations [10, 11]. Georgiadis et al. [12, 13] assessed the accuracy of modified two-equation turbulence models in flow field predictions of a subsonic (Mach number 0.5) heated and unheated jet. They showed that all the modified equations provided improved predictions compared to the standard models. However, all the models underestimated initial jet mixing rate and the turbulence kinetic energy fields.

Xiao et al. [14] examined experimentally and numerically the effect of both the nozzle expansion ratio and the NPR on the entrainment from CDN. The computations showed that the nozzle expansion ratio has a greater effect on the entrainment than the NPR. Among the RANS models, the SST  $k - \omega$  model compared the best with experiment, which was attributed to its ability to predict the flow separation after the shock correctly. For a fixed nozzle expansion ratio of 1.5, their experimental study showed the best mixing was achieved when the NPR was in the range of 1.4-1.6. In a numerical study conducted on CDN with Mach number in the range  $0.9 < Ma < 1.2$  and NPR of 4 and 6, DalBello et al. [15] found that the SST  $k - \omega$  model could match well with experimental measurements. The RANS models prediction accuracy decreases as the flow compressibility effects become more important. To account for these effects, modified RANS models were considered and their prediction performance were compared against experiment [16] [13].

Sarkar and Sarkar et al. [17, 18] studied compressible shear layers using a Reynolds Stress Model (RSM). When the compressibility effects were not considered explicitly, the model failed to predict the dependence of the shear layer growth rate on the Mach number. In comparison, when the compressibility effects were considered explicitly, the computed results compared better with experiment. Lijo et al. [19] used RSM to study transient flows in a rocket propulsion nozzle which involves free and restricted shock separation, and they found RSM model results were in good agreement with experiment. Balabel et al. [20] assessed RSM and different RANS models for gas flow in a two-dimensional CDN with steady, compressible and turbulent flow. In their investigation to predict the separation point and the shock wave location, they found that the SST  $k - \omega$  model gave the best results when compared to experiment. The objective of this paper is to study the compressible turbulent flow picture within a specific converging-

diverging nozzle with a finite length throat of constant area, and specifically to compare the nozzle flow field including the axial velocity, mass entrainment, Mach number and turbulent kinetic energy, predicted by different turbulence models.

Figure 1: A flare with (right) and without (left) smokeless air, which shows the nozzles' advantage [1].

## 2. NUMERICAL METHOD

In this section, the numerical formulations employed to obtain the CFD results using ANSYS Fluent 18.0 are presented.

### 2.1 Governing Equations

The governing-equations require special treatment, i.e. closure, when the flow is turbulent. In the time-averaging of the governing equations, the physical quantity  $\phi$  is decomposed into its mean component  $\bar{\phi}$  and fluctuating component  $\phi'$  via the Reynolds decomposition as  $\phi = \bar{\phi} + \phi'$ . To account for the effects of the density fluctuations due to turbulence, Favre-averaging or density-weighed averaging is adopted in turbulent compressible flows. The density-weighted average of  $\phi$  is obtained as  $\phi = \tilde{\phi} + \phi''$ , where  $\tilde{\phi} = \bar{\rho}\bar{\phi}/\bar{\rho}$ . The details of the Favre averaging can be found in [21].

The mass-averaged conservation of mass in terms of mean velocity vector  $\tilde{u}_i$  is given by Equation (1). The governing equations for the transport of momentum is given by Equation (2).  $p$  is the mean pressure and related to mean temperature and density as  $p = \bar{\rho}R\bar{T}$ . The viscous stress tensor  $\tau_{ij}$  for an isentropic Newtonian fluid is defined as given by Equation (3) where  $\delta_{ij}$  is the Kronecker delta function, and  $\mu$  is the dynamic viscosity. The Reynolds stresses  $\bar{R}_{ij} =$

$-\widetilde{\rho u_i'' u_j''}$ , arising from the Favre-averaging of the momentum equations, require modelling. One of the most common approaches to close the set of equations is to use the Boussinesq hypothesis to relate the Reynolds stresses to the mean deformation rates and the turbulent kinetic energy  $k$  as given in Equation (4). The turbulent viscosity  $\mu_t$  is given by  $\mu_t = \rho C_\mu k^2/\varepsilon$ , where  $\varepsilon$  is the dissipation of turbulent kinetic energy and  $C_\mu$  is a constant.

The Realizable  $k - \varepsilon$  employs Equation (5) and Equation (6) as transport equations for  $k$  and  $\varepsilon$ , respectively.  $\bar{R}_{ij} \partial \tilde{u}_i / \partial x_j$  is the generation of turbulence kinetic energy due to the mean velocity gradients.  $Y_M$  is the contribution of fluctuating dilation to the dissipation rate.  $S = \sqrt{2S_{ij}S_{ij}}$  is the modulus of the mean deformation rate tensor.  $\sigma_k = 1.0$ ,  $\sigma_\varepsilon = 1.2$  are, respectively, the turbulent Prandtl numbers for  $k$  and  $\varepsilon$ . In contrast to the standard  $k - \varepsilon$  model,  $C_\mu$  is no longer a constant but rather depends on the mean deformation and rotation rates, the angular velocity of the rotation frame, and the turbulence quantities [22].

The SST  $k - \omega$  employs Equations (8) and (9), respectively, as transport equations for  $k$  and the specific dissipation rate  $\omega$ .  $\sigma_k$  and  $\sigma_\omega$  are the turbulent Prandtl numbers for  $k$  and  $\omega$ , respectively. The turbulent viscosity is computed as  $\mu_t = f \rho k / \omega$ , where  $f$  is a function of the strain rate magnitude, the specific dissipation rate, a limiter function, and a Reynolds number defined as  $Re_t = \rho k / \mu \omega$ . The details of the model constants can be found in [23]. This formulation accounts for the transport of the turbulence shear stress in the definition of the turbulent viscosity. The Favre-averaged energy equation is given by Equation (10). The turbulent flux  $-\rho u_j'' h$  is given based on the averaged enthalpy, turbulent Prandtl number, and the turbulent eddy viscosity as given in Equation (11). The Favre-averaged material derivative is defined in Equation (12).

### 2.2 Meshing and Boundary Conditions

Figure 2 shows the geometry of the specific nozzle studied in this paper. This geometry is used commonly in gas flares. The converging and diverging sections of this nozzle are connected via a throat with a constant diameter and a finite length. Figure 2 also shows the computational domain used for the simulations with the associated boundary conditions. The domain extends from  $50r_{exit}$  downstream of the nozzle exit, where  $r_{exit}$  is the nozzle exit radius. The domain dimensions are given in Figure 2. The lateral walls,

Table 1: List of Governing Equations

Conservation  
of Mass

$$\frac{\partial \bar{\rho}}{\partial t} + \frac{\partial}{\partial x_i} (\bar{\rho} \tilde{u}_i) = 0 \quad (1)$$

Conversation  
of Momentum

$$\frac{\partial}{\partial t} (\bar{\rho} \tilde{u}_i) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j \tilde{u}_i) = - \frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} (\bar{\tau}_{ij} - \bar{R}_{ij}) \quad (2)$$

$$\bar{\tau}_{ij} = \mu \left( \frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i} - \frac{2}{3} \frac{\partial \tilde{u}_k}{\partial x_k} \delta_{ij} \right) \quad (3)$$

$$\bar{R}_{ij} = -\bar{\rho} \tilde{u}_i'' \tilde{u}_j'' = \mu_t \left( \frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i} \right) - \left( \frac{2}{3} \rho k + \mu_t \frac{\partial \tilde{u}_k}{\partial x_k} \right) \delta_{ij} \quad (4)$$

Realizable  
 $k - \varepsilon$

$$\frac{\partial}{\partial t} (\bar{\rho} k) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j k) = \frac{\partial}{\partial x_j} \left( \left[ \mu + \frac{\mu_t}{\sigma_k} \right] \frac{\partial k}{\partial x_j} \right) + \bar{R}_{ij} \frac{\partial \tilde{u}_i}{\partial x_j} - \rho \varepsilon - Y_M \quad (5)$$

$$\frac{\partial}{\partial t} (\bar{\rho} \varepsilon) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j \varepsilon) = \frac{\partial}{\partial x_j} \left( \left[ \mu + \frac{\mu_t}{\sigma_\varepsilon} \right] \frac{\partial \varepsilon}{\partial x_j} \right) + \rho C_1 S \varepsilon - \rho C_2 \frac{\varepsilon^2}{k + \sqrt{v \varepsilon}} \quad (6)$$

$$C_1 = \max \left[ 0.43, \frac{\eta}{\eta + 5} \right], \eta = S \frac{k}{\varepsilon}, C_2 = 1.9 \quad (7)$$

$$\mu_t = \rho C_\mu k^2 / \varepsilon$$

SST  $k - \omega$

$$\frac{\partial}{\partial t} (\bar{\rho} k) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j k) = \frac{\partial}{\partial x_j} \left( \left[ \mu + \frac{\mu_t}{\sigma_k} \right] \frac{\partial k}{\partial x_j} \right) + \bar{R}_{ij} \frac{\partial \tilde{u}_i}{\partial x_j} - \rho \beta^* k \omega \quad (8)$$

$$\frac{\partial}{\partial t} (\bar{\rho} \omega) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j \omega) = \frac{\partial}{\partial x_j} \left( \left[ \mu + \frac{\mu_t}{\sigma_\omega} \right] \frac{\partial \omega}{\partial x_j} \right) + \frac{\alpha \alpha^*}{v_t} \bar{R}_{ij} \frac{\partial \tilde{u}_i}{\partial x_j} - \rho \beta \omega^2 + \gamma \rho \frac{1}{\omega \sigma_{w,2}} \frac{\partial k}{\partial x_j} \frac{\partial \omega}{\partial x_j} \quad (9)$$

$$\frac{\partial}{\partial t} (\bar{\rho} \tilde{h}) + \frac{\partial}{\partial x_j} (\bar{\rho} \tilde{u}_j \tilde{h}) = \frac{\tilde{D} \bar{p}}{\partial t} + \overline{u_j'' \frac{\partial \bar{p}}{\partial x_j}} + \frac{\partial}{\partial x_j} (-\overline{\rho u_j'' h}) + \bar{\tau}_{ij} \frac{\partial \tilde{u}_j}{\partial x_j} + \overline{\tau_{ij} \frac{\partial u_j''}{\partial x_j}} + \frac{\partial}{\partial x_j} \left( \frac{\mu}{Pr} \frac{\partial \tilde{h}}{\partial x_j} \right) \quad (10)$$

Conservation  
of Energy

$$-\overline{\rho u_j'' h} = \frac{\mu_t}{Pr_t} \frac{\partial \tilde{h}}{\partial x_j} \quad (11)$$

$$\frac{\tilde{D}}{Dt} = \frac{\partial}{\partial t} + \tilde{u}_j \frac{\partial}{\partial x_j} \quad (12)$$

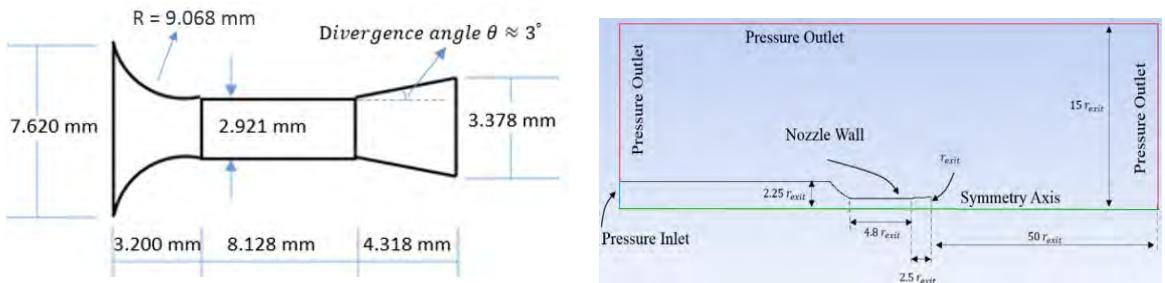

Figure 2: (Left) The geometry of the nozzle. (Right) Schematic of the computational domain used for the simulations with the associated boundary conditions; the dimensions of the computational domain are also shown in terms of nozzle exit radius  $r_{exit}$  (not shown to scale).

considered as the pressure outlet boundary condition, are extended to  $15r_{exit}$  to assure their impact on the jet flow is insignificant. The typical computational mesh used in the simulations, shown in Figure 3, highlights the small mesh size used in regions of high velocity gradients and around the shock location.

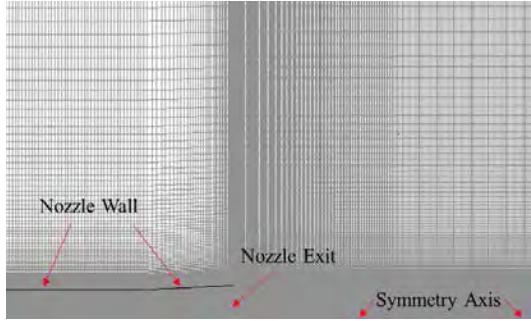

Figure 3: The typical computational mesh used in the simulation; the mesh around the nozzle exit is only shown for the sake of illustration.

### 2.3 Mesh Independency Check

To ensure that the simulations are mesh-independent, several flows were simulated with different mesh densities (number of cells was  $1 \times 10^5$ ,  $1.5 \times 10^5$  and  $3 \times 10^5$  for the coarse, medium and fine mesh, respectively). In the refinement procedure, we refined the boundary layer mesh close to the nozzle wall, the flow region around the jet shear layer, and the shock areas. Additionally, we slightly refined the mesh in the outer region of the flow. The velocity profiles at  $x = 2.256 r_{exit}$  downstream of the nozzle exit for  $P_{in} = 160$  kPa for different mesh sizes are shown in Figure 4. To estimate the discretization error, we followed the procedure recommended in [24] for the velocity profiles. The numerical uncertainty in the fine-grid solution was found to be 1.6% for the velocity profiles.

### 2.4 2D vs. 3D Comparison

For a highly over-expanded flow within a converging -diverging nozzle, the flow is inherently not axisymmetric [25]. The complex pattern of the shock surfaces (oblique and normal shocks) is three-dimensional, which means that the azimuthal derivatives of quantities should be accounted for in the governing equations. However, for the range of operating conditions of interest in this study, the flow remains attached to the nozzle walls and no flow separation was observed. These characteristics should permit one to use with reasonable accuracy a 2D axisymmetric model instead of full three-dimensional

modelling. Using the 2D model avoids long computational times.

To verify that the 2D axisymmetric modelling is capable of capturing the shock surfaces and flow details, some 3D simulations were conducted to compare the simulations results with those of the corresponding 2D axisymmetric simulations. The SST  $k - \omega$  turbulence model was chosen for both sets of simulations. The Mach number and the pressure coefficient profiles along the nozzle symmetry axis for the same upstream pressure are shown in Figure 5. The 2D profiles are almost identical to their 3D counterparts.

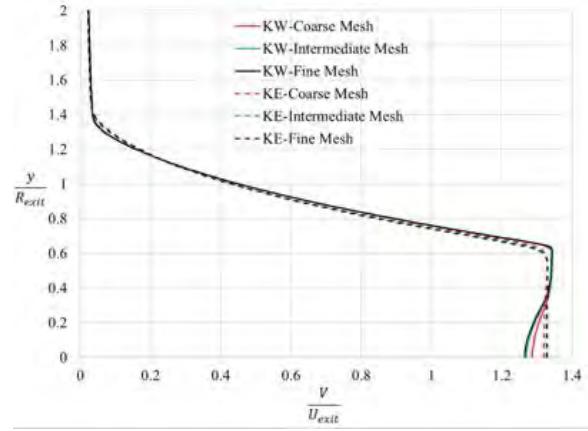

Figure 4: Velocity profile at  $x = 2.256 r_{exit}$  downstream of the nozzle exit for  $P_{in} = 160$  kPa.

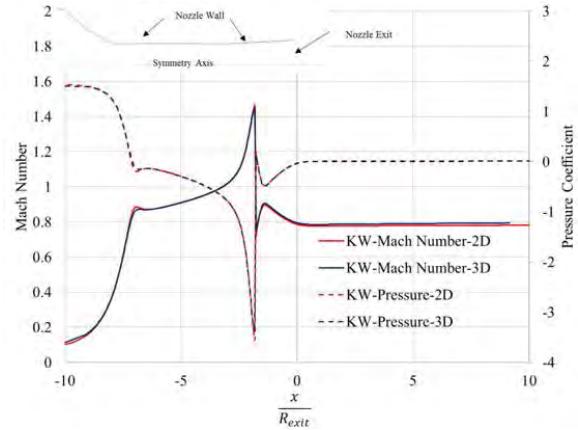

Figure 5: Mach number and pressure coefficient profiles along the nozzle symmetry axis for 2D axisymmetric and 3D simulation. The upstream pressure is  $P_{in} = 160$  kPa.

## 2.5 Model Validation against Experimental Data

This section contains a comparison between the simulation results on the Acoustic Reference Nozzle (ARN) [26] from the ANSYS Fluent solver and those reported in [13] and [26]. The geometry details are reported in [26]. The jet is issued from a nozzle with an exit diameter of 50.8 mm. The Setpoint 3, where the jet is unheated ( $T_j/T_\infty = 0.950$ ) and the compressibility effects (Mach = 0.513) on the flow evolution could be insignificant, was chosen for the comparison reported here. The NPR of this point is 1.197.

Figure 6 and Figure 7, respectively, show a comparison of the axial velocity and turbulent kinetic energy along the symmetry axis between the current simulations and those reported in [13] and [26]. In Figure 6, the present simulation shows a good agreement with both the experimental data and previous simulation [13] results.

Both the present simulation and the previous simulation [13] predict a longer potential core than that observed experimentally. The current simulation, however, predicts a potential core shorter than the previous simulation [13]. Furthermore, the current simulation predicts a decay rate faster than both the experimental results and the previous simulation [13]. On the other hand, the turbulent kinetic energy (TKE) predicted by the current simulation using the SST  $k - \omega$  turbulence model is in better agreement with experimental data than the previous simulations [13].

A comparison of the velocity profile at different positions downstream of the nozzle exit is shown in Figure 8. Very good agreement exists in the dimensions of the potential core and shear layer between the experimental data, the earlier simulation [13], and the current simulation. The above results show that the utilized modeling approach in this paper is adequate to capture the flow features of the flow field studies in this investigation, especially at Mach number of 0.5.

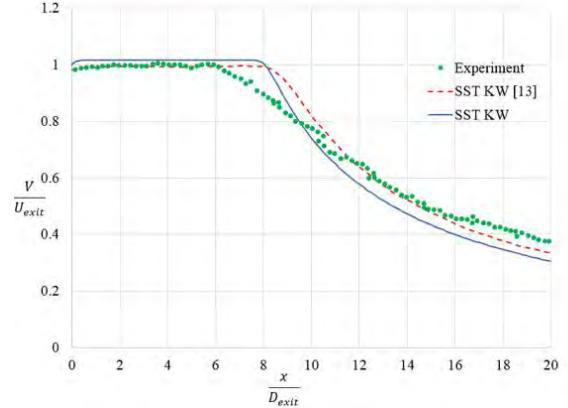

Figure 6: Comparison of axial velocity profile along the symmetry axis between current simulations, those in [13], and experiments [26].

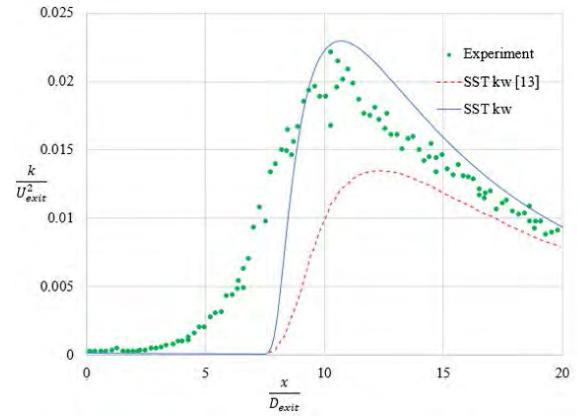

Figure 7: Comparison of turbulent kinetic energy profile along the axis of symmetry between current simulations, those in [13], and experiments [26].

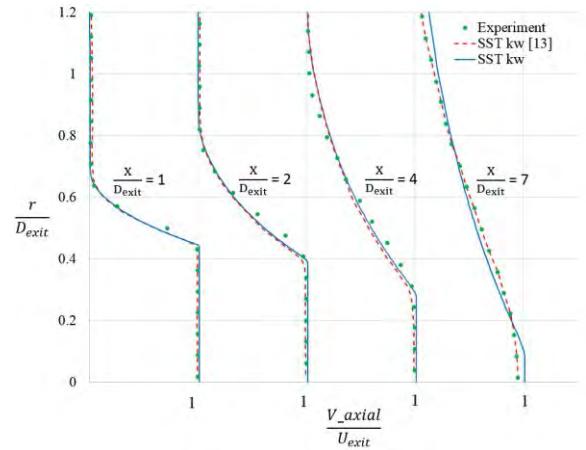

Figure 8: Comparison of velocity profile downstream of the nozzle exit between current simulations and results in [13] and [26].

### 3. RESULTS AND DISCUSSIONS

In this section, simulation results of the converging-constant throat-diverging nozzle, as shown in Figure 2, are presented. The nozzle has an exit to throat area ratio of 1.34. The flow fields are studied at different pressure ratios (NPR) in the range  $1.18 \leq \text{NPR} \leq 1.78$ , corresponding to  $120 \text{ kPa} \leq P_{\text{in}} \leq 180 \text{ kPa}$ . The downstream pressure is set to standard atmospheric pressure at sea level (101 kPa). The working fluid is air. Velocity, TKE, and Mach number variations within and downstream of the nozzle are presented.

#### 3.1 Mean Axial Velocity Profiles

Figure 9 shows a comparison of the normalized axial velocity profiles as computed by the different turbulence models for two upstream pressures:  $P_{\text{in}} = 140 \text{ kPa}$  and  $P_{\text{in}} = 160 \text{ kPa}$ . The profiles are extracted at two locations downstream of the nozzle exit,  $x_1 = 2.256 r_{\text{exit}}$  and  $x_2 = 11.278 r_{\text{exit}}$ .

The normalized velocity profiles predicted by different turbulence models follow each other closely at  $P_{\text{in}} = 140 \text{ kPa}$ ; they start with a potential core close to the jet centerline and transition to the slow moving outer flow through a shear layer. The potential core at  $x = 2.256 r_{\text{exit}}$  exists in  $0 < y/r_{\text{exit}} < 0.6$ . The extent of the potential core in the cross-stream direction at  $x = 11.278 r_{\text{exit}}$  shrinks to  $0 < y/r_{\text{exit}} < 0.1$  due to the mixing. The SST  $k - \omega$  model predicts a slightly faster decay in the potential core compared to the Realizable  $k - \varepsilon$  model. The shear layer is contained in  $0.6 < y/r_{\text{exit}} < 1.5$  at  $x = 2.256 r_{\text{exit}}$ , while it has a far-reaching extent  $0.1 < y/r_{\text{exit}} < 3.5$  at  $x = 11.278 r_{\text{exit}}$  (for comparison purposes the profiles at  $x = 11.278 r_{\text{exit}}$  are clipped to  $y/r_{\text{exit}} = 2.0$ ). The flow at this inlet pressure approaches sonic conditions at the throat.

At  $P_{\text{in}} = 160 \text{ kPa}$  the velocity profiles predicted by the Realizable  $k - \varepsilon$  model are similar to those at the lower pressure except that the potential core reaches a higher normalized peak velocity. The SST  $k - \omega$ , however, predicts a velocity deficit in the near field in the potential core, which seems unphysical. This can be seen at the centerline ( $y=0$ ) as velocity profile is dented backward between  $0 < y/r_{\text{exit}} < 0.4$ . Note that the flow within the nozzle at this pressure is supersonic (both turbulence models predict a peak Mach number of  $\approx 1.45$  in the diverging section), where the compressibility effects play a critical role in

the flow evolution. This velocity deficit, however, disappears in the far field (after  $x \geq 11.278 r_{\text{exit}}$ ). In fact, both turbulence models predict almost the same normalized axial velocity profile in the far field at  $x = 11.278 r_{\text{exit}}$  regardless of the flow condition.

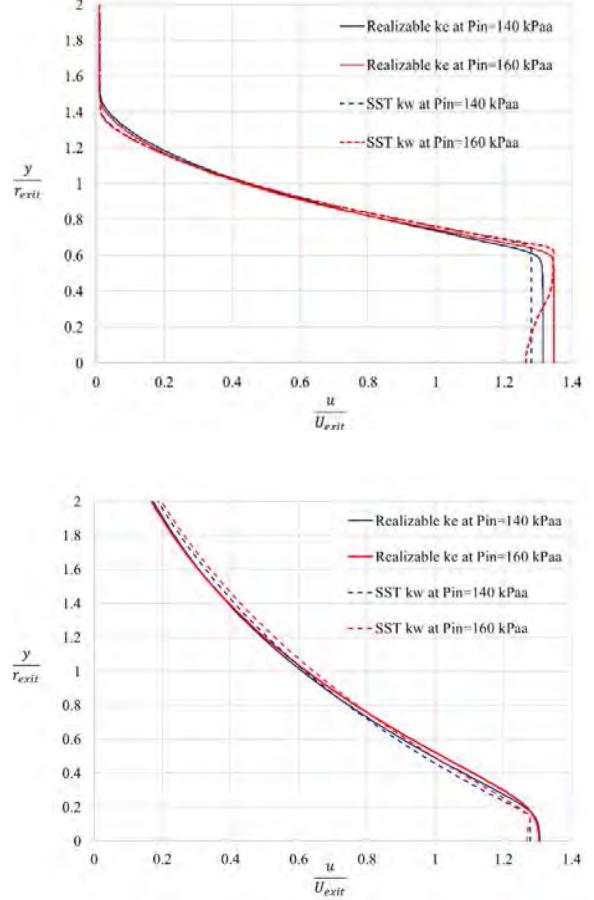

Figure 9: The normalized axial velocity profiles downstream of the nozzle exit for the different turbulence models; Extraction line is at (top)  $x = 2.256 r_{\text{exit}}$  (bottom)  $x = 11.278 r_{\text{exit}}$  downstream of the nozzle exit.

#### 3.2 Turbulent Kinetic Energy Profiles

The normalized turbulent kinetic energy (TKE) along the axis of symmetry at  $P_{\text{in}} = 140 \text{ kPa}$  and  $P_{\text{in}} = 160 \text{ kPa}$  is compared between different turbulence models in Figure 10. The transport of TKE to the jet centerline and the evolution of TKE predicted by the two turbulence model is almost the same. The Realizable  $k - \varepsilon$  model, however, predicts some turbulence upstream and downstream of the nozzle exit for  $x/r_{\text{exit}} \lesssim 12$ . This level of turbulence is absent in the predictions of the SST  $k - \omega$  model, which

predicts almost zero turbulence along the symmetry axis up to  $x/r_{exit} \approx 12$ , where the potential core exists.

After the end of the potential core, in the shear layer region, the diffusion of turbulence reaches to its maximum value at a downstream distance of  $x/r_{exit} \approx 18$ , where the normalized TKE graph attains a maximum value. This maximum value is slightly greater than 0.04 for the Realizable  $k - \varepsilon$  model and slightly less than 0.04 for the SST  $k - \omega$  model. The dissipation of the TKE after the peak point is slightly higher for the SST  $k - \omega$  model for  $x/r_{exit} < 22$ , and thereafter the Realizable  $k - \varepsilon$  model predicts a slightly faster decay, and consequently more mixing, farther downstream.

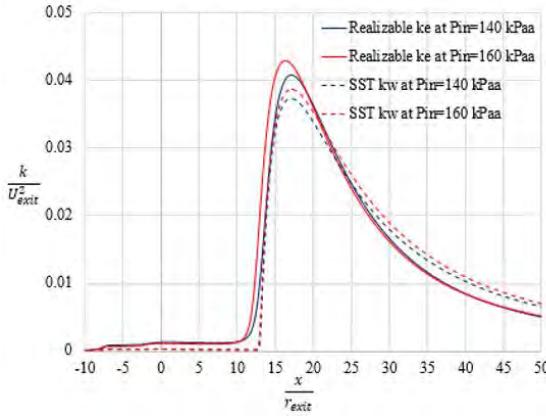

Figure 10: The normalized turbulent kinetic energy along the axis of symmetry predicted by the turbulence models at  $P_{in} = 140$  kPa and  $P_{in} = 160$  kPa.

### 3.3 Mach Number Profiles

Figure 11 shows the Mach number profiles along the symmetry axis predicted by both turbulence models at  $P_{in} = 140$  kPa and  $P_{in} = 160$  kPa. Generally, both turbulence models predict almost the same Mach number evolution inside and outside the nozzle. The location of the shocks in the nozzle (when  $P_{in} \geq 160$  kPa) predicted by the two models are the same. In addition, both models show that the sonic flow condition along the centerline is always reached at the constant throat around  $x/r_{exit} = -3.2$ , just upstream of the divergent section (which starts at  $x/r_{exit} = -2.556$ ).

However, when the flow is subsonic ( $P_{in} \leq 140$  kPa), the SST  $k - \omega$  model predicts slightly higher flow velocities than the Realizable  $k - \varepsilon$  model in the converging and constant-throat sections

(between  $-9.3 < x/r_{exit} < -2.6$ ). The difference disappears after that and the profiles perfectly match.

When the flow is supersonic ( $P_{in} \geq 160$  kPa), both turbulence models predict the same Mach number profiles inside the nozzle. Outside the nozzle, there are some slightly higher values predicted by the Realizable  $k - \varepsilon$  model within the potential core, i.e.,  $0 \leq x/r_{exit} \leq 10$ , followed by a slightly earlier decay in velocity. The difference disappears after that and the profiles match. Another difference between the SST  $k - \omega$  and Realizable  $k - \varepsilon$  models is that the former model predicts a sharp velocity decay; whereas the latter model predicts a much smoother velocity decay at the end of the potential core.

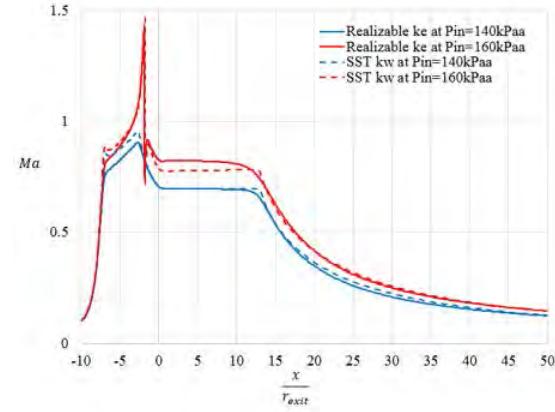

Figure 11: Mach number profile along the jet symmetry axis predicted by different turbulence model at  $P_{in} = 140$  kPa and  $P_{in} = 160$  kPa.

### 3.4 Entrainment Rate Profiles

This specific nozzle is used to provide gas flares with air to facilitate smokeless combustion. Therefore, it is important to quantify the variation of the mass entrainment along the jet centerline with the upstream pressure. The total mass flow rate through a given cross-section downstream of the nozzle is denoted by  $M$  and the mass flow rate at the nozzle exit is denoted by  $M_{exit}$ . The entrainment rate coefficient, defined as

$K_e = \frac{dM}{dx} \frac{r_{exit}}{M_e} \left( \frac{\rho_e}{\rho_x} \right)^{0.5}$  [27], where  $\rho_e$  and  $\rho_x$  are the initial and entrained fluid densities, respectively, increases linearly as shown in Figure 12. For sake of illustrations,  $K_e$  graphs at lower pressure (where nozzle flow is subsonic with  $0.5 < Ma < 0.9$ ) and higher pressure ( $1.5 < Ma < 2.0$ ) are not shown on the graph. However, the normalized entrainment graphs at operating pressures of  $120$  kPa  $\leq P_{in} \leq 180$  kPa almost collapse on the presented graphs with insignificant difference.

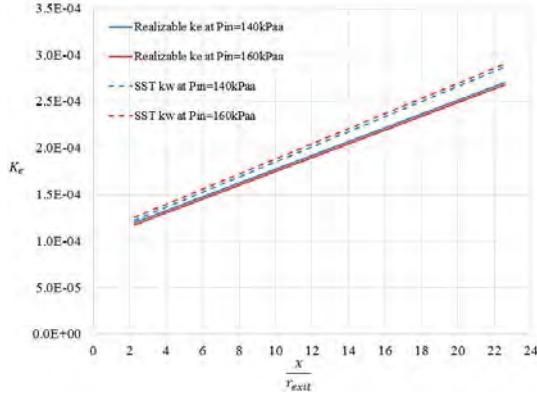

Figure 12: The entrainment rate coefficient  $K_e$  as a function of distance along the jet for different turbulence models.

#### 4. CONCLUSIONS

Numerical studies of compressible flow in a specific converging diverging nozzle were conducted. The nozzle consists of converging and diverging sections connected via a throat section with a finite length and constant diameter. The jet generated by the nozzle is used to control the performance of typical industrial flare systems by entraining the right amount of air into the flame to assure a smokeless flame. The numerical studies characterized the nozzle performance at various pressure ratios (NPR) in the range  $1.18 \leq \text{NPR} \leq 1.78$  for two different turbulence models. The mean axial velocity profiles at different streamwise locations, mass entrainment rates, the turbulent kinetic energy and Mach number along the jet centerline were presented.

In the case of subsonic nozzle flow, the mean axial velocity profiles were found to be insensitive to the turbulence models used. However, for supersonic flow this insensitivity was seen only downstream of the nozzle exit and outside the potential core region, while within this region the SST  $k - \omega$  model showed an unexpected deficit in the mean axial velocity profiles. The turbulent kinetic energy profiles for different turbulence models follow each other closely, with the Realizable  $k - \varepsilon$  model predicting a slightly higher peak value.

For this nozzle design, the flow along the centerline becomes supersonic at the end of the finite-length throat right before entering the diverging part. The turbulence models capture the same normal shock location along the nozzle symmetry axis. The SST  $k - \omega$  predicts a slightly higher Mach number in the converging and constant-throat parts of the nozzle when the flow is subsonic. The Realizable  $k - \varepsilon$  model, on the other hand, predicts a slightly higher

velocity in the potential core when the flow is supersonic. The entrainment rate coefficient increases linearly with the distance along the jet centerline, as reported in [27].

Finally, it is found that the SST  $k - \omega$  model, which is a superior model when the flow contains a separation region, predicts an unrealistic velocity deficit in the potential core when the flow became supersonic inside the nozzle. This velocity deficit was not associated with any flow separation at the wall as the diverging section angle in this nozzle was relatively small and no flow separation was observed for the flow.

chandra@mie.utoronto.ca

**Abstract**—When thin paint layers are exposed to heat, evaporation of the solvent begins, and significant movement within the paint film occur, causing temperature and concentration gradients. A clear coat paint was used, which had a density of  $988 \text{ kg/m}^3$ , viscosity of  $240 \text{ cP}$  and a surface tension of  $26 \text{ mN/m}$  and was mixed with spherical solid blue particles with a mean diameter  $26 \mu\text{m}$  were added to the paint at 2% concentration of the total mass. A knife edge was used to coat stainless steel substrates at different thicknesses and placed in a convection oven at  $121^\circ\text{C}$  for 30 minutes. Images of the samples during the curing process were taken, showing how the pigments moved from low to high surface tension areas. Colour measurements were taken to show that increasing the thickness of the same paint significantly decreases the lightness value.

## I. INTRODUCTION

The paint applied on a car serves two functions: to appear attractive and uniform in colour, as well as protecting the car from abrasion and corrosion. In recent years, the automotive industry has been investigating the incorporation of metallic pigments within solvent based paints, due to their visual appeal and increased ability to protect against the aforementioned factors [1]. However, the manufacturing process of spraying this paint onto car parts does not yield consistent colour reading results [1]. This problem was approached in two directions; varying the composition of the paint, and varying the coating process of the paint.

The location of the pigments within the paint film significantly impacts the colour of a sample [2]. Kirchner and Houweling [2] conducted a study on changing the paint composition to use different types of metallic pigments of different shape and surface roughness with various toners and metallic pigment orientation controlling agents. Their results for solvent based

paints stated that flop controlling agents had limited success on improving the orientation of the metallic pigments, with just  $1^\circ$  decrease in the flop angle [2]. The conclusions were that other alternative mechanisms are responsible for the disorientation of pigments, but it was still unclear as to what those mechanisms were [2]. Kirchner [3] then conducted another study, which was focused on the orientation of the pigments during the curing process from a cross sectional perspective. It was determined that the evaporation of the solvent does significantly influence the orientation of the pigments, however is again is not the only mechanism causing it [3].

This, film shrinkage, that Kirchner [3] investigated is caused by a well-researched effect. Once a sample is exposed to heat in a convection oven, convective cells (Bénard-Marangoni cells) begin forming as a result from concentration and temperature gradients [4, 5]. These convective cells move from low to high surface tension areas [4]. In paint applications, once the Bénard-Marangoni cells occur and all the solvents has evaporated, the paint beings to harden in these hexagonal structures, creating an effect known as “orange peel”, which is defined by a surface resembling the skin of an orange [6]. It is not desirable to this effect occur, as the increased roughness due to the waves from the hardened Bénard-Marangoni cells adversely impacts the colour readings of the paint samples [7].

This paper will focus on changing the thickness of the paint with solid spherical nonmetallic pigments, as these pigments used in this study are within the same order of magnitude of the metallic pigments used in the automotive industry.

## II. EXPERIMENTAL SYSTEM

A clear coat model paint was used, which had a density of  $988 \text{ kg/m}^3$ , viscosity of  $240 \text{ cP}$  and a surface tension of  $26 \text{ mN/m}$  [6]. Spherical solid blue particles of a mean diameter  $26 \mu\text{m}$  were added to the paint, at a concentration of 2% of the total mass of the paint. A knife edge, shown in Figure 1, was used to coat reflective stainless steel substrates with a diameter of  $50.8\text{mm}$  and a surface roughness of  $0.1 \mu\text{m}$ .

Funding for this project was provided by NSERC and Magna Exteriors.

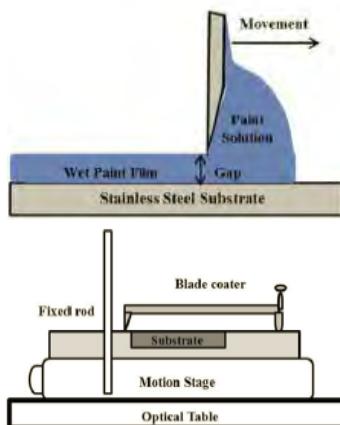

Figure 1. Knife edge coating apparatus [6]

After each sample was coated, it was given a flash off time of 20 seconds before it was placed in the oven, to avoid air entrapment within the sample. The sample was then placed in the convection oven to bake for 30 minutes at approximately  $121.1^{\circ}\text{C} \pm 1.5^{\circ}\text{C}$ .

Figure 2 shows the schematic of the experimental system of the convection oven. Two flexible heating sheets at  $1.55\text{W/cm}^2$  were placed on opposing sides of the oven and secured with an adhesive. Each heating sheet was connected to a variac, which was then connected to a temperature controller. This controller received readings from the thermocouple placed behind each heating sheet. An additional thermocouple was placed right beside the sample in the oven, to continuously measure the temperature. Excluding the oven's legs and the observation window, the rest of the oven was covered with thermal insulation to reduce the heat loss. The sample was then observed with a Pixelink PL-D7715CU-T camera with a resolution of  $4608 \times 3288$  [8], which took images during the curing process. Mass measurements were collected every 60 seconds with a resolution of 0.1 mg.

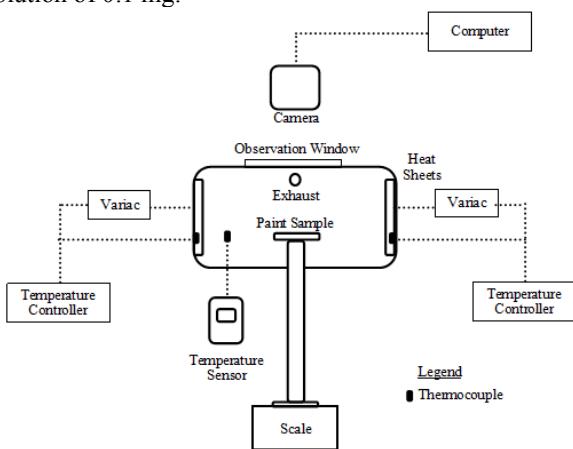

Figure 2. Convection oven curing system

### III. RESULTS AND DISCUSSION

Once the sample is placed in the oven, the solvent begins to evaporate, causing the paint resin and pigments to move. This creates concentration and density gradients within the paint film, which results in surface tension gradients.

Figures 3 to 5 (with Figures 4 and 5 on the following page) show how the pigments move within the Bénard-Marangoni cells throughout this curing time. The initial thicknesses were extrapolated by determining the volume of the paint on the substrate and measuring the mass of the substrate. The field of view in each photo is 5.7mm wide.

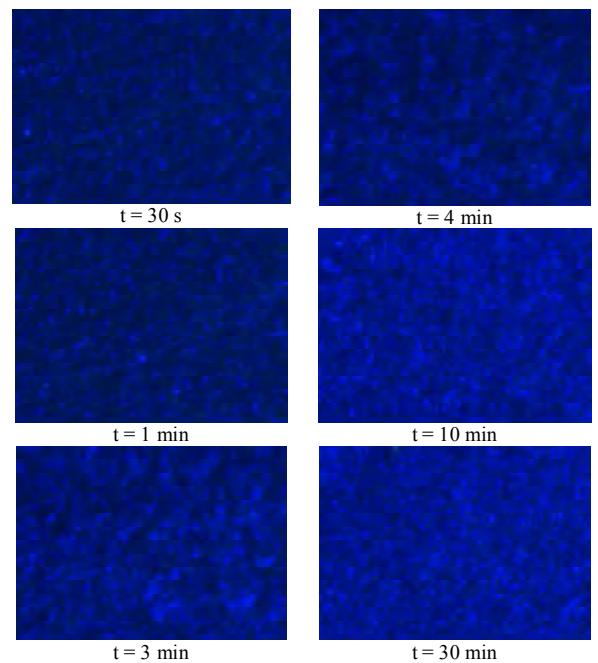

Figure 3.  $300 \mu\text{m}$  sample blue pigments moving within the Bénard-Marangoni cells

In Figure 3, at  $t = 30$  seconds, the boundaries of the Bénard-Marangoni cells at the  $300 \mu\text{m}$  sample are present. After  $t = 3$  minutes, the  $300 \mu\text{m}$  sample appears to have a significant decrease in magnitude, as the changes between the images in minutes 3 to 4 are negligible. At  $540 \mu\text{m}$ , Figure 4 shows that there is continuous movement of the pigments for the first 4 minutes before the velocity magnitude decreases, with significantly larger Bénard-Marangoni cells than shown in Figure 3. Lastly, Figure 5 shows the pigments moving within the Bénard-Marangoni cells within the first 6 minutes of the curing process. Similarly seen in Saranjam [6], a secondary quasi-stationary period, with elongated cells are observed after the primary Bénard-Marangoni cells.

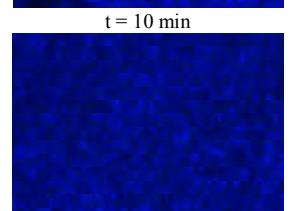

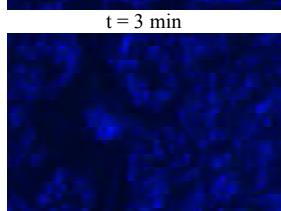

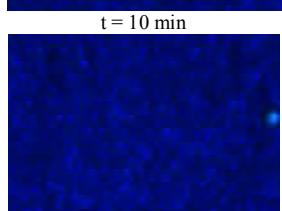

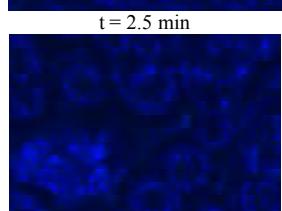

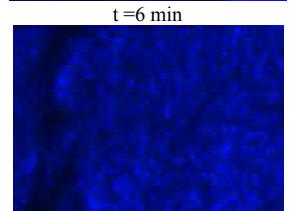

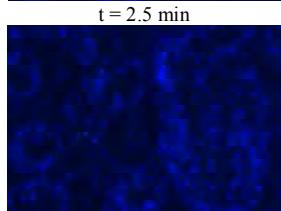

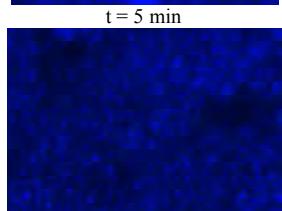

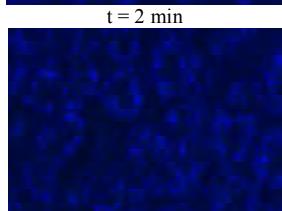

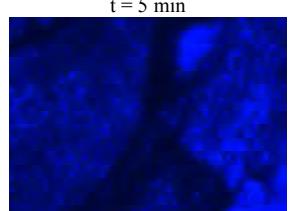

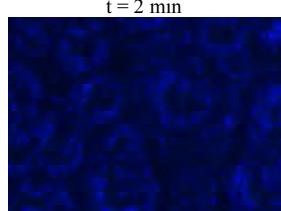

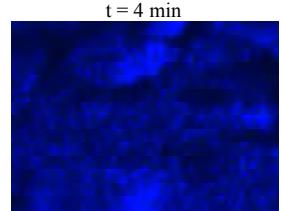

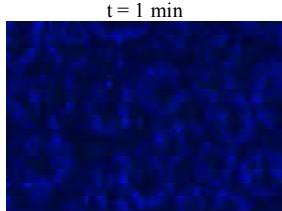

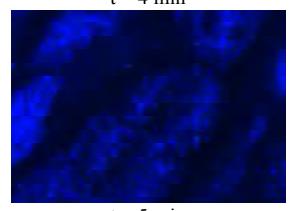

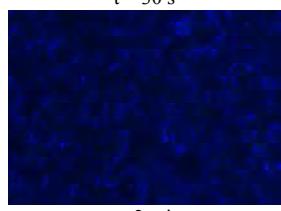

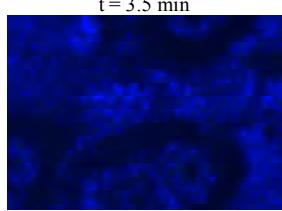

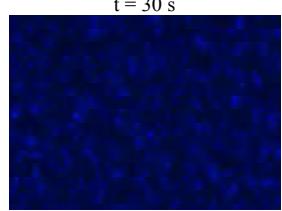

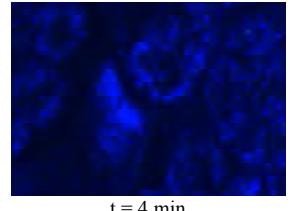

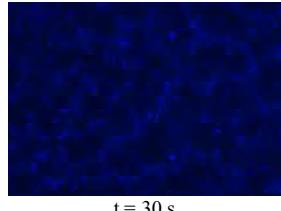

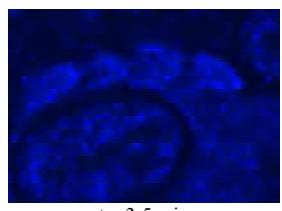

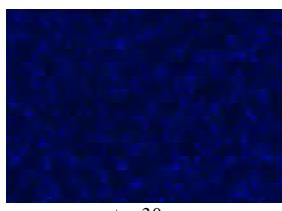

Figure 4. 540  $\mu\text{m}$  sample blue pigments moving within the Bénard-Marangoni cells

All the images collected during the curing process were then analyzed using Particle Image Velocimetry (PIV) in Matlab [9, 10, 11], which calculated the velocity magnitude between frames throughout the 30-minute curing process, which is shown in Figure 6.

This PIV analysis concludes what Figures 3-5 already show- the larger the paint film thickness, longer the pigments move within their cells. Additionally, Figure 6 shows that the velocity of these pigments increases with increasing paint thicknesses. This is expected as there is more solvent and pigments that would cause greater concentration gradients and therefore higher surface tension gradient.

Figure 5. 750  $\mu\text{m}$  sample blue pigments moving within the Bénard-Marangoni cells

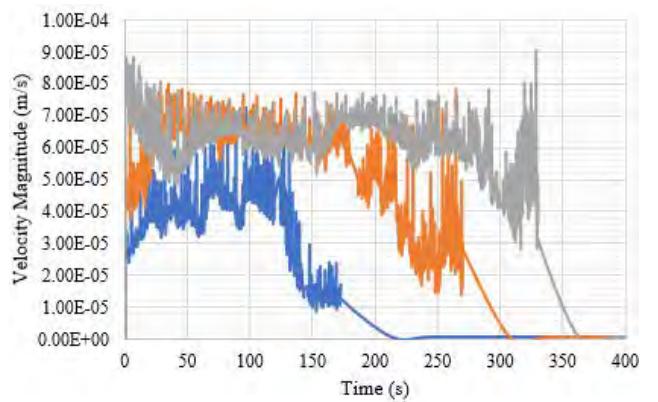

Figure 6. Velocity magnitude of the pigments within the paint. 300  $\mu\text{m}$  in blue, 540  $\mu\text{m}$  in orange and 750  $\mu\text{m}$  in grey.

After the samples were cooled, their colour was measured using the Nix Color Pro Sensor [12]. This sensor can be used under different lighting and observation angle conditions. The lighting condition was set to illuminate at the D65° setting, which simulates daylight, and both observation angles of 2° and 10° were used [12]. This is to simulate the multiple different observation angles that is used in the automotive industry [13]. The sensor measured colour using the CIELAB colour space, as it is the standard used in industry [13], and the colour was measured in 5 different places on the sample. In the CIELAB colour space, parameters are linearly proportional to the change in colour. Figure 7 shows how many units the parameters, lightness (L), the red to green value (a), and yellow to blue value (b) change from the initial colour of the substrate, where an increase in any parameter corresponds to the name of the parameter, and a decrease corresponds to the converse of the parameter's name [13]. Since the human eye is most susceptible to changes in the lightness value, it is that change in parameter that has the most significance in colour standards [14]. Figure 7 shows the change in CIELAB colour readings from the sample's colour reading minus the reflective substrate's colour reading. Since the difference in colour readings between the observation angles are negligible, the readings taken at an observation angle of 10° is shown in Figure 7.

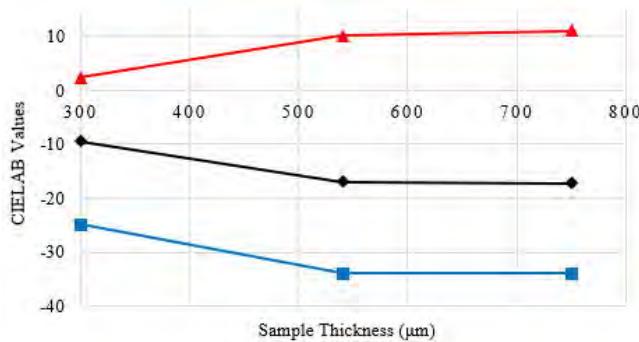

Figure 7. Change in colour readings reading at observation angle 10° L is grey, a is green, and b is yellow.

The most significant change colour change occurred by increasing the paint's thickness from 300 to 540 μm. This increase made the 540 μm appear to be darker, redder and bluer. Meanwhile, the increase in paint thickness from 540 to 750 μm did not have as large of an impact, with the 750 μm sample appearing darker and redder.

#### IV. CONCLUSION AND FUTURE WORK

During the paint curing process, evaporation of the solvent creates concentration and temperature gradient throughout the paint film. The thickness of the paint moves the pigments within the paint, outlining the Bénard-Marangoni cells which occurs due to the fluid moving from low to high surface tension areas. The velocity magnitude of the pigments moving between these low to high surface tension areas increases as the paint thickness increases. The understanding of this flow will be essential for

the next sets of tests involving metallic pigments-with a significantly larger size and shape at different amounts.

The thicker paint films resulted in significantly darker colour readings. These set of tests will be repeated with a lowered percentage of pigments to total paint mass; to observe this effect on the velocity magnitude and colour.

With these variation of the paint composition, an analytical mass diffusion analysis will be compared to the experimental results and the concentration gradients will be calculated, to see the paint composition's effect on the mass diffusion.

**Abstract**— Particle image velocimetry (PIV) data processing is a computationally expensive process. The immense time taken to analyze data can limit the maximum dataset size. Using graphics processing units (GPUs) has been shown to drastically decrease the processing time for PIV image pairs. The open-source PIV data processing software OpenPIV has been ported to run on a GPU to boost speed and efficiency and has outperformed the CPU version of the software. A multi-pass method is being implemented in OpenPIV to improve both speed and accuracy. The completed algorithm will be tested on an embedder CPU-GPU device, a desktop computer, and the SOSCIP GPU-accelerated supercomputing cluster. Ultimately, OpenPIV will run on a wide variety of computer platforms and enable larger datasets to be collected, leading to better statistics on the resulting velocity fields.

**Keywords-** *PIV; GPU*

## I. INTRODUCTION

Particle image velocimetry (PIV) has become a powerful tool for studying aerodynamic flow. However, the time required to process PIV data can be considerably large which limits the maximum size of a dataset, leading to concerns about statistical convergence. Normally, PIV data is processed on serial computers, utilizing multiple cores and multithreading technology to speed up calculations. Despite advances in serial computing hardware, the processing remains too slow for large datasets. Therefore, PIV algorithms are being developed to run on parallel architectures equipped with graphics processing units (GPUs).

Most PIV algorithms use cross-correlation-based methods which are extremely parallelizable and therefore can be considerably accelerated using GPUs. Executing a PIV window deformation algorithm with multiple GPUs on a  $256 \times 256$  pixel image, researchers were able to increase processing speed by 120 times, resulting in a processing speed of 30 pairs per second [1]. In another study, by storing matrices as texture maps on the GPU, images were processed at a speed of 13 pairs per second for a  $1024 \times 1024$  pixel image [2]. Taking a different

approach, researchers using a gradient-based cross-correlation algorithm (FOLKI) on an NVIDIA Tesla C1060 GPU achieved a  $50 \times$  speedup on  $1376 \times 1040$  pixel images, resulting in a processing speed of 5 image pairs per second [3]. This is an immense speedup, considering that analyzing a single image pair on serial computers can take on the order of one minute.

It is clear that GPUs can be used in various PIV algorithms to accelerate data processing. Some commercial PIV software has added support for GPUs, but the code is proprietary and thus cannot be developed, optimized for specific architectures, or ported to different architectures such as ARM processors or supercomputing clusters. Therefore, the open-source PIV data processing code OpenPIV has been developed to utilize GPUs. Transferring the cross-correlation portion of the algorithm to the GPU resulted in a  $10 \times$  speedup when compared to running on a CPU. The total processing time only decreased by a factor of 2. The majority of processing time was spent on the CPU performing sub-pixel peak approximations and velocity field calculations, both of which could be accelerated using a GPU. Another shortcoming of OpenPIV is it does not have full support for multi-pass. A PIV multi-pass algorithm first calculates a coarse velocity field (usually on a  $64 \times 64$  pixel grid), then uses that information to calculate a finer velocity field. This process repeats until noise levels becomes too great and the highest resolution velocity field is achieved. Furthermore, for complex flows with turbulence and regions of high shear, the absence of a multi-pass PIV algorithm results in more spurious vectors in the final velocity field. Correcting for the spurious vectors is computationally expensive and can not be ported to a GPU, inevitably slowing down the computations. Developing the multi-pass portion of OpenPIV to execute on the GPU would greatly reduce the number of spurious vectors as well as the processing time.

Having a fast, open-source platform for PIV data processing using GPUs would be a valuable tool for multiple researchers. The code can run on any platform, and can be optimized for specific systems. For this to be fully realized, more of the code must be rewritten to run on the GPU, and full support for multi-pass must be added. To ensure universality of the code across

platforms, the OpenPIV software will be tested on a desktop computer with a GPU, an embedded CPU-GPU development system, and the SOSCIP GPU-accelerated supercomputing cluster at SCINET.

## II. METHODS

All software development is done using an NVIDIA Jetson TX1, referred to from now on as the TX1, which is an embedded CPU-GPU platform for developing GPU accelerated software. The TX1 includes a quad-core ARM Cortex-A57 processor (host) with 4GB of RAM, a 256-core NVIDIA Maxwell GPU, and a variety of I/O ports for peripherals. The host runs the algorithm and transfers certain calculations to the GPU. The data transfer between the host and the GPU is time consuming and often comprises most of the GPU related processing time. Therefore, maximal speed is obtained by strategically and efficiently managing data transfer between the host and GPU. For further testing, the software will be run on a desktop CPU with 16GB of RAM and an NVIDIA GEFORCE GT 710 GPU, as well as the SOSCIP cluster at SCINET which includes 14 IMB servers, each with  $2 \times 10$  core CPUs with 512GB of RAM and 4 NVIDIA Tesla P100 GPUs.

The version of OpenPIV being developed was originally written in Python. However, Python is unable to execute on the GPU. To run code on an NVIDIA GPU, the CUDA interface must be used. CUDA is a layer of software that allows certain languages, such as C, C++, and Fortran, to execute on the GPU. Therefore, the library PyCUDA [4], a Python wrapper for CUDA functions, was used to insert C code into OpenPIV and interface with the GPU. Additionally, some functions from the GPU accelerated Scikits-CUDA library were used. For increased speed, OpenPIV was compiled using Cython.

The PIV algorithm works by cropping an image pair into smaller overlapping regions called interrogation windows (IW) and then uses a FFT-based cross-correlation algorithm on each IW pair to calculate the velocity field. A depiction of the process is shown in Figure 1. This portion of the algorithm has already been written for the GPU, resulting in a  $10 \times - 35 \times$  speedup depending on IW properties. To further improve OpenPIV, multi-pass capabilities will be added to the software.

A PIV multi-pass algorithm iteratively refines the resolution of the velocity field until the maximum resolution is achieved. First, a coarse velocity field is calculated over the domain. Then, the grid is refined and corrections to the velocity on the finer grid are calculated. This process is then repeated until the noise becomes excessive, or the properties in each grid cell are not optimal for PIV calculations. The iterative method being developed in OpenPIV is based on the work done by Scarano and Riethmuller [5]. The multi-pass algorithm in OpenPIV must be parallelized to run on the GPU. The algorithm contains multiple loops for bounds checking, correction calculations, interpolations, and velocity calculations that can be massively accelerated using the GPU.

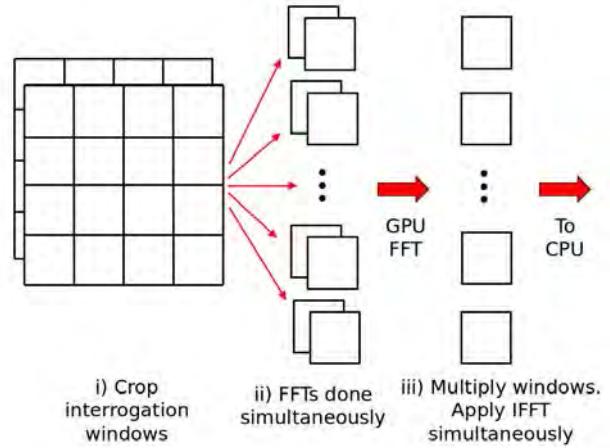

Figure 1. Scheme for calculating FFTs on the GPU

## III. EXPECTED RESULTS

The OpenPIV software will be tested on two datasets. The first contains data on a flow control experiment of low Reynolds Number airflow over an airfoil. The experiment was done at a range of angles of attack using a variety of flow control parameters. Details of the experimental setup can be found in [6]. 1000 image pairs were taken at a resolution of 2560 x 2160 pixels. This data was originally processed using the commercial software package LaVision, which provides a set of results for comparison.

The second dataset is open-source and was originally intended to test PIV uncertainty quantification algorithms [7]. The experiment consists of a single turbulent jet with multiple sets of images taken at different regions of the jet, including the jet-core and shear layer. The dataset at each location contains an accurate velocity field calculated from ultra-high resolution images as well as a set of lower resolution images to use with PIV software.

For both datasets, three properties will be investigated. First, the difference in processing time between the GPU-accelerated and CPU version of OpenPIV will be calculated. It is expected that the GPU-accelerated version will be more than  $2 \times$  faster than the CPU version as more portions from the previously accelerated algorithm are being moved to the GPU. Second, the number of spurious vectors produced in the final velocity field with and without multi-pass will be compared. It is expected that the multi-pass version will produce far less spurious vectors as it should reduce the relative noise level in the calculations. Third, velocity field results of the full GPU-accelerated, multi-pass algorithm will be compared to the LaVision and high resolution velocity field in each dataset. Comparisons for each image pair, the resulting velocity field, and other statistics will be made. When previously compared to LaVision, the CPU version of OpenPIV which did not use multi-pass performed well, except in regions of high shear, such as the boundary layer over the airfoil. The addition of multi-pass is expected to greatly improve

the accuracy of the algorithm, especially in regions of turbulence and high-shear.

The processing time will be tested on three different computer platforms to investigate how the algorithm performs across architectures. The platforms, mentioned before, are the Jetson TX1, a desktop computer equipped with an NVIDIA GPU, and the SCOSCIP GPU-accelerated supercomputing cluster at SCINET. The comparison between the TX1 and the desktop computer will be interesting, as the TX1 has a two times more powerful GPU, but the desktop has four times more RAM. It is still expected that the TX1 will outperform the desktop computer, as the bulk of the calculations will be done on the GPU.

Despite the fact that the SCOSCIP cluster is expected to massively outperform the other platforms, the results can be used to infer a maximum PIV dataset size when using supercomputing clusters. When using normal desktop computers, reasonable PIV datasets range from 500 - 1000 images. This puts severe limits on the statistical convergence of some calculations, and increasing the image size by an order of magnitude or more using a supercomputer cluster would be extremely advantageous.

#### IV. CONCLUSION

Running PIV algorithms on GPUs can greatly decrease processing time. The open-source PIV data processing software OpenPIV is currently being developed to run on a GPU with added support for multi-pass. The software is written in a combination of Python and CUDA C which is then compiled using Cython, which can run on any architecture that has a

CUDA capable GPU. Once complete, OpenPIV will be tested in a variety of datasets for speed and accuracy. The software will also be run on an embedded computer, desktop computer, and supercomputing cluster to compare performance. Ultimately, this project will provide an open-source tool for PIV analysis that will operate on a wide variety of computing platforms.

# A Droplet Deformation and Fragmentation in a High Speed Air Jet

Maryam Medghalchi, Nasser Ashgriz  
 Department of Mechanical and Industrial Engineering  
 University of Toronto  
 Toronto, Canada  
 medghalchi@mie.utoronto.ca, ashgriz@mie.utoronto.ca

**Abstract**— Impingement of a gas jet on a suspended water droplet is modeled numerically. The jet velocity and jet diameter effects on the penetration length and the shape of the gas tunnel inside the droplet are studied. The gas tunnel inside the droplet is smaller on the windward and larger on the leeward of the droplet. Different types of breakup processes are identified and categorized according to jet to droplet diameter ratio, as well as the droplet Weber number.

**Keywords:** droplet breakup; fragmentation; jet ;

## I. INTRODUCTION

The droplet deformation and fragmentation are involved in many different systems, such as in fuel injection systems and powder production system. The process of droplet fragmentation is a complex one involving large interface deformations and interface breakups, and mostly in turbulent conditions. In order to characterize this complex process, usually the droplet breakup process is studied in a more controlled condition. For instance, a single droplet is injected into a high velocity gas flow and its deformation and breakup is determined at different gas flow velocities. Almost all prior studies on the droplet deformation and breakup have considered a droplet in a gaseous crossflow, where the gaseous crossflow is much larger than the droplet diameter. The present study has taken a different approach. Here, the deformation and a breakup of a droplet subject to a cross flow that its diameter is in the order of the droplet diameter is considered.

The droplet behavior is generally characterized using a Reynolds, a Weber and an Ohnesorge number defined as [1]:

$$Re = \frac{\rho_l U D_{drop}}{\mu_l} \quad (1)$$

$$We = \frac{\rho_l U^2 D_{drop}}{\sigma} \quad (2)$$

$$Oh = \frac{\sqrt{We}}{Re} = \frac{\mu_l}{\sqrt{\rho_l D_{drop} \sigma}} \quad (3)$$

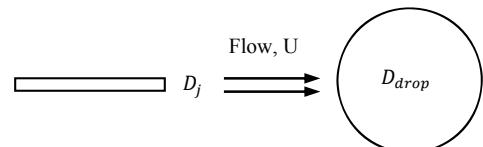

where  $D_{drop}$  is the droplet diameter,  $U$  is the relative velocity between the gas and the droplet,  $\rho_l$  is the liquid density,  $\mu_l$  is the liquid viscosity, and  $\sigma$  is the coefficient of surface tension.

Gelfand [2] categorized the droplet breakup into several different modes as a function of  $We$  and  $Oh$ . The following modes are identified: Vibrational, bag breakup, multimode, sheet thinning and catastrophic modes. In the vibrational mode, the drop oscillates until it divides into smaller droplets. In the bag breakup mode, a thin shell is generated, which later bursts forming many small fragments. The multimode breakup is similar to the bag breakup except that it includes a stamen, which forms in the leeside of the droplet (opposite to the gaseous flow). In the sheet thinning breakup, the surface of the droplet is sheered forming a thin liquid sheet, which later breaks forming small fragments. In the catastrophic breakup, the droplet instantly fragments into many small droplets. Guildenbacher et al. [3] reviewed the droplet secondary breakup and they found that viscous forces do not play a significant role at moderate Weber numbers. There are many other studies on the droplet breakup, and readers are referred to see the following references [4-10].

In the present study, we consider the impingement of a gas jet on a droplet, where the gas jet diameter is about the size of the droplet.

## II. METHODOLOGY

Figure 1 shows the problem parameters. An initially stationary droplet with diameter  $D_{drop}$  is exposed to a gas jet with diameter and velocity. The dynamics of the droplet deformation and breakup is simulated numerically.

**Figure 1: Schematic diagram of the nozzle and droplet**

The numerical code used is ANSYS/FLUENT. The gas-liquid interface is tracked by Volume Of Fluid (VOF) method. Continuity, momentum and energy conservation equations are solved with presence of the gravity. The turbulence model is RANS, standard  $k-\varepsilon$  [11].

The governing equation are:

$$\frac{1}{\rho_q} \left[ \frac{\partial}{\partial t} (\alpha_q \rho_q) + \nabla \cdot (\alpha_q \rho_q \vec{u}_q) \right] = 0 \quad (4)$$

$$\frac{\partial}{\partial t} (\rho \vec{u}) + \nabla \cdot (\rho \vec{u} \vec{u}) = -\nabla p + \nabla \cdot [\mu (\nabla \vec{u} + \nabla \vec{u}^T)] + \rho g + \vec{F} \quad (5)$$

$$\frac{\partial}{\partial t} (\rho E) + \nabla \cdot (\vec{u} (\rho E + p)) = \nabla \cdot (k_{eff} \nabla T) \quad (6)$$

where in equation (4),  $\alpha_q$  is the volume fraction of the secondary phase,  $\rho_q$  is the density of the secondary phase and  $u$  represents the velocity. In equation (6),  $k_{eff}$  is the effective thermal conductivity.

The continuous phase volume fraction is determined by,  $\sum_{q=1}^n \alpha_q = 1$  and  $\rho = \sum \alpha_q \rho_q$ , and  $\mu = \sum \alpha_q \mu_q$ . In equation (6),  $E$  is the mass average of specific heats of phases.

$$E = \frac{\sum_{q=1}^n \alpha_q \rho_q E_q}{\sum_{q=1}^n \alpha_q \rho_q} \quad (7)$$

#### A. Numerical Setup

To reduce the computational time the numerical simulations are run on a  $3cm \times 1cm$  rectangular 2D-axisymmetric geometry with the total of 1,140,000 computational cells in fine mesh cases. In coarse mesh cases, the number of cells is reduced to 58,000.

The air density is determined using the ideal gas equation of state and the droplet density is assumed to be constant.

Three different nozzle sizes with different jet velocities and droplet sizes are simulated. Results are presented in the following section.

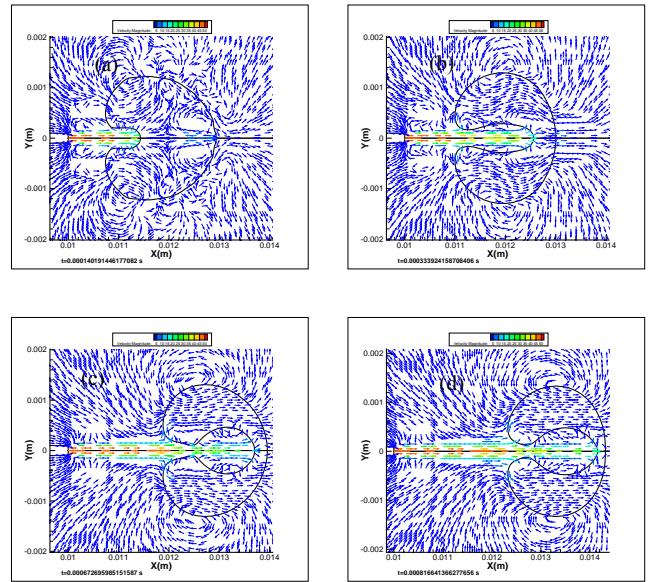

### III. RESULTS AND DISCUSSION

Two different droplet sizes of  $2.4mm$  and  $4.8mm$ , and three different air jet diameters of  $0.2mm$ ,  $0.4mm$  and  $3.8mm$  with two different gas velocities of  $49.7m/s$  and  $99.4m/s$  are considered.

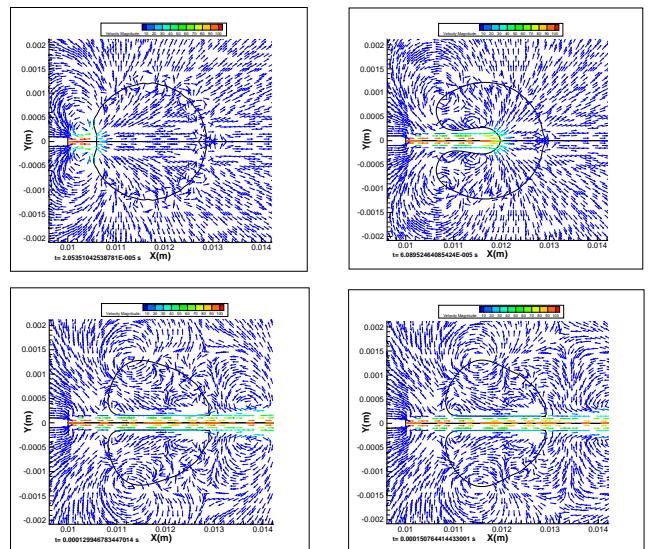

Figure 2 shows the impingement of a  $0.2mm$  air jet with jet velocity of  $49.7m/s$  on a  $2.4mm$  water droplet. The Weber number based on droplet diameter for this case is  $We_{Drop} = 124$ . The air jet impinges on the droplet and penetrates into the droplet forming an air tunnel. The liquid surface tension forces resist the jet flow. Therefore, the incoming gas goes through a circulation pattern forming a large cavity inside the droplet (see the evolution of the cavity in Figure 2a to 2d). In addition, the liquid at the windward of the droplet is pushed together to close the jet opening zone. Moreover, Figure 2 shows that droplet oscillates between circular and oval shape.

Figure 3 shows the droplet deformation for a gas jet velocity of  $99.4m/s$  (Weber number 496) for the same jet and droplet diameters as in Figure 2. In this case, the air jet is strong enough to overcome droplet inertia and surface tension forces, and pierces through the droplet.

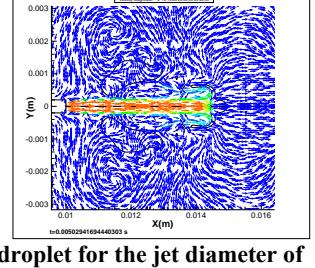

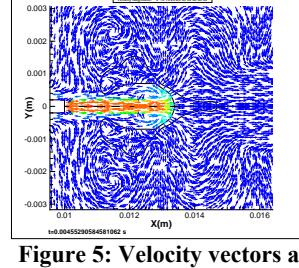

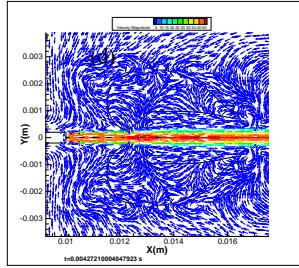

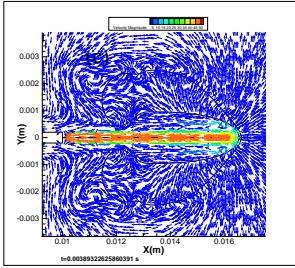

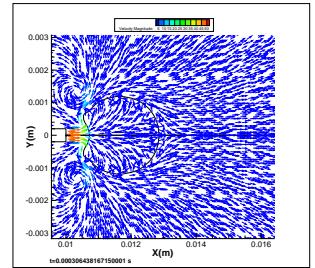

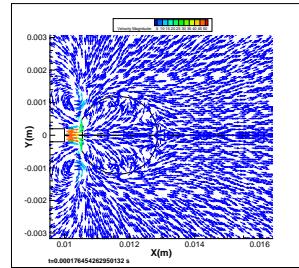

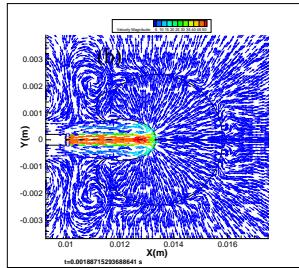

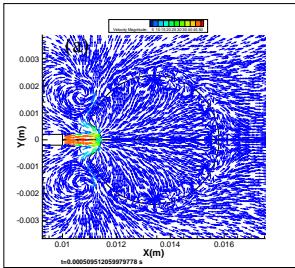

Figure 4 shows the velocity vectors on the droplet plane for a jet diameter of  $0.4mm$  and a droplet diameter of  $4.8mm$ . Both the jet diameter and droplet diameter are increase such that their ratio is kept the same as those shown in Figure 2 and Figure 3. The jet velocity in this case is  $49.7m/s$  (same as Figure 2, however, the Weber number is 248). In Figure 4, the jet impinges, penetrates and pierces through the droplet. A similar type of cavity as in Figure 2 is observed in this case. However, in this case, because of higher inertia, the jet can force through the droplet. The bursting of a liquid layer that is formed at the time that the gas jet emerges out of the droplet results in the formation of several small droplets.

**Figure 2: Velocity vectors and droplet for the jet diameter of  $0.2mm$ ,  $U = 49.7m/s$  and  $We_{Drop} = 124$**

**Figure 3: Velocity vectors and droplet for the jet diameter of  $0.2mm$ ,  $U = 99.4m/s$  and  $We_{Drop} = 496$**

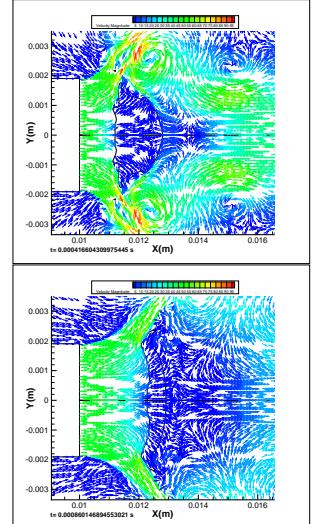

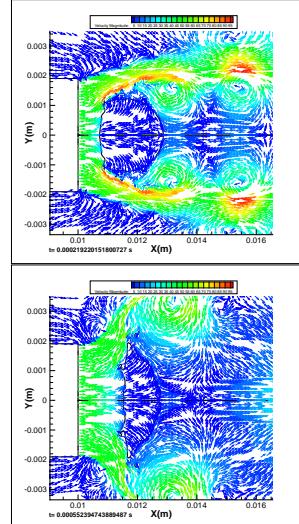

**Figure 4:** Velocity vectors and droplet for the jet diameter of  $0.4\text{mm}$ , droplet diameter of  $4.8\text{mm}$ ,  $U = 49.7\text{m/s}$  and  $We_{Drop} = 248$

Figure 5 shows droplet breakup for the same jet as in Figure 4 but with a smaller droplet size ( $2.4\text{mm}$ ). The jet diameter to droplet diameter ratio and the Weber number are reduced by 50%. Comparing two figures shows that the larger droplet breaks earlier than the smaller droplet. Moreover the shape of the air tunnel inside the droplet is different in two cases. For the larger droplet (Figure 4) the air tunnel is long and thin, however, in the smaller droplet, the air tunnel is wide and short. Furthermore, the droplet in Figure 5, is significantly deformed, indicating that the inner flow behavior influences the droplet shape.

Comparing Figure 2 and Figure 5, which have the same droplet size and different gas jet sizes, shows that by doubling the jet size and keeping the Weber number constant the droplet stretched by the flow and its thickness is decreased until it bursts.

Figure 6 shows the droplet breakup for the jet diameter of  $D_{jet} = 3.8\text{ mm}$  and the droplet size of  $D_{Drop} = 2.4\text{mm}$ . Air jet flattens the windward of the droplet and does not pierce the droplet. The droplet deforms from circular shape to a thin disk and the fragments are released from the top and bottom of the droplet.

**Figure 5:** Velocity vectors and droplet for the jet diameter of  $D_{jet} = 0.4\text{mm}$ , droplet diameter of  $D_{drop} = 2.4\text{mm}$ ,  $U = 49.7\text{m/s}$  and  $We_{Drop} = 124$

**Figure 6:** Velocity vectors and droplet for the jet diameter of  $3.8\text{mm}$ ,  $U = 49.7\text{m/s}$  and  $We_{Drop} = 124$

#### IV. CONCLUSION

Impingement of a gas jet of a liquid droplet for cases with gas jet diameter being smaller or in the order of droplet diameter are simulated numerically. The results indicate that the droplet deformation behavior is quite different than those reported in the literature for droplet deformation in a gaseous cross flow. The results show that for the jet to droplet diameter ratios less than one, a gas tunnel is formed inside the droplet that may have different configurations. At low gas jet velocities, a closed tunnel is formed which may result in an air entrapment inside the droplet. At larger gas velocities, the jet may penetrate through the droplet with less of an effect on the droplet deformation.

**Abstract**—The dynamics of a free pitching flexible cantilever NACA 0012 airfoil were investigated at transitional Reynolds numbers. This work builds on previous investigations based on a quasi-2D rigid wing, moving elastically in pitch and heave. Wind tunnel tests were performed at various speeds, and three limit cycle oscillation (LCO) branches were observed. Further work is required to supplement this preliminary analysis, such as modeling, FEA simulation, and evaluation of the strain and acceleration information of the wing deformation

**Keywords-transitional Reynolds numbers, flexible wing, LCO, free pitching, NACA0012, flexible cantilever**

## I. INTRODUCTION

The purpose of this series of experiments is to characterize the dynamics of a free pitching flexible cantilever NACA0012 wing at transitional Reynolds numbers. The wing experiences both rigid body and flexible body mode dynamics. It is well noted that the aerodynamics at transitional Reynolds numbers are complex, and include such phenomena as laminar boundary layer separation, which subsequently forms a laminar separation bubble (LSB) [1]. This paper is an extension of previous work performed on a rigid, elastically mounted in pitch and heave, quasi-2D NACA0012 wing.

### A. Wind Tunnel

The tests were performed using the RMC wind tunnel, which is a closed circuit low speed tunnel powered by a 75kW three-phase motor. The flow velocity is controlled by varying the fan speed. The freestream velocity was measured with a pitot static tube (located approximately 9 chords upstream of airfoil), which was connected to an analog pressure transducer. The test section inner dimensions are 1.07 m x 0.76 m. The turbulence intensity of the tunnel is below 0.2% [1]. There is also a safety net located approximately 3 chords downstream from the wing.

### B. Flexible Wing Configuration

The wing testing apparatus consists of the flexible NACA 0012 wing, mounted over a thin cantilever steel beam. Its kinematics can be seen in Fig. 1. The beam is fixed at its root to a free rotary base. The beam provides the structural stiffness, while the wing provides the aerodynamics loads. The wing and beam parameters can be seen in Tables I and II, respectively. The mass moments of inertia of the wing, beam and base can be seen in Table III.

TABLE I. WING PARAMETERS

<i>Material</i>	Fiberglass epoxy, foam, and plastic
<i>Span</i>	0.445 m
<i>Chord</i>	0.15 m
<i>Aspect Ratio</i>	3
<i>Mass</i>	0.145 kg

TABLE II. BEAM PARAMETERS

<i>Material</i>	AISI O1 steel
<i>Length (exposed)</i>	0.45 m
<i>Width</i>	0.051 m
<i>Thickness</i>	0.0014 m
<i>Young's Modulus</i>	200 GPa
<i>Mass</i>	0.222 kg

TABLE III. MASS MOMENTS OF INERTIA (ABOUT PITCH AXIS)

<i>Mass Moment of Inertia of Beam</i>	$5.5 \times 10^{-5} \text{ kgm}^2$
<i>Mass Moment of Inertia of Rotary Base</i>	$1.6 \times 10^{-4} \text{ kgm}^2$
<i>Mass Moment of Inertia of Wing</i>	$6.6 \times 10^{-4} \text{ kgm}^2$

The free rotary base that holds the beam is connected to translational springs on a pulley. The pitch stiffness,  $K_\theta$ , was found to be 0.24 Nm/rad.

Pitch data was measured using contactless potentiometers. The potentiometer used for the large amplitude oscillation (LAO) tests was the RLS RMA05A3A00 contactless rotary magnetic actuator, and the corresponding RM22VA0010B10F1B00 encoder body, (resolution of 0.5°). The potentiometer used for the small amplitude oscillation (SAO) tests utilized the Contelec Co-Vert-X 22E2 836 221 505 78107 1307 1 (resolution of 0.18°). LAO and SAO will be further discussed in section 3.

The beam was outfitted with two PCB Piezoelectronics 352C22 accelerometers and eight Vishay CEA-13-240UZ-120 strain gauges (four for bending and four for torsion). The data from the accelerometers fed into a PCB 483C signal conditioner. The strain gauge data fed into a model 2120 Strain Gauge signal conditioner. The conditioned strain gauge and accelerometer data, along with the potentiometer data, fed into the National Instruments cDAQ 9174, which connected to the computer and LabVIEW via USB; see Fig. 2.

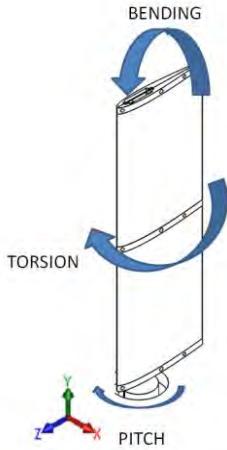

Figure 1. Illustration of Pitch, Bending and Torsion Motion

### C. Considerations for Design and Testing

The wing was supported in the wind tunnel such that the wing support was flush with the wing tunnel floor. The ratio of wing span to tunnel height was calculated and found to be less than 0.6, which ensured that the effects of the tunnel wall were negligible. [2].

The centre of gravity (CG) of the wing and beam combination was found to be 0.057 m aft of the leading edge (LE). Fig. 3 depicts the relative locations of the aerodynamic centre (AC), centre of gravity (CG), elastic axis (EA), and pitch axis (PA). In the current configuration, the EA, PA, and AC are all aligned.

The maximum blockage was calculated to be 8.3% (wing at 90° pitch angle) while the minimum blockage was calculated to be 1.0% (wing at 0° pitch angle).

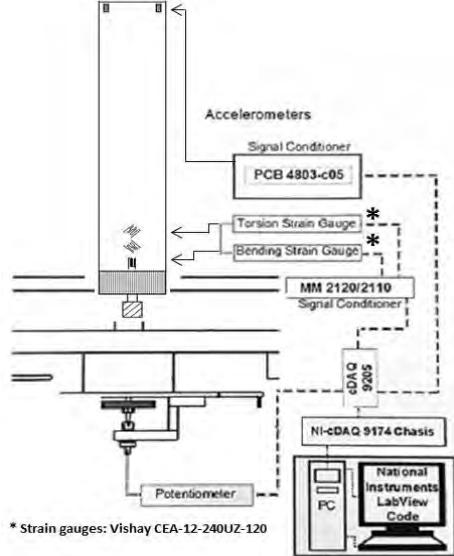

Figure 2. Experimental Test Set-Up

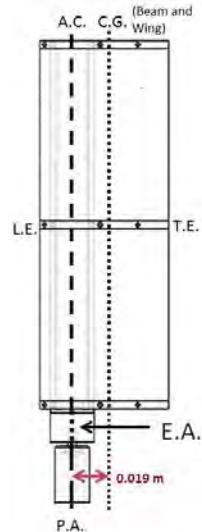

Figure 3. Relevant System Axes

## II. METHODOLOGY

### A. Testing Procedure

A total of six valid tests were performed. The test section was installed and lined up to ensure symmetry with the wind tunnel; the wing was set to zero angle of attack and set vertically straight.

The instrumentation was turned on to allow at least 20 minutes before testing, which allowed time for steady state to be reached. The wires were hooked up, isolated, and loosely taped to create support but still mitigate adding to the damping of the wing. In order to assess the ambient and equipment noise for each test, three recordings were done with the wind tunnel off, motor on, and motor and clutch on at zero RPM.

The sampling frequency was 1000 Hz. This data would be used two-fold: to find the baseline noise frequencies of the system and calculate the mean bias of the wing. Following this, the first type of ground vibrational testing (GVT1) was performed. GVT1 consisted of two free decay tests: one test with the pitch lock off (allowing for bending, torsion, and pitch, with a pitch initial condition) and one test with the pitch lock on (bending and pitch only, with a bending initial condition). With the pre-test GVT1 complete, tests were performed at various airspeeds, in combinations of increasing or decreasing airspeed sweeps, with the goal of obtaining the behavior of different amplitudes of LCO's. In an effort to locate the LCO branches, initial conditions were applied to the wing in the form of pitch perturbations and changes in airspeed. When changing sweep direction, hysteresis was noted in response due to the change in initial conditions via airspeed [3]. Following the airspeed tests, GVT1 (i.e. no-flow) was once again performed, wherein the purpose was to check if the system parameters changed. Following GVT1, the second type of ground vibrational was performed (GVT2), which was comprised of two free decay tests (with pitch initial conditions) for each of the three configurations, defined as such: S1 (rotary base, shaft, pulley, and encoder), S2 (rotary base, steel beam, eight strain gauges, two accelerometers, wires, shaft, pulley, encoder, and adhesives), and S4\*(rotary base, steel beam, NACA 0012 wing, eight strain gauges, two accelerometers, wires, shaft, pulley, encoder, and adhesives) configurations as seen in Fig. 4-6, respectively. This data would allow us to find the decay rate and damping coefficient of the system in future work.

The 1<sup>st</sup> and 2<sup>nd</sup> analytical natural frequencies were calculated for bending and torsion of the S2 configuration (based on elastical beam theory), and the pitch damped natural frequency was experimentally determined for the S2 configuration as well, as seen in Table IV.

TABLE IV.  
NATURAL FREQUENCIES (S2 CONFIGURATION)

Natural Frequencies (Hz) based on [4], [5], [6], and [7]		
Motion	Mode 1	Mode 2
Pitch	5.3	n/a
Bending	6.0	38
Torsion	102	308

Note that the bending and torsion modes (as defined by the motion of the EA) are uncoupled due to the beam uniformity. The pitch motion is also considered to be uncoupled from the torsion motion due to the large difference in frequency scale. This assumption was confirmed from results of a finite difference (FD) solution of the S2 configuration. FD modeling of the S4\* configuration resulted in the first three modes at 2.56 Hz, 5.0 Hz and 29.4 Hz. These numerical results also match those obtained from the GVT. The first mode is pitch dominated, and the second mode is bending dominated.

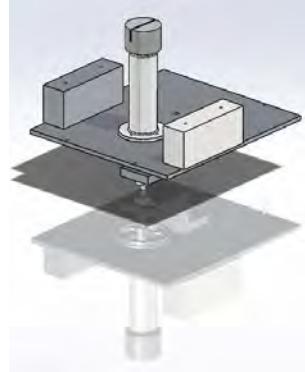

Figure 4. S1 Configuration (Rotary base only)

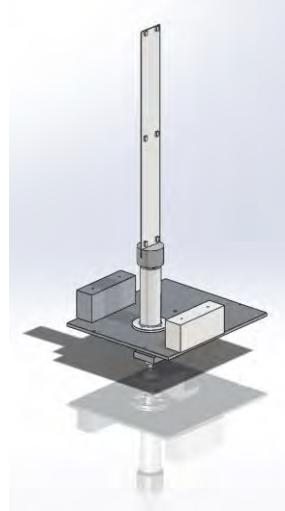

Figure 5. S2 Configuration (Rotary base and Beam)

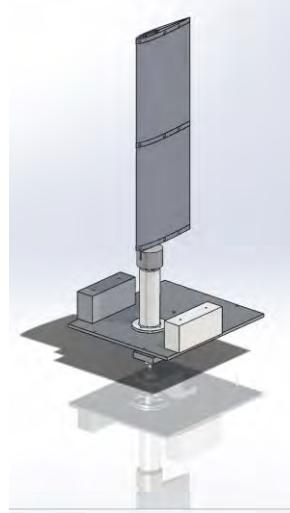

Figure 6. S4\* Configuration (Rotary base, Beam and Wing)

## B. Analysis Procedure

The data obtained from testing was recorded into text-files using LabView, which were then manipulated into suitable excel files for post-processing with Matlab code. The aforementioned codes first took the potentiometer noise data, and converted it into root pitch angle (in degrees). The data was sorted in ascending order to find the fundamental frequency, which in turn was used to filter the data and find the mean bias of the filtered data portion which had a Gaussian distribution.

The ambient test data (temperature, pressure) were used to find the air density, airspeed, and Reynolds number. The varying airspeed data was then filtered and adjusted using a low pass filter, and the mean bias. The time histories were filtered to remove high frequency noise, since they have no impact on the dynamics. The time history served to visually indicate where the LCO behavior [3] occurred and select an appropriate portion of the signal, as well as to confirm if steady-state had been attained. If no global trends indicating increasing/decreasing root pitch angle was observed, the data was assumed to be gleaned during steady state. Histograms served to provide information on the data spread and whether the dynamics were symmetrical, along with the even harmonics of the PSD's which further confirmed symmetry. Once the data was deemed properly selected and filtered, the mean and mode positive pitch angle peak amplitudes were located using the filtered time history data, while the LCO frequency was found using the filtered root pitch angle PSD's. This was performed for all five tests and yielded final values of mean and mode positive root pitch angle peak amplitudes, pitch LCO frequency, airspeed, and Reynolds number.

## III. RESULTS AND DISCUSSION

### A. Positive Mean Peak Amplitude of Root Pitch Angle Results

Values of the mean positive peak amplitude of the root pitch angle were plotted versus airspeed for all five tests (Fig. 7). The mode positive peak amplitude of the root pitch angle values were also found, and determined to be sufficiently close to the mean values, thus further substantiating that the time response was symmetrical.

It is worthy to confirm that the range of airspeeds corresponded to a Reynolds number range of  $9.11 \times 10^4 < Re_c < 1.19 \times 10^5$ , which is indeed in the range of transitional Reynolds number. Previous research has observed that the range of Reynolds numbers where LCO's occur is  $5.5 \times 10^4 < Re_c < 1.2 \times 10^5$  [8]. Hitherto for the quasi-2D rigid wing, elastically mounted in pitch and heave, two LCO regions (also called branches) had been observed [8]. These regions can be described as SAO and LAO. In this paper, we tentatively define the ranges of  $0^\circ$ - $15^\circ$ , and  $30^\circ$ - $70^\circ$  for SAO and LAO, respectively.

Referring to Fig. 7, it is substantial to notice that along with the evident SAO and LAO branches, a third branch is observed, which we have deemed very large oscillations (VLAO) and tentatively defined as the range of  $70^\circ$ - $120^\circ$ .

It is important to note that the LAO region across all tests did not appear to be stationary and at steady state, i.e. there was significant amplitude modulation and a slight global increase in peak amplitude over time. No explanations are offered at this time.

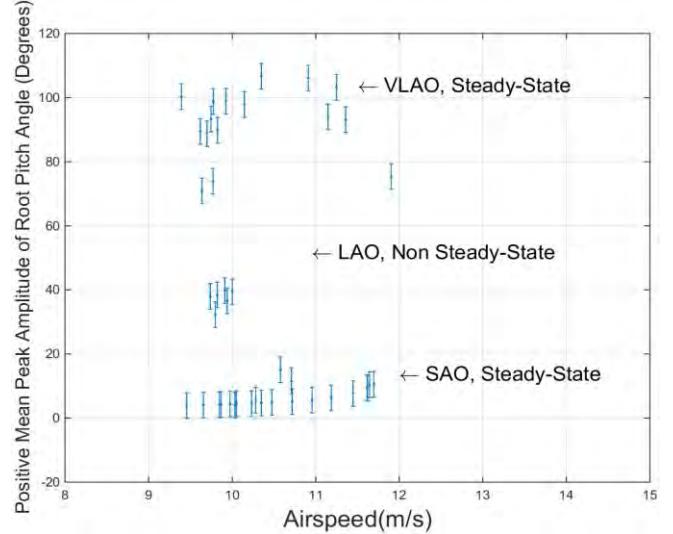

Figure 7. Positive Mean Peak Amplitude of Root Pitch Angle Versus Airspeed

It is meaningful to state that the wing could possibly be experiencing coalescence flutter or stall flutter for the LAO and VLAO branches. For the possibility of coalescence flutter, this could be a result of the coupling of the pitch and 1<sup>st</sup> bending mode as these two frequencies are close to each other (Table IV); ergo, data reduction of the torsion and bending information is an important part of future work ponderations. The information can then be compared to the bending and torsion natural frequencies in Table IV.

This preliminary focus on pitch data is important because we use it as a guide; if we ascertain that it is well behaved, we thusly assume that the bending and torsion data will also be well behaved.

While we theorize that SAO is caused by laminar flow separation, along with the free pitching wing motion which causes negative aerodynamic damping, the physical mechanisms which cause LAO and VLAO are still to be confirmed. Hence, LAO and VLAO will be the primary focus, with the SAO serving to confirm that the Reynolds number effect is present, which provides information on the state of the flow. For our testing, the existence of the Reynolds number effect confirms that the flow is laminar and the wing is smooth.

## B. LCO Frequency Results

The LCO frequencies as measured from the root pitch angle were also found, and shown in Fig. 8. For the LCO frequency behaviour (Fig. 8), an average frequency resolution  $f = 1/F_s \Delta t = 0.0305$  Hz was used, since  $\Delta t$  varied for each test. From Fig. 8, we see that once again, there are three distinct branches, corresponding to SAO, LAO and VLAO. All LCO frequencies are within the small frequency spectrum of 2.5 - 4.5 Hz. Note that these are lower than the experimental natural pitch frequency of approximately 5 Hz. Overall, as the mean peak amplitude of the root pitch angle increases, the LCO frequency decreases. Also for consideration is that the work from the quasi-2D wing [8] observed that the SAO had an approximate frequency range of 2.5 – 5 Hz, whereas LAO had an approximate frequency range of 2 – 2.5 Hz (for a frequency ratio of 0.74). This is parallel to the results shown in this paper, where the frequency ranges are approximately 3.7 - 4.5 Hz for SAO, 3.2 - 3.7 Hz for LAO and 2.8 - 3.1 Hz for VLAO.

While this work provides a good basis in the ongoing research to characterize the dynamics of a free pitching flexible cantilever NACA0012 wing, more detailed work is required. For instance, FEA modelling will be performed, where we will attempt to couple finite elements with a simple aerodynamic model, using Theodorsen's or Wagner's functions for instance for the linear case, as well as performing a modal analysis. Additionally, the strain gauge and accelerometer data will be fully analyzed. LAO tests will be redone in order to try and attain steady-state results. Post-work calculations will also include assessing the damping and stiffness values.

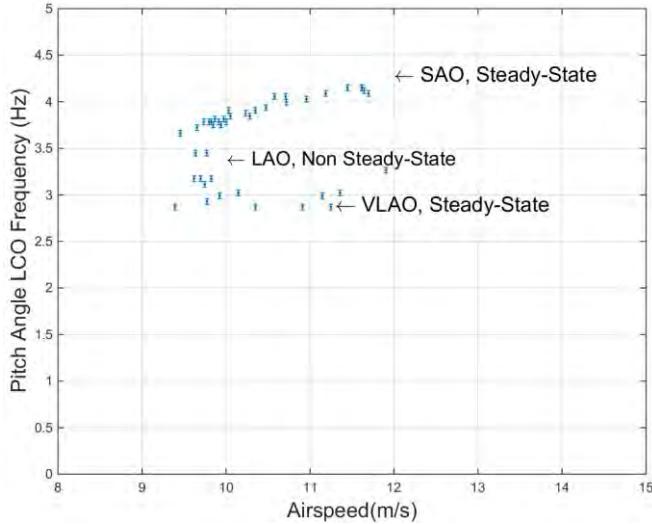

Figure 8. Pitch Angle LCO Frequency Versus Airspeed

## IV. CONCLUSIONS

A series of tests were performed on a free pitching flexible cantilever NACA0012 wing, in order to characterize the dynamics at transitional Reynolds numbers. Data was recorded using a potentiometer, strain gauges (in bending and torsion) and accelerometers. The potentiometer data was filtered and

used to generate plots of the mean positive peak amplitude of the root pitch angle versus airspeed and LCO frequency versus airspeed. Three LCO branches were found corresponding to SAO, LAO and VLAO. It is theorized that the SAO is caused by flow separation at small angles of attack due to transitional Reynolds number and wing free pitching, which in turn causes negative aerodynamic damping. The mechanisms responsible for LAO and VLAO have yet to be confirmed through future testing and analysis. The range of Reynolds numbers where LCO's are observed, as well as the LCO frequencies are consistent with previously published work suggesting either coupled or stall flutter in these cases. Further tests will be performed to better capture LAO. Furthermore, the strain gauge and accelerometer data will be analyzed. FEA and numerical modelling will be done and used for corroboration of results, and post-work damping and stiffness values will be calculated.

**Abstract**—A set of new correlation equations characterizing the spatial decay of isotropic homogeneous turbulence has been formulated in the current study. The correlation equations are based on the results from the current numerical simulations combined with data from earlier relevant experimental studies [10], [15], [16]. The correlation equations can be effective for predicting the local values of turbulent properties (turbulence intensity (TI) and integral length scale ( $L_u$ )) from well specified initial conditions and, similarly, the magnitudes of inlet turbulence (TI and  $L_u$ ) can be estimated from the local magnitudes of length scale and turbulent kinetic energy (TKE) using the same prediction methodology. The set of prediction tools should be useful in the design of wind tunnel experiments to characterize bluff body aerodynamics in response to different incident turbulence conditions.

**Keywords-** *isotropic, homogeneous, integral length scale, turbulence intensity*

## I. INTRODUCTION

The streamwise dissipation of isotropic, homogenous, free stream turbulence is one of the fundamental and widely explored topics in turbulence theory and its effects on various bluff body aerodynamics and thermal physics problems has been discussed over the past few decades [1–4]. In the absence of any external turbulent kinetic energy (referred to as TKE in the text hereafter) generation mechanism, the kinetic energy carried by the integral length scales of motion will decay, mostly due to inertial eddy interaction at high turbulent Reynolds number. Similarly, for low turbulent Reynolds number flows, molecular viscous forces dominate which causes the decay of TKE carried by the small scale dissipative eddies [1]. This decay of turbulent velocity fluctuations has an influential impact on the development of laminar and turbulent boundary layers over bluff bodies which in turn alters the heat and mass transfer rates from them [2–4]. Therefore, quantitative prediction of the free stream turbulent flow parameters incident on any bluff body, based on upstream inlet conditions, becomes an important factor for accurate determination of the dynamic properties of fluid and thermal responses in laminar, turbulent and transitional boundary layers.

There have been inconsistencies observed from the studies carried out for homogeneous and isotropic flows of freely decaying turbulence that have created disparities in the estimates of the spatial and temporal decay rates of TKE. Experimental grid-generated turbulence decays with a typical power law of the form,  $\frac{k}{\bar{U}^2} = D * \left(\frac{x - x_0}{M}\right)^{-n}$  [1], [5], where  $k$  is the TKE in the streamwise direction,  $\bar{U}$  is the mean velocity,  $D$  is the dimensionless dissipation constant,  $x$  is the streamwise distance,  $x_0$  is the virtual origin,  $M$  is the mesh width of the grid, and  $n$  gives the decay exponent. However, it was observed that different structures of geometrical grids generate turbulence with different decay rates and, hence, there is a need to achieve consistency, since the large-scale decay structures are known to affect the structure of turbulence at small scales [6], [7]. Numerous wind tunnel experiments have focused on generating homogeneous turbulence by different grids; passive [8], [9], active [10], [11], and multiscale (fractal) [12–15]. Numerical steady-state simulations [16] have also been carried out to reconcile the differences but no quantitative data have been presented at the inlet that would characterize the decay of turbulence downstream of a grid based on those specified initial conditions. A variation in the observed decay exponent  $n$  (from 1.0 to 1.4) implies that there might not be a universal state of decay mechanism.

It is generally agreed that the large scale turbulent properties, notably turbulence intensity (%) (referred to as TI in the text, hereafter, given by  $(\frac{u'}{\bar{U}}) \times 100$ ) and integral length scale ( $L_u$ ) are the decisive factors governing the decay of quasi-static homogeneous isotropic turbulence, since both these parameters evolve according to power laws [1] and play an intrinsic role in dictating the dissipation rate of the TKE given by  $\varepsilon \approx -(u'^3 / L_u)$

, where  $u'$  is the root-mean square of the characteristic turbulent velocity fluctuation and  $L_u$  is the size of the average energy containing eddy. Therefore, the decay of free stream turbulence should be reflected in the values of  $u'$  and  $L_u$  at any point in the flow system and both parameters should be considered in the formulations that characterize the spatial decay of TKE.

Hence, the aim of the current study is to employ Large Eddy Simulation (LES) models to develop simple yet powerful correlation equations that systematically quantify the spatial decay of turbulence, based on upstream inlet conditions, in a nearly isotropic and homogenous regime of turbulence. The final goal from the current study is to use those correlation functions as a prediction tool to estimate local and initial values of TKE and length scale which can then assist in numerous wind tunnel experiments of the flow over bluff bodies.

## II. METHODOLOGY

### A. LES equations

In LES the largest scales of turbulent motions are solved, whereas the smallest fluctuation scales are modelled. A spatial filtering is then applied to the continuity and the Navier-Stokes equations and the corresponding equations of the filtered velocity fields are obtained. The equations are then solved numerically using the concept of sub-grid viscosity  $\nu_t$  proposed by Smagorinsky [17], at each time-step, for each computational cell of the flow domain. More information about the numerical models associated with the LES formulation can be found in [18].

Among the sub-grid scale models that are available for LES, the dynamic sub-grid scale model by Smagorinsky [17], and Germano *et al.* [19] was used in the present work for simulating spatially decaying homogeneous isotropic turbulence.

### B. Solution parameters

Different solution parameters used for handling the flow variables in LES are summarized in Table I. In order to maintain the convergence and the accuracy of the solution, the Courant-Friedrichs-Lowy (CFL) number [20] is maintained at less than 1.0 by setting the time-step accordingly, based on the grid-spacing. The LES simulations were carried out for 20,000 time-steps and statistically averaged results are presented. The simulations were performed using SHARCNET [21] a high-computing cluster facility available at Western University.

TABLE I. Solution Parameters used in LES

Time discretization	Second order implicit
Momentum discretization	Bounded central difference
Pressure discretization	Second order
Pressure-velocity coupling	Segregated
Under relaxation factors	0.5 for the velocity and 0.2 for the pressure

## III. CFD MODELLING DETAILS

### A. Computational Domain and Boundary Conditions

A three dimensional (3D) computational domain was created with sufficient length in the streamwise direction to allow for spatial decay of turbulence to develop fully. The geometry, along with the mesh, was generated using ICEM v.16.0 [22].

The domain was discretized using a perfect structured hexahedral mesh in all the three directions for accurate interpolation of the mean flow quantities and to be consistent with the cut-off scales for the spatial filtering. The physical dimensions of the grid were  $L_x = 4\text{m}$ ,  $L_y = 1\text{m}$ ,  $L_z = 1\text{m}$ .

Generating a proper inflow boundary condition for LES simulations is important [23-25] as the inflow should maintain proper spectra and coherency to replicate the spatial turbulent flow characteristics throughout the domain. Hence, to develop an isotropic homogeneous inflow boundary condition, the Consistent Random Flow Generation (CDRFG) technique was used. More information about this technique can be found in [26]. Pure slip wall conditions with zero shearing were imposed at the walls to negate the effect of the physical boundaries on the decay of TKE. A pressure outlet was specified as a suitable boundary condition for the outlet boundary. The parameters for generating the inlet velocity conditions are summarized in Table II.

TABLE II. Parameters used for generating the inlet velocity field

Parameters	Values
Mean velocity	4m/s
Integral length scale	0.1m
Turbulence intensity	10%
Cut-off frequency	100Hz
No. of samples generated	20000

### B. Grid-Independency

Three different grid resolutions M1, M2 and M3 were created and used for the present grid-independence tests. The properties of these three grids are summarized in table III. The grid-independence study was carried out for a mean inlet velocity ( $\bar{U}$ ) of 4m/s, initial TI of 10% and integral length scale ( $L_u$ ) of 0.1m.

TABLE III. Properties of the employed grids in the current study

Grid	Type	Element size ( $\Delta x$ )	No. of cells
M1	Coarse	40mm	250,000
M2	Medium	20mm	500,000
M3	Fine	10mm	1,000,000

For LES, the variability in non-dimensional TKE going from M1 to M2 grid in proportion to its average value over the constant region where the TKE becomes fairly uniform (i.e.  $x=2\text{m}$  to  $x=4\text{m}$ ) is 13.1%, whereas the variability of the same variable going from M2 to M3 is 4.8%. On a similar note, the variation of the magnitude of  $L_u$  in proportion to its average value over the constant region from M1 to M2 is 5.9% and from M2 to M3 it is 2.3%.

Hence, the grid (M3) with 1,000,000 cells was chosen for the LES computations, corresponding to the least relative discretization error with an acceptable value of convergence [27]. The employed grid also resolves the most energy

containing eddies (ensuring that 80% of the TKE is resolved in the present case).

### C. Validation of the current CFD model

The time-averaged, non-dimensional TKE profiles along the centreline of the domain in the streamwise direction using the Dynamic-Smagorinsky LES model is compared with the previous existing experimental and numerical data of [10], which are more recent than the classical Comte-Bellot and Corrsin experiments [28], [29] in high turbulent Reynolds number flows (fig. 1). It is clear from figure (1) that the quantitative agreement between the LES and different sets of data presented from that study [10] is remarkably good with a proper choice of virtual origin  $x_0$  value (which refers to the distance downstream of an experimental grid origin, where the wake vortices from the grid has decayed sufficiently and the turbulence has started to become well-developed and nearly isotropic and homogeneous in nature). It should be noted that the choice of the virtual origin is sensitive to the decay rate of TKE and, in this comparison, the virtual origin of the experiments was typically taken at 20 mesh widths i.e.  $x_0 = 20M$ , for comparison [1].

The agreement between these two studies show that in the absence of mean shear and boundary layer wall effects, well-developed turbulent flow decays at a similar rate and there exists a universal decay mechanism of turbulence that would fit a single non-dimensional curve.

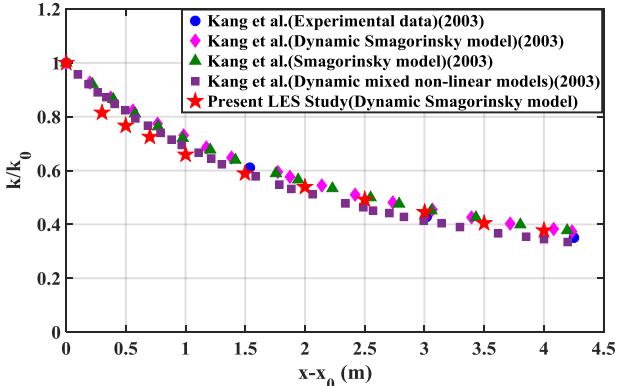

Figure 1. Comparison of decay of TKE in the streamwise direction between the studies of Kang et al. (2003) and present LES results.

Further comparison between the two studies reveals that the magnitude of  $\frac{dk'}{dx}$  at the virtual origin ( $x_0$ ), computed from the values of  $D$ ,  $u'$ ,  $\bar{U}$  and  $L_u$  gives an approximate value of  $0.014\text{m}^{-1}$  for the experiments [10] and  $0.010\text{m}^{-1}$  for the present LES study which are close to each other. Since the initial spatial TKE gradient rate controls the downstream decay of the TKE, a similar tendency of its decay in the nearly isotropic and homogeneous region of turbulence is observed.

## IV. RESULTS & DISCUSSIONS

### A. Predictive Methods for Spatial Decay of TKE

A new predictive algorithm based on the current methodology has been formulated in the present study which

provides an estimate of the local and initial turbulence levels in the uniform flow approaching the leading edge of a bluff body. The predictive algorithm is based on the simple inviscid estimation of the turbulence dissipation rate  $\varepsilon$  at a given length scale, represented by  $\varepsilon = \frac{dk}{dt}$ . Starting from the inviscid estimation of  $\varepsilon$  given by  $\varepsilon = -D(u'/L_u)^3$  (where  $D$  is the dimensionless dissipation constant, taken here as being unity, for convenience) and invoking Taylor's hypothesis of frozen turbulence, both these forms of  $\varepsilon$  can be related and a new power law equation derived (which includes both TKE and  $L_u$ ) that gives the spatial variation of TKE in the streamwise direction presented in the form

$$\frac{k}{k_0} = \frac{k'}{k_0} = \left( \frac{A(k_0')^{0.5} x}{L} + 1 \right)^{-n} \quad (1)$$

where  $k$  and  $k_0$  are the local and initial TKE (at  $x = 0$ ),  $k'$  and  $k_0'$  are the dimensionless local and initial TKE (at  $x = 0$ );  $k$  is normalized using the mean velocity  $\bar{U}$ ,  $A$  is a dimensionless constant having a magnitude of 0.27 (where  $A = 0.27 \times D$ ;  $D = 1$ ),  $n$  is the decay exponent of magnitude 2,  $x(m)$  is the streamwise distance starting from the origin of the physical grid and  $L_u$  is the integral length scale (m) which is taken as a constant in this derivation for simplicity. This correlation equation (1) assumes turbulence is strictly isotropic and Taylor's hypothesis has been invoked while deriving spatial functions of the velocity field. However, in reality, the integral length scale ( $L_u$ ) grows in the streamwise direction as turbulence decays and cannot be treated as a constant which then alters the magnitude of the power law exponent,  $n$ , obtained from the correlation function presented in equation (1). Hence, to incorporate the effects of the spatial evolution of the length scale ( $L_u$ ), the correlation equation (1) is rewritten in a general form as

$$\frac{k}{k_0} = \frac{k'}{k_0} = \left( \frac{A_1(k_0')^{0.5}(x - x_0)}{L} + 1 \right)^{-n_1} \quad (2)$$

where  $x_0$  is the virtual origin, and  $A_1$ ,  $n_1$  are the decay coefficient and decay exponent, respectively, for the above correlation (eq. 2).

Replacing  $L_u$  with  $L_{u0}$  another form of decay power law can be achieved with the following form

$$\frac{k}{k_0} = \frac{k'}{k_0} = \left( \frac{A_2(k_0')^{0.5}(x - x_0)}{L_{u0}} + 1 \right)^{-n_2} \quad (3)$$

where  $L_{u0}$  is the initial value of the integral length scale (at  $x = 0$ ),  $A_2$  and  $n_2$  are the new decay coefficient and decay exponent, respectively, for the above correlation equation (3).

The correlations presented in equations (2,3) clearly depict a power law form analogous to the grid-generated TKE decay law given in [1].

The correlation equation obtained in equation (2) is tailored specifically to include the effects of the TKE and the integral length scale into a single correlation equation, since the

evolution of length scales influence the energy decay of the turbulent velocity fluctuations [9], [30].

The range of decay exponent ( $n$ ) values obtained for different types of grids and numerical simulations is large because it depends on the initial conditions of the flow, the physical characteristics of the experimental grids (shape, size, width and porosity) and the choice of the virtual origin ( $x_0$ ) [7], [31]. A faster or slower rate of decay of TKE is also possible depending upon the solidity of the grid which depends on the porosity ( $\beta$ ) which, in turn, is a function of the rod or wire diameter used and the mesh width ( $M$ ), as reported in [6].

Hence, the present work does not aim to address the question of determining definitive and precise values of the decay exponent ( $n$ ) exhibited in eq. (2), but, rather, to come up with a global decay exponent ( $n$ ) and dimensionless constant ( $A$ ), that best fits the correlation function when using all the relevant previous experimental studies and the present numerical simulations, within an acceptable degree of accuracy, in the region of well-developed, homogeneous and isotropic turbulence.

The correlation (eq.2 and eq. 3) can be used to obtain an estimate of the local statistical turbulence parameters ( $k$  and  $L_u$ ) at any location downstream of a grid based on the specified initial turbulence conditions ( $k_0$  and  $L_{u0}$ ) at the inlet. Similarly, the same set of prediction equations (2 and 3) also helps to recover the initial free-stream turbulence levels relevant to any bluff-body aerodynamics problem knowing the local magnitudes of turbulence scales, thus making this prediction method a complete closure solution to the choice of experimental turbulence generating grid required to achieve a particular level of turbulence.

#### B. Prediction equation based on the local value of the integral length scale ( $L_u$ )

Figure (2) shows the direct comparisons between the earlier experimental studies of Kang *et al.* (2003) [10], Krogstad and Davidson (2011) [15], Torrano *et al.* (2015) [16] and the present LES with a best fit curve for the correlation function presented in equation (2). The streamwise evolution of non-dimensional TKE profiles ( $k/k_0$ ) are plotted against a non-dimensional parameter  $(x-x_0)*(k'_0)^{0.5}/L_u$  where,  $(x-x_0)$  is

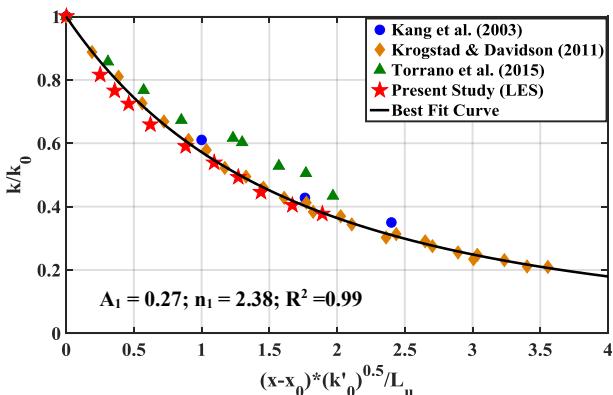

Figure 2. Spatial decay of TKE profiles of earlier experimental studies and present LES , plotted with a solid line that shows the best-fit power law

the effective origin, ( $k'_0$ ) is the non-dimensional initial TKE value and ( $L_u$ ) is the local value of the integral length scale. The magnitude of the initial normalized TKE and integral length scale values are digitized and extracted from the previous studies to achieve a direct comparison between the variables used in the plots by using the above scaling, even though the initial conditions of the different experiments and the LES are different. The fitted coefficient values of  $A$  and  $n$  estimated from the best-fit curve are ( $A_1 = 0.27$  and  $n_1 = 2.38$ ). The goodness of the fit is excellent at  $R^2=0.99$ . Figure (4) also reveals that the numerical results are fairly consistent (within 3%) with the experimental data and both the studies reproduce a similar tendency of the predicted turbulence energy decay.

#### C. Prediction equation based on the initial value of the integral length scale( $L_{u0}$ )

Figure (3) shows the comparison of the spatial decay of the TKE profiles for different experiments stated earlier and the LES study, with the x axis variable  $(x-x_0)*(k'_0)^{0.5}/L_{u0}$  now normalized with the initial constant value of  $L_u$ , i.e. ( $L_{u0}$ ), instead of local values of  $L_u$ . The scaling parameter has been changed to see its effect on the quantitative agreement between the LES and the experimental studies. Here  $R^2=0.97$ , which is not as good as the previous scaling, whilst the values of  $A_2$  and  $n_2$  are 0.44 and 1.16, respectively. It turns out that the  $A_2$  and  $n_2$  values obtained from the regression fit (eq. 3) have different

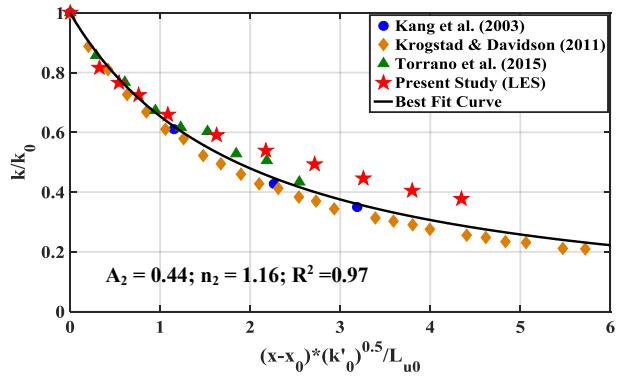

Figure 3. Spatial decay of TKE profiles for different experiments and the present LES study scaled with initial integral length scale ( $L_{u0}$ ) plotted with a solid line that shows the best-fit power law

magnitudes compared to the  $A$  and  $n$  obtained while deriving equation (1) even though both correlations assume a constant  $L_u$ . The values of the decay coefficient  $A$  and the decay exponent  $n$  obtained from equation (1) are 0.27 and 2 respectively.

There are reasons for this observed variation, between the magnitudes of decay coefficient  $A$  and decay exponent  $n$ , obtained from the simple inviscid estimation of  $\varepsilon$  (eq. 1) and the best-fit curve over all the experimental data and LES results (eq. 3).

Firstly, strictly isotropic turbulence has been assumed while deriving the correlation (eq. 1), which in reality is difficult to

achieve in turbulence generated in computer simulations [32]. However, this is not surprising as such inhomogeneity of the flow has already been observed in the earlier experiments of [33], [34]. Secondly, while deriving the correlations presented in equations (1), (2) and (3), it was assumed that D is a non-dimensional constant of magnitude unity, having no temporal or spatial dependency in the streamwise direction, but D is seen to have spatial dependency in the studies reported in [9]. Therefore, the estimate of  $A_2$  and  $n_2$  obtained from the best fit curve shown in figure (3) inherently incorporates the variability of D if any, present in the current simulations.

#### D. Prediction equation based on the local magnitude of TKE ( $k'$ ) and local magnitude of integral length scale( $L_u$ )

Figure (4) shows another form of the spatial decay of TKE profiles from both the experiments and LES data, but with the x ordinate scaled with the local non-dimensional TKE,  $k'$ , and the local magnitude of the integral length scale ( $L_u$ ). Figure (6) reveals a linear relationship between  $(k/k_0)$  and  $(x-x_0)*(k')^{0.5}/L_u$  which implies

$$\frac{\frac{d}{dx}(k/k_0)}{\frac{d}{dx}(x-x_0)*(k')^{0.5}/L_u} \approx C \quad (4)$$

This holds true and is manifest through the power law dependency of  $k$  and  $L_u$  along the streamwise direction which is given by the following equation

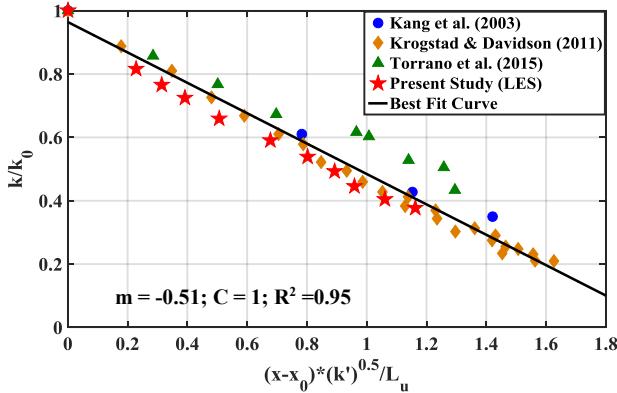

Figure 4. Spatial decay of TKE profiles for different experiments and the present LES data with the x ordinate scaled with local  $k'$  and  $L_u$

$$\frac{k'}{k_0} = (a_1 x + 1)^{-p} \quad (5)$$

$$\frac{L_u}{L_{u0}} = (a_2 x - 1)^q \quad (6)$$

In order to arrive at linearity; ( $a_1 \approx a_2$ ) and a slight deviation from the numbers can affect the linearity of the experimental data sets and the LES results seen in figure (4), which is simply a consequence of the curve fitting performed for the best fit for equations (11), (12). Similarly, p and q are closely related to each other in the form of  $q/2 - p = 1$  for the LES results, which

is verified by the exponents derived in [9]. The left-hand side of equation (4) can be then solved to arrive at a constant value. The best linear fit line is drawn in the figure which gives a  $R^2=0.96$  with the slope m being -0.51 and the intercept C being 1. Hence the final equation of the spatial decay of TKE stands in the form of

$$\left(\frac{k}{k_0}\right) = \left(\frac{x-x_0}{L_u}\right) = m \left(\frac{(x-x_0)*(k')^{0.5}}{L_u}\right) + C \quad (7)$$

It is worthwhile mentioning that the correlation functions presented in equation (3) along with equation (7) also helps one to predict the initial TKE ( $k_0$ ) and length scale values ( $L_u$ ), provided one knows the local values of TKE ( $k$ ) and length scale ( $L_u$ ), thus giving another method of estimating the statistical turbulence parameters in the domain.

There are, altogether, 3 sets of data, which have been used here for the predictive methodology, in accordance with the previous experimental studies, to estimate the magnitude of the TKE and  $L_u$  values. The values of the fitted coefficients for all sets of data are summarized in table IV and V.

TABLE IV Constants obtained from best regression curve fitting procedure using the method of non-linear least squares

Normalization parameter of the x ordinate	$R^2$	Decay coefficient (A)	Decay exponent (n)	Equation number
$k_0$ and $L_u$	0.99	0.27	2.38	2
$k_0$ and $L_{u0}$	0.97	0.44	1.16	3

TABLE V Constants obtained from best regression curve fitting procedure using the method of non-linear least squares

Normalization parameter of the x ordinate	$R^2$	m (slope)	C (intercept on the y ordinate)	Equation number
$k'$ and $L_u$	0.95	-0.51	1	4

It is worth mentioning that these correlations (2,3), while written in logarithmic form along with the correlation given by equation (7), each represent a simple linear form of equations involving one known and one unknown variable which can then be used to estimate either the local turbulence parameters at any downstream location or to predict the initial turbulent parameters for any turbulent flow. Thus, the equations (2), (3) and (7) complete the prediction tool for designing turbulence generating grids. More information about the applicability of these prediction equations can be found in [35].

## V. CONCLUSIONS

The present work attempts to simulate freely decaying isotropic homogenous turbulence using Large Eddy Simulation (LES). The current results show good quantitative agreement with the previous experimental results from [10], [15], [16]. Three different correlations were formulated which can be useful in estimating the local and initial values of turbulent parameters (i.e. TKE and  $L_u$ ) which can then aid the design of wind tunnel experiments.

# Water Droplet Impact and Spreading on a Narrow Gap

D. Jordan Bouchard and Sanjeev Chandra

Department of Mechanical Engineering  
University of Toronto  
Toronto, Canada

**Abstract**— The impact and spreading of a water droplet on a gap between two parallel plates has been studied experimentally. A deionized water droplet (2.03 mm diameter) impacted the plates at velocities of 0.06, 0.5, 1.0, and 1.5 m/s; the tested gap spacings of the parallel glass plates were 50, 100, and 150  $\mu\text{m}$ . Using a high-speed camera, we simultaneously photographed the drop spreading both above and within the gap. We show that water begins to penetrate the gap immediately after impact. On the largest spacing tested, up to 10% of the initial drop volume can penetrate the gap before the maximum spreading diameter is reached.

*drop spreading; drop impact; parallel plates;*

## I. INTRODUCTION

Many porous surfaces that droplets can interact with – paper, soil, textiles and fabrics – are opaque. This opaqueness makes it difficult to observe how the porous surface interacts with the drop during droplet impact and spreading. In addition, an impacting drop will spread to its maximum diameter in a few milliseconds, well below the temporal resolution of non-destructive scanning techniques.

There remains some uncertainty as to the amount of water that absorbs into a porous media during droplet impact and spreading, and if this volume of water influences the maximum spread of the droplet. Chandra & Avedisian [1] and Lee et al. [2] analyzed photographs of the drop impacting on a porous surface to estimate the volume of water that penetrated a porous material. They conclude that the volume of water is negligibly small for the materials they studied. Roisman et al. [3] find that a porous surface will increase the probability of drop deposition instead of splashing, which they suspect is due to some liquid penetration during impact. Lembach et al. [4] and Yamamoto et al. [5] show that water penetration can occur during droplet impact on their fabricated porous medias. Their medias were fabricated in such a way that allowed them to simultaneously photograph the drop above and below the surface, but the focus of their papers was not on the maximum spread of the droplet.

Thus, there is a need for more experiments that can simultaneously photograph a droplet above and below a surface

during impact in order to understand the role the pore size has on droplet spreading. This is the first experiment in a series designed to investigate how porous media affects how a droplet spreads and penetrates a porous media. Here, we study the influence of a long narrow pore, created by two closely spaced glass plates.

## II. EXPERIMENTAL APPARATUS

Two uncoated N-BK7 borosilicate glass plates (50 mm x 50 mm x 4 mm) (Edmund Optics, Inc; stock# 47-944) were used to create a narrow gap between two parallel surfaces. The gap spacing between the two plates was set by inserting two steel feeler gauges between the plates and then clamping the plates together. Between individual trials, the surfaces of the glass plates were rinsed with deionized water and dried with compressed air. Periodically, the surfaces were cleaned with ethanol and thoroughly rinsed with tap water and then deionized water.

A 10 ml BD syringe was used in a syringe pump to dispense deionized water through a 33-gauge syringe needle (#91033, Hamilton) at a flow rate of 10  $\mu\text{l}/\text{min}$ . A separate test found the average diameter of a drop generated by this method to be 2.03 mm (N=50, 95%CI). The three gap sizes tested were 50, 100, and 150  $\mu\text{m}$ . The plates were also clamped together with no feeler gauges to get a fourth gap size of approximately 0  $\mu\text{m}$ . Drop impact velocities of 0.06, 0.5, 1.0, and 1.5 m/s were tested by increasing the height at which the drop detached from the syringe needle. Each of the impact velocity-gap spacing pairs was repeated between three and five times. Very good repeatability of the data was achieved.

A high-speed camera (FASTCAM SA5, Photron, USA) equipped with a 105 mm f/2.8 Nikon lens, an extension bellow, and a 55 W LED light (AOS Technologies AG) were used to photograph the droplet spread at a resolution 16.8  $\mu\text{m}/\text{pixel}$ . Photographs were taken at 4000 fps, shutter speed of 1/6000 s. A schematic of the experiment is shown in Figure 1.

Image analysis was performed in MATLAB using an automated script to convert the photographs from the high-speed camera to binary images. The measurement of interest was obtained by counting the number of pixels and multiplying it by the image resolution.

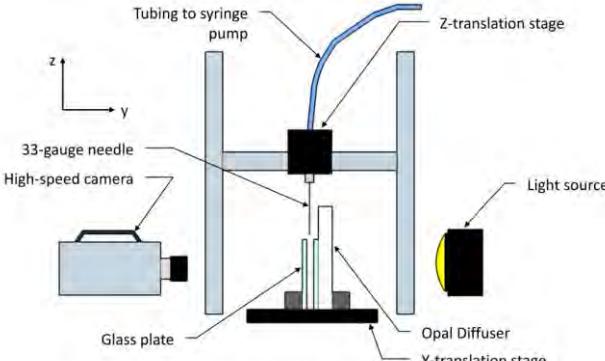

Figure 1. Schematic representation of experiment apparatus

### III. RESULTS AND DISCUSSION

We compare the maximum spreading diameter by first making the spreading diameter and time dimensionless. The droplet spreading diameter is made dimensionless by dividing it by the initial drop diameter,  $\beta = D/D_0$ ; time is made dimensionless by multiplying it by the impact velocity and dividing by the initial drop diameter,  $\tau = Ut/D_0$ , where  $U$  is the impact velocity. Figure 2. shows the dimensionless spreading coefficient,  $\beta$ , plotted against dimensionless time,  $\tau$ . The top, middle, and bottom charts of Figure 2. show the effect of the gap spacing at the constant impact velocities of 0.5, 1.0, and 1.5 m/s, respectively.

At each impact velocity, the maximum spreading diameter increases as the gap spacing decreases. In the 1.5 m/s impact velocity graph of Figure 2. , where this observation is most pronounced, the maximum spreading diameter doubles as the gap spacing is reduced from 150  $\mu\text{m}$  to 0  $\mu\text{m}$ .

Also, the time required to reach the droplet maximum spreading diameter increases as the gap size decreases. At all three impact velocities the drop takes the longest time to spread at zero gap spacing. For example, at an impact velocity of 1.5 m/s, the maximum spreading diameter is reached shortly after  $\tau = 1$  for the 150  $\mu\text{m}$ ; the 100  $\mu\text{m}$  and 50  $\mu\text{m}$  gap sizes take progressively longer, and the longest time of  $\tau = 2.7$  is reached for the at 0  $\mu\text{m}$ .

The maximum spreading diameter and time to maximum spread increase with a decreasing gap size because there is less kinetic energy and liquid available for the drop to spread when a gap is present. We observe that the drop starts to penetrate the gap almost immediately after impact. Photographs of the droplet spreading on the gap at  $\tau = 0.5$  are shown in Figure 3. At every gap spacing and impact velocity a semi-circular profile can be seen developing below the drop before the maximum diameter is reached. With less water remaining in the drop it is unable to spread as far. Time to the maximum spreading diameter is reduced because there is less distance to travel.

It is also interesting to point out in Figure 3. that the shape of the drop is very similar for each impact velocity at each gap

spacing. This is despite there being an increasingly larger volume of water within the gap at successively larger gap spacings. What this means is that immediately after impact the droplet behavior is dominated by inertia, but the influence of the gap spacing becomes apparent before maximum spread is reached. We can see this transition in Figure 2. : the spreading coefficient for each gap size lie on a single curve immediately after impact and then start to diverge before the maximum spreading diameter is reached.

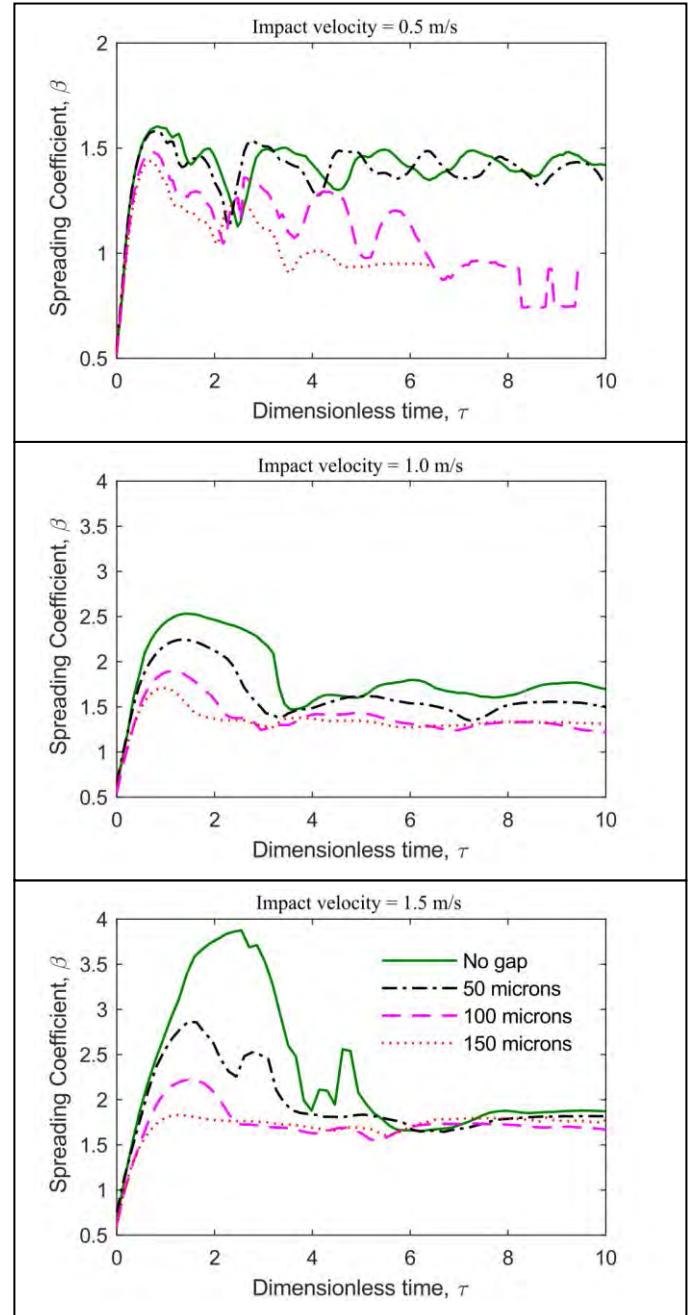

Figure 2. Comparison of dimensionless spreading diameter for impact velocities of 0.5, 1.0, and 1.5 m/s.

Shortly after the drop contacts the glass plates and begins to spread, water wicks into the gap. The width of the profile grows at the same rate as the droplet spreads, but the depth of the profile grows at a different rate. For the 50  $\mu\text{m}$  spacing in Figure 3., the profile depth reached at  $\tau = 0.5$  decreases slightly as the impact velocity increases. This suggests that the growth rate of the profile width depends on the impact velocity, and that the growth rate of the profile depth depends on the gap spacing, which determines the developed capillary pressure.

Figure 4. shows the fraction of the initial drop volume that penetrates between each plate spacing. The top, middle, and bottom chart are plotted with the gap spacing held constant at 50, 100, and 150  $\mu\text{m}$ , respectively. In the initial stages of the droplet impact and just prior to the maximum spreading diameter being reached, the volume of water in the gap is approximately the same for the 0.5, 1.01 and 1.5 m/s impact velocities. Oalso shows that the flow rate into the gap is constant shortly after impact, times greater than  $\tau = 0.25$ . Water penetration into the gap during droplet spreading is mostly capillary driven.

The volume of water that can penetrate the gap during droplet spreading is significant for the larger gap spacings. For

the 100 and 150  $\mu\text{m}$  gap spacing, between 5-10% of the drop's initial volume has already entered the gap at  $\tau = 0.5$ . For the 50  $\mu\text{m}$  gap spacing the volume of water that has left the drop by this time is less significant. Despite this large difference in the volume of water that has penetrated the gap, the drops in Figure 3. look very similar for a constant impact velocity. This highlights the difficulty of estimating the volume of water that has penetrated a porous medium during the droplet spreading phase.

#### IV. CONCLUSIONS

When a drop impacts a narrow gap, the maximum spreading diameter will be less than the maximum spreading diameter that could be attained on a solid surface. This is partly due to water penetrating the gap during the spreading phase, so there is less water available within the drop to spread. The volume of water that penetrates the gap is mostly dependent on the width of the gap. A higher fraction of the initial drop volume will be lost to the gap at the time of maximum spread the larger the gap spacing is. The water penetrates mostly due to capillary forces—the impact forces only have a minor influence

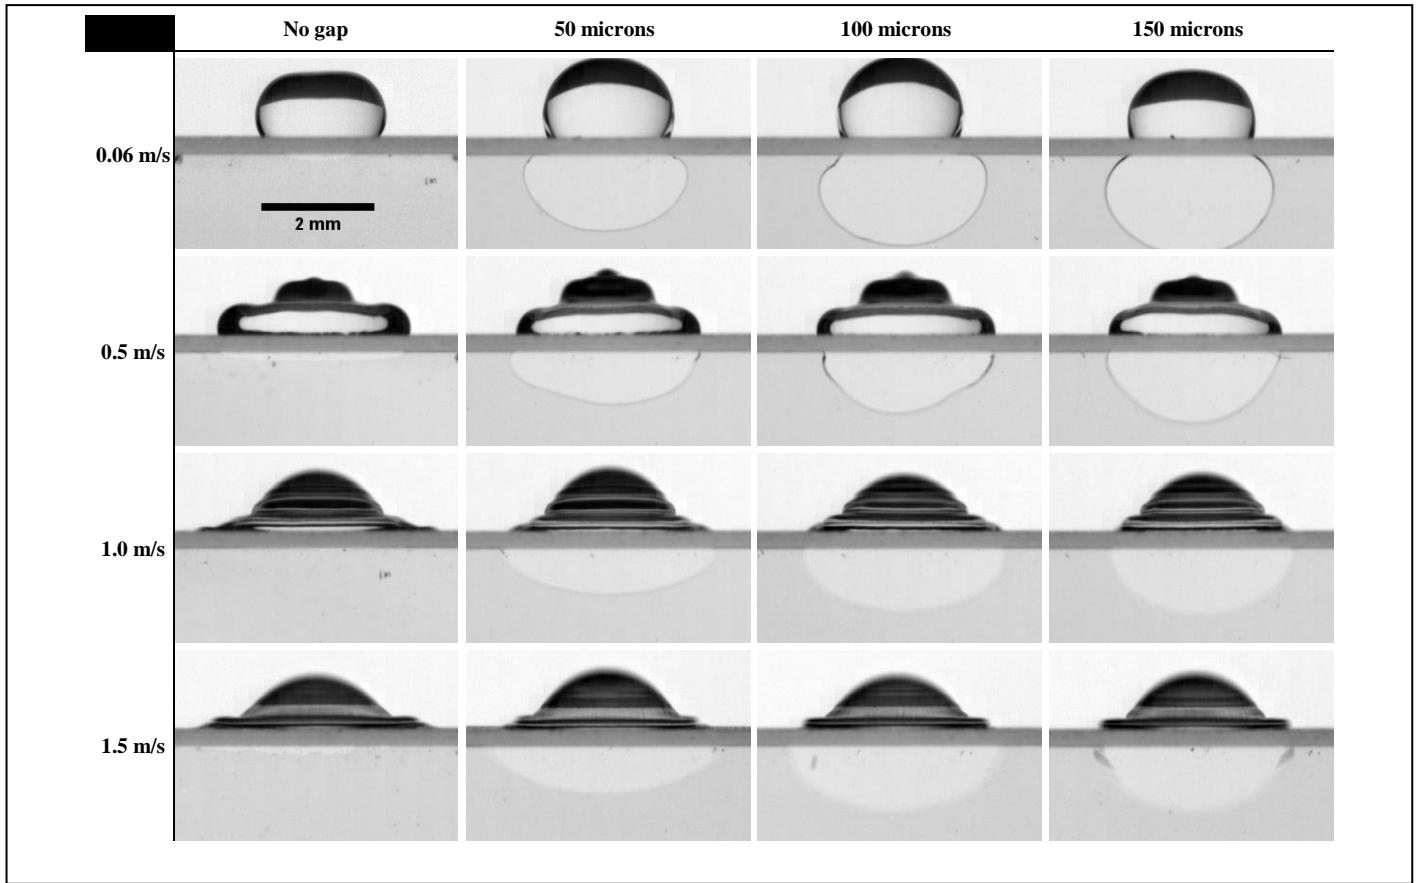

Figure 3. Photographs of a drop impacting on a narrow gap. Rows are a constant impact velocity; columns are a constant gap spacing. Each photograph was taken at dimensionless time,  $\tau = 0.5$ . The images were cropped, scaled, and adjusted for contrast and brightness in ImageJ [6]

**Abstract**—A conventional way of studying the flow characteristics of flow over a bluff body is by extracting the velocity distribution in horizontal planes crossing the bluff body near the bed, mid-height and close to the free-end location. The intention of selecting the planes at these levels is to examine the horseshoe vortex and the bed effect, flow separation at the mid-height, and the downwash flow from the free-end. In some cases, where a relatively short cylinder is studied along with a taller cylinder, the mid-height level of each may present very different flow structures. It is proposed in this study that a better way of selecting the planes of interest could be based on the pressure distribution imposed on the front surface of the bluff body by the approaching flow. This paper uses a sample numerical study of wall-mounted finite-length square cylinder with three aspect ratios of 1, 2 and 4, immersed in the air flow with a thin boundary layer. The horizontal planes based on the front face pressure distribution are selected and examined to show the advantage of the proposed method.

**Keywords:** Bluff body; flow separation; Detached-eddy-simulation

## I. INTRODUCTION

A wall-mounted finite-length square cylinder immersed in a flow field has many engineering applications in the real world, such as flow over low-rise buildings, skyscraper stacks, chimney stacks, etc. The aspect ratio ( $AR = h/d$ , where  $h$  and  $d$  are the height and width of the object, respectively) plays an important role in establishing the flow features around the body (Kawamura et al. [1]). As AR increases, the shear layer in the overhead region induced by the top edge becomes more energetic and then interacts with the base vortices. This phenomenon slowly diminishes when AR approaches a critical value.

When an oncoming flow with a boundary layer impinges on the front surface of a square cross-section cylinder, a stagnation point (or zone) is induced on the front side of the cylinder surface (Fig. 1). The location of the stagnation point ( $h_{stg}$ ) is defined by the maximum value or the middle point of the near-constant region on the pressure distribution of the front surface. The flow below the stagnation streamline rolls up into the horseshoe vortex (HSV), while the flow above it separates from the top edge of the body. The separated flow forms the wake region as indicated in the schematic.

When discussing the wake structures behind the cylinder of different AR, researchers tend to present results in different horizontal planes. These planes usually include the one at mid-depth (50%  $h$ ), one near the wall (25%  $h$ ) and one near the free-end of the cylinder (75%  $h$ ). However, the induced flow structures are not simply decided by the cylinder's height. When comparing flow past cylinders of different height, it is quite possible that the flow structures are different at a certain value of the cylinder height to width ratio. For instance, the mid-height level of a short cylinder may be heavily influenced

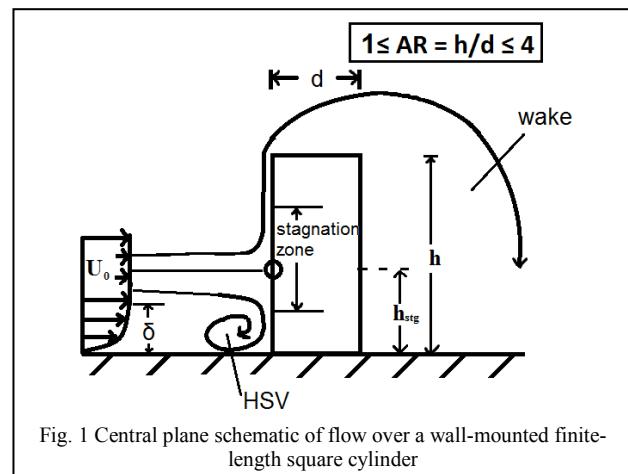

Fig. 1 Central plane schematic of flow over a wall-mounted finite-length square cylinder

by the bed-effect, but the mid-height level of a taller object may not be influenced either by the distance to the wall or to the top edge of the body. A new scheme based on the pressure distribution on the object's front surface which could be potentially used in the analysis of the flow over a bluff body problem is introduced in this paper.

## II. COMPUTATIONAL DOMAIN

The schematic of the flow field is shown in Fig. 2. A wall-mounted square cylinder with the width ( $d$ ) of  $12.7 \times 10^{-3}$  m is immersed in an air flow. The air flow is at a Reynolds number of 12,000 (based on freestream velocity and cylinder width), with the free stream velocity of 15 m/s and dynamic viscosity of  $1.855 \times 10^{-5}$  Pa·s. Three aspect ratios (AR = 1, 2 and 4) of the square cylinder are studied.

The origin of the coordinate system is located at the center of the square at the bed level. The x-, y- and z- coordinate directions correspond to the streamwise, spanwise and normal directions, respectively. The two side-walls and the ceiling are slip-walls, and the bottom bed and the cylinder faces are no-slip walls. The square cylinder is placed 6d downstream of the inlet, 40d upstream of the pressure outlet, 7d under the ceiling (9d and 10d for AR = 2 and AR = 1, respectively), and 15d away to each side-wall. The side length of the computational domain is guided by the work of Nasif et al. [2], which showed the need for a distance of 15d between each side-wall and the cylinder to maintain a small enough blockage ratio. This length is larger than that used by Saeedi and Wang [3] in their direct numerical simulation (DNS) of a similar flow field.

In the experimental study by El Hassan et al. [4], the cylinder was placed at the location along the bottom wall where the boundary layer thickness was  $9.1 \times 10^{-3}$  m (72% d) in the absence of the cylinder. To properly benchmark the numerical setup with the experiment, the inlet condition is set to reproduce the velocity profile at the same location in the absence of the cylinder. Based on a grid independency study, the proper grid was chosen to simulate the flow field using Detached Eddy Simulation. The results were validated using the experimental results of El Hassan et al. [4] in several horizontal and vertical planes through the wake.

## III. RESULTS AND DISCUSSION

Fig. 3 shows the pressure distribution on the front surface of the cylinder along the central plane ( $y/d = 0$ ). Two points of

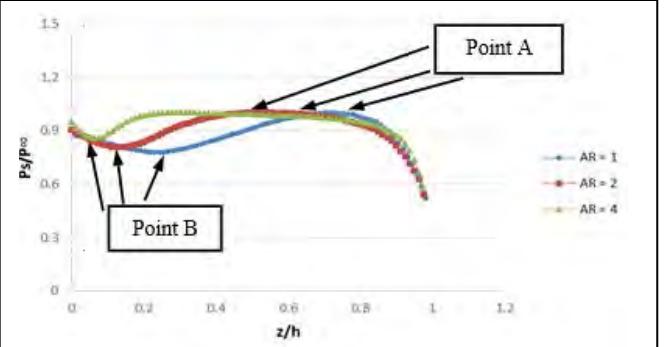

Fig. 3 Pressure coefficient distribution on the front surface of the cylinder at central plane  $y/d = 0$

interest are labeled as Point A and Point B, which are the maximum pressure (or maximum pressure zone) on the surface and local minimum pressure, respectively. Point A characterizes the stagnation point in each case. Only in the case of AR = 1, a distinctive maxima is found on the cylinder's front surface at  $z/d = 0.727$ , while the cylinders AR = 2 and 4 have a near constant pressure region. In the cases of AR = 2 and 4, Point A is marked at the center of the constant pressure region, which are  $z/d = 1.2$  and 2, respectively.

As seen in Fig. 3, the constant pressure region increases in size as the cylinder AR increases. Since the free-end of the cylinder moves further away from the bed, there is more space in the middle section that is not influenced by either end. The stagnation point's location with respect to the cylinder width increases as the AR increases, and the stagnation point's location with respect to the cylinder's height decreases as the cylinder's AR increases.

Point B describes the local minimum pressure on the front surface and lies closer to the bed region. The location of Point B with respect to the cylinder's width are relatively close for all three ARs. Therefore, Point B can be understood as a critical point induced by the bed effect, namely the horseshoe vortex. The core of HSV (where the highest vorticity is found) is roughly half of the distance between Point B and the bed. If the HSV is seen as a symmetric structure about its core, the incoming flow at the level of Point B in each case is at the upper boundary of the HSV.

By extracting the velocity field on the horizontal planes passing through Point A and Point B, flow structures for each AR are expected to share similar features. Therefore, the comparison between different ARs would be more meaningful than only considering the comparison at a certain cylinder height to width ratio, especially when one cylinder is significantly shorter than the other.

Figs. 4 (a), (b), and (c) show the time-averaged streamwise velocity on a horizontal plane passing through Point A for AR = 1, 2, and 4, respectively. The flow separates at the sides of the cylinder and accelerates in the downstream direction. The flow with high velocity slowly reduces as it moves downstream. Even though the size of the wake structure and

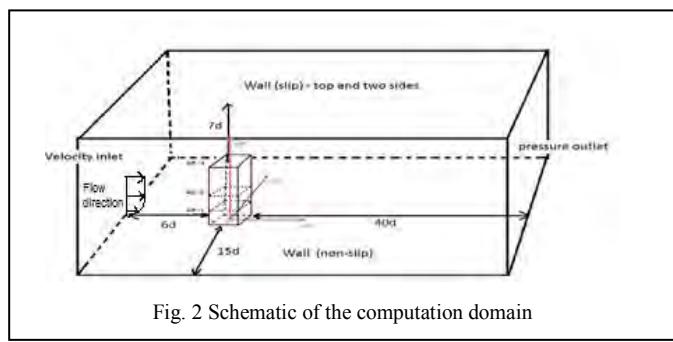

Fig. 2 Schematic of the computation domain

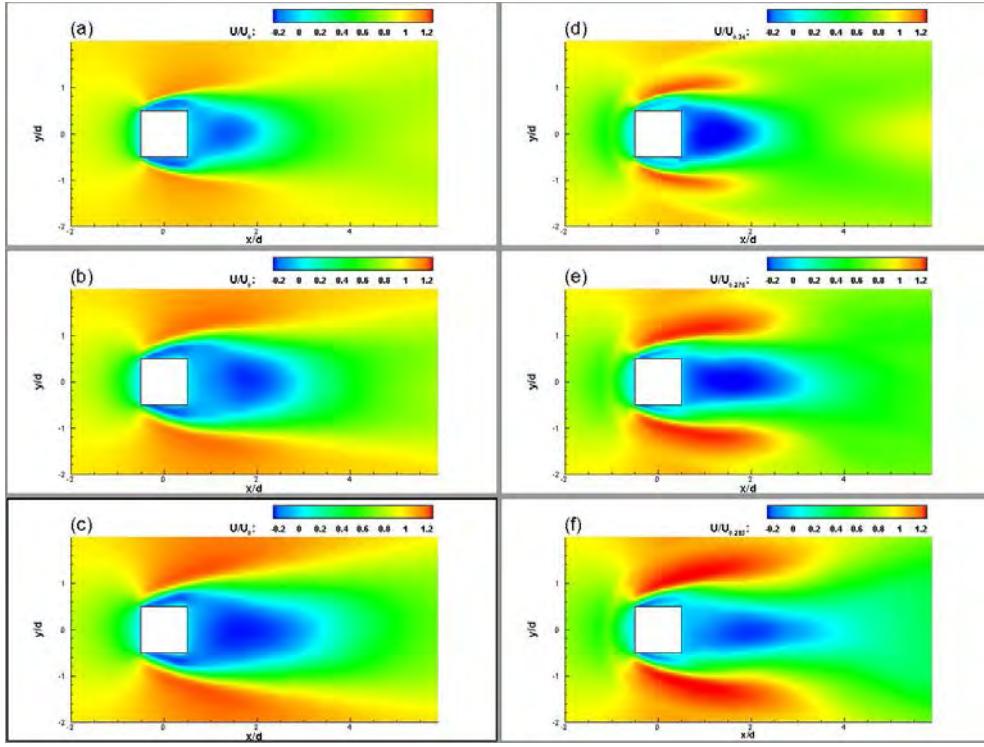

Fig. 4 Horizontal planes shaded by the time-averaged streamwise velocity at the location of Point A: (a), (b) and (e) for the cylinder AR = 1, 2, and 4 respectively; and Point B: (d), (e), and (f) for the cylinder AR = 1, 2, and 4 respectively.

the value of the streamwise velocity are different, the contour of the flow structures shows many similarities.

Figs. 4 (d), (e), and (f) show the time-averaged streamwise velocity on a horizontal plane passing through Point B for AR = 1, 2, and 4, respectively. The planes at Point B show many different features than the planes at the stagnation point (Point A), while the planes at Point B share a lot of similarities among themselves. Two zones (red and blue regions), which represent the separating shear layer (outer) and the collar vortex (inner) (Nasif et al. [2]), lie on each side of the cylinder. Although the characteristics of the flow structures are different due to the increase of AR, the flow structures presented are similar.

#### IV. CONCLUSION

The comparison made by selecting the planes based on the pressure distribution show similar structures in the flow field at all aspect ratios. The pressure distribution on the front face is clearly a function of the aspect ratio. The choice of the

horizontal planes based in the maximum and minimum pressure values enables a direct comparison at different value of AR. Further analysis of the use of the front face pressure distribution is necessary to understand the characteristics of the flow past bluff objects.

# Piercing a Liquid Droplet by a Gas Jet

Maryam Ebrahimiazar, Amirreza Amighi, Nasser Ashgriz

Department of Mechanical and Industrial Engineering

University of Toronto

Toronto, Ontario, Canada

**Abstract**—Impingement of a gas jet on a suspended water droplet is studied experimentally. The jet penetration process depends on the jet velocity and jet to droplet diameter ratio. At small jet to diameter ratios and large enough jet velocities, the jet penetrated through the droplet. At larger jet to droplet diameter, the droplet fragmentation becomes more significant, with large droplet deformation. For this experiment, different types of breakup process are categorized, and theoretical explanations are provided.

**Keywords**-droplet breakup, atomization, Rayleigh-Taylor instability

## I. INTRODUCTION

Fragmentation of a liquid into small droplets by a gaseous jet has numerous industrial applications. Although the fragmentation process is studied extensively, it still cannot be predicted accurately. All of the presently available models are based on empirical correlations and/or simplified physical models. For instance, the breakup of a liquid droplet is experimentally studied and the breakup process is categorized based on a Weber number:

$$We = \frac{\rho U^2 D_{drop}}{\sigma} \quad (1)$$

where  $\rho$  can be the density of the gas or the liquid,  $U$  is the relative velocity between the gas and droplet,  $D_{drop}$  is the droplet diameter, and  $\sigma$  is the surface tension. It is also found that the viscosity of the fluid that the droplet is composed of also plays a role in preventing the deformation and dissipating the energy from the aerodynamic forces imposed on the droplet. The ratio of droplet viscous forces to surface tension forces can be quantified using the Ohnesorge number [2]:

$$Oh = \frac{\mu_l}{\sqrt{\rho_l D_{drop} \sigma}} \quad (2)$$

where  $\mu_l$  and  $\rho_l$  are the droplet viscosity and density, respectively. When the  $Oh$  number is greater than 0.1, drop viscous forces are significant and should be accounted for. Different types of droplet breakups are identified and categorized based on the Weber number: Vibrational ( $0 < We < \sim 11$ ), bag ( $\sim 11 < We < \sim 35$ ), multimode ( $\sim 35 < We < \sim 80$ ), sheet thinning ( $\sim 80 < We < \sim 350$ ), and catastrophic ( $We > \sim 350$ ).

There are a wide variety of methods to perform the fragmentation process. The most common method is by applying a large relative velocity between an external gas and the liquid, thus shearing off small drops from the liquid surface. The relative velocity can be induced by either accelerating the liquid and shooting it out of a nozzle, thus having a high velocity liquid jet with respect to the surrounding gas, or by applying a high velocity gas onto the surface of the liquid. Both these effects have been studied extensively. The atomization method that is introduced here is within the later category, and in particular, on the breakup of a liquid droplet by a high velocity gaseous flow.

## II. EXPERIMENTAL SETUP

The experimental system comprises of a suspended droplet, a gaseous jet and an imaging system. A droplet is suspended at the tip of a capillary needle (see Fig.1). The droplet is suspended so that it is fixed in space and its dynamics can be studied. A capillary needle is used to continuously and easily replace the droplet. The capillary needle is connected to a syringe pump to provide the mass needed for the droplet. The size of the droplet is controlled by the syringe pump. The liquid is pumped to the needle until a desired droplet size is obtained.

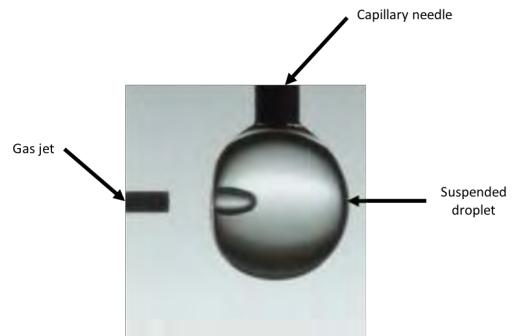

Fig. 1. Experimental Setup

A capillary needle is positioned horizontally next to the suspended droplet. The needle is connected to a high-pressure air-line, through a solenoid valve. Pressure gauges are installed on the line to control the flow conditions. The

flow is controlled by a processor. Direct visualization is used to study the droplet dynamics. Both time lapsed photography, using a still camera with a short duration flash, and a high speed video camera are used in this study. The photographs provided in this paper are from still camera. The schematic of experimental setup is shown in Fig.2.

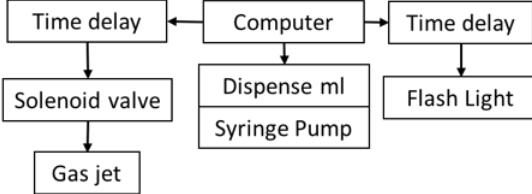

Fig. 2. Schematic of Experimental Setup

### III. RESULTS AND DISCUSSION

#### A. Observations

In our experimental study, a droplet with an average diameter of 2.6 mm is exposed to an air jet, and the dynamics of the droplet is studied. Droplet dynamics differ according to jet to droplet diameter ratio, as well as droplet Weber number based on air density. By progressively increasing the nozzle diameter from 0.2 mm to 0.8 mm, the following dynamics were observed (Fig. 3).

- 1) An air tunnel is formed inside the droplet (Fig.3-1). Contrary to one's expectation, the gas jet does not just form a cylindrical tunnel inside the droplet (e.g., bullet through an apple). The gas jet slightly expands as it penetrates into the droplet. By the time the jet reaches to the end of the droplet, the front opening of the droplet is almost closed, forming a conical shape at the front side (Fig.3-1, t=0.8 ms). At this time, the air jet pushes through the droplet forming another inner jet, which has the same diameter as the initial gas jet. Therefore, two different size cavities are formed inside the droplet.
- 2) The jet can reach to the end of the droplet and pierce through. Once the jet pierces through, another liquid front forms on the upstream side of the tunnel. In addition, capillary waves form on the drop surface. These capillary waves interact with the front opening and distort the incoming jet (Fig.3-2, t=2 ms). Magnified images are shown in Fig.4.
- 3) In the third row, the jet reaches to the end of the droplet and then stretches the water forming a balloon (Fig.3-3, t=1.2 ms); the balloon burst (Fig.3-3, t=1.6 ms); the balloon front retreats collapsing on itself (Fig.3-3, t=2 ms), and the incoming jet bursts it again (Fig.3-3, t=2.4 ms). Magnified images are shown in Fig.5.
- 4) In this case, the jet diameter is so large that it generates a large cavity inside the droplet. Therefore, the liquid thickness around the cavity is small and susceptible to disturbances. In this case, the drop becomes very wavy in the beginning. As the balloon is formed and

stretches, the liquid thickness becomes thinner. The liquid thickness around the cavity is small and susceptible to disturbances. In this case, the drop becomes very wavy in the beginning. As the balloon is formed and stretched, the liquid thickness becomes thinner and thinner and also smoother. The balloon can stretch for a long distance before it bursts. This is shown in Fig.3-4.

#### B. Flow Regime Map

In this part, the dynamics of the droplet are characterized based on the jet to droplet diameter ratio and air pressure. In regime (a), two separated cavities (bubbles) are observed in the droplet and there is a clear boundary between the two cavities (bubbles). When  $\frac{D_{jet}}{D_{drop}} = 0.08$  and  $p = 70\text{psi}$  the dynamics of the droplet starts to change. In regime (b), still two bubbles are seen in the droplet; however, there is not a clear boundary between them. In regime (c),  $\frac{D_{jet}}{D_{drop}}$  is large enough to stretch the droplet and form a bag shape; meanwhile, a bubble is seen at the back of the bag shape. In regime (d), the air jet goes through the droplet, forming a large cavity inside it. The four different regimes are shown in Fig. 6.

#### C. Rayleigh-Taylor Waves

In large jet to drop diameter ratios, the air jet forms a large cavity inside the droplet, the droplet stretches, forming a front rim (windward). This liquid rim goes through Rayleigh-Taylor (RT) instability and breaks into small droplets. The size of the droplets can be estimated based on the RT instability theory. For a RT instability, the wavelength,  $\lambda_{max}$ , corresponding to the maximum growth rate is found to be :

$$\lambda_{max} = 2\pi \left( \frac{3\sigma}{\rho a} \right)^{1/2} \quad (3)$$

where  $a$  is the acceleration, and  $\rho$  is the density of the denser fluid. To consider the effect of viscosity and surface tension, Eq.(3) changes to the following:

$$\lambda_{max} = 2\pi \left[ \left( \frac{3\sigma}{\rho a} \right)^{1/2} + A_2 \left( \frac{\mu^2}{\rho^2 a} \right)^{1/2} \right] \quad (4)$$

where  $\mu$  is the dynamic viscosity of the denser fluid, and  $A_2$  is a coefficient. This simplified equation was obtained by Aliseda et al[1], which agrees favorably with the results of their experiments . For small  $Oh$  , the viscosity effects can be neglected, and Eq. (3) can be used instead of Eq. (4). In the present study, for large enough jet to droplet diameter ratios and large enough jet velocities, Rayleigh-Taylor waves appear at the front rim of the droplet (Fig. 7). In our case ( $Oh = 2.2 \times 10^{-3}$ ), Ohnesorge number is small enough to ignore the viscosity effects. Thus, we will use Eq.(3) to find the critical wavelength of Rayleigh-Taylor Instability. In Eq. (3), all the parameters are known except for the acceleration. Drop acceleration is found using a force balance[3]. The drag force is found through:

$$F_{drag} = \frac{1}{2} \rho_g u^2 C_D A \quad (5)$$

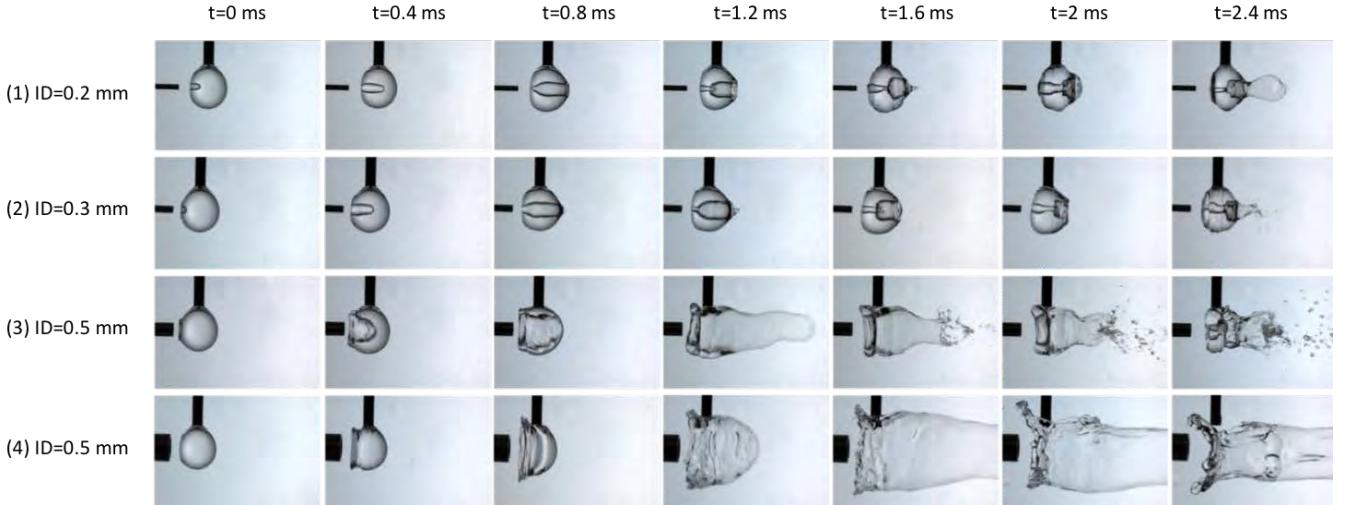

Fig. 3. Droplet dynamics for different nozzle diameters at  $p=10$  psi

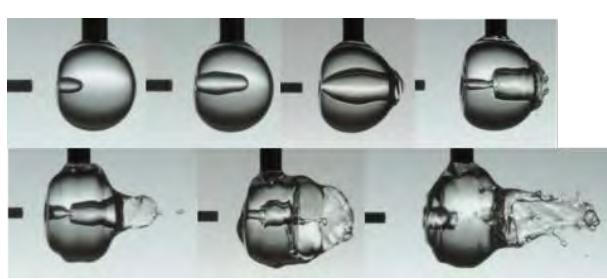

Fig. 4. Droplet dynamics for nozzle with diameter of 0.3 mm

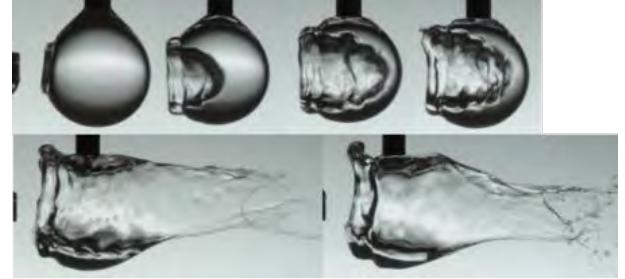

Fig. 5. Droplet dynamics for nozzle with diameter of 0.5 m

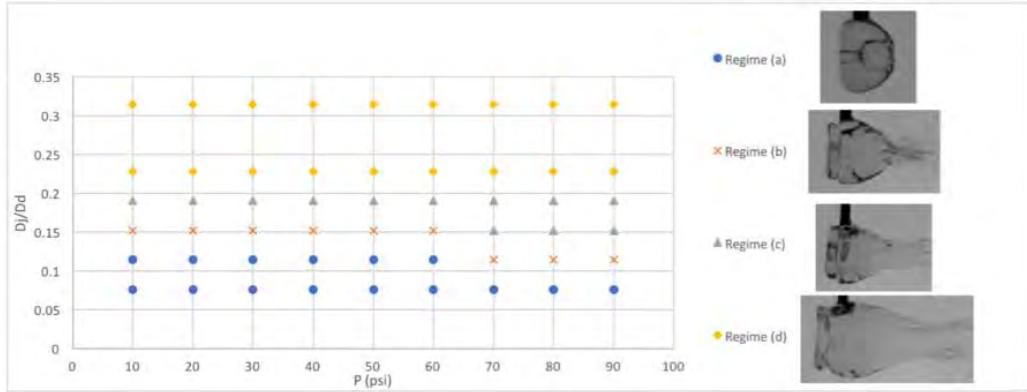

Fig. 6. Flow Regime Map

where  $\rho_g$  is the gas density,  $u$  is the air jet velocity,  $C_D$  is the drag coefficient, and  $A$  is the cross sectional area. This area is shown in Fig. 8. By this definition, the drag force equation will be

$$F_{drag} = 2\rho_g u^2 C_D \pi (R^2 + rR) \quad (6)$$

The other force acting on the droplet is surface tension, which can be found from Eq. (7)

$$F = \frac{2\sigma}{R} \times A \quad (7)$$

where  $\frac{1}{R}$  is the surface curvature, and  $A$  is the surface on which the surface tension force is acting. Thus, the surface tension force can be written as:

$$F = 8\pi\sigma(R+r) \quad (8)$$

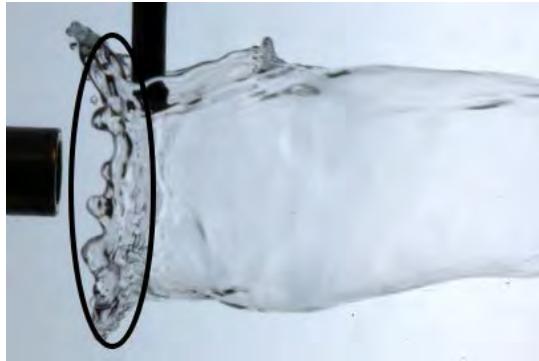

Fig. 7. Rayleigh-Taylor Waves for nozzle with diameter of 1.6 mm

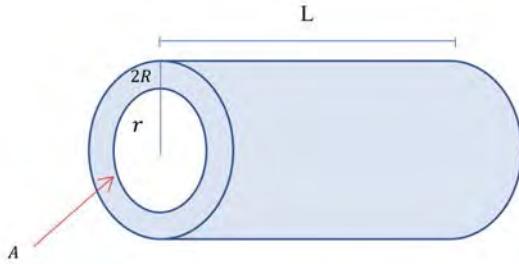

Fig. 8. Hollow cylinder forming after the jet injection

The front rim of the droplet is assumed to have a torus shape with inlet radius of  $r$  and outlet radius of  $R$ . The mass of this torus can be found from Eq. (9).

$$m = \frac{1}{4}\pi^2(2r+2R)(2R)^2 \quad (9)$$

Then, the drop acceleration can be written as:

$$a = \frac{\rho_g u^2 C_D R + 4\sigma}{\pi R^2 \rho_l} \quad (10)$$

In Eq. (10), all the parameters are defined except  $R$ . In order to find the value of  $R$ , mass balance is written. The mass of the initial droplet is equal to the mass of the hollow cylinder which is formed after the air jet injection. This is shown in Eq. (11) .

$$\pi \frac{D_{drop}^3}{6} = 4\pi(R^2 + rR)L \rightarrow R = \frac{-r + \sqrt{r^2 + \frac{D_{drop}^3}{6L}}}{2} \quad (11)$$

RT instabilities are observed for the 1.6 mm jet diameter case. For smaller nozzle diameters the front rim is smooth. The calculations are done for nozzle with diameter of 1.6 mm, and the results are shown in Fig. 9. As the figure shows, the experimental data compare favorably with the theoretical study.

#### D. Penetration Velocity

Penetration velocity is defined as the velocity of the air jet when penetrating through the droplet from one side to the other side. By processing the images, and measuring the distance traveled by the air jet, the penetration velocity is

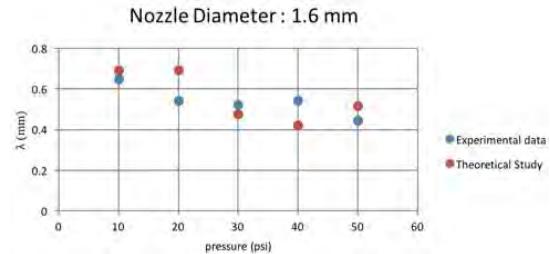

Fig. 9. Experimental and theoretical results for Rayleigh-Taylor waves

calculated. The results are shown in Fig. 10. As the figures show, the air jet is penetrating through the droplet with constant velocity. Moreover, as it is expected, by increasing the air pressure, the penetration velocity is increasing as well.

By writing a pressure balance, the penetration velocity can be found theoretically.

$$\frac{1}{2}\rho_a V_j^2 = \frac{1}{2}\rho_{V_l}^2 + \frac{4\sigma}{D_{drop}} + \frac{4\sigma}{D_j} \quad (12)$$

where  $\rho_a$  and  $\rho_j$  is air and water density,  $V_j$  is jet velocity,  $\sigma$  is the surface tension of water,  $D_{drop}$  and  $D_j$  are droplet and jet diameter, respectively. For nozzle with diameter of 0.2 mm, the penetration velocity is calculated theoretically. Table 1 shows both theoretical and experimental results. As the table shows, for low pressure, the theoretical and experimental velocity are in good agreement. However, by increasing the pressure, the theoretical penetration velocity is no longer a good estimate.

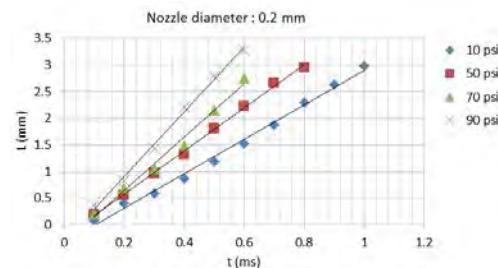

Fig. 10. Experimental penetration velocity

TABLE I  
Experimental and theoretical values of penetration velocity for nozzle with diameter of 0.2 mm

Nozzle Pressure (psi)	Experimental Penetration Velocity (m/s)	Theoretical Penetration Velocity (m/s)
10	3.24	3.32
50	4.06	6.34
70	5.04	7.52

**Abstract** — Counter-flowing wall jets are often used in heat transfer and combustion applications. While several experimental and numerical studies have been conducted to evaluate the characteristics of counter-flowing wall jets, their internal turbulence structure is not well understood. This paper presents the results of a three-dimensional, unsteady, Improved Delayed Detached Eddy Simulation conducted on a counter-flowing wall jet. The mean flow features captured by the simulation are presented with relevant discussions. The shear layer instabilities caused by the vortical structures in the recirculation zone are analyzed by examining the instantaneous flow field. The flow mechanism that causes the fluctuations in the penetration length is also evaluated. The results depict the complexity of the turbulence structure in a counter-flowing wall jet.

**Keywords-** *Counter-flowing jets; turbulent wall jet; IDDES; shear layer instability; penetration length fluctuations*

## I. INTRODUCTION

A turbulent wall jet issued opposite to the direction of a moving main / ambient stream is known as a counter-flowing wall jet (CFWJ). Counter-flowing wall jets are particularly effective as mixing devices, such as effluent mixing in rivers and streams, air-fuel mixture for combustion, etc. This is due to the fact that the turbulence in a counter-flowing wall jet is more enhanced than cross and co-flowing jets or even a counter-flowing free jet (CFFJ). Fig. 1a shows the schematic of a typical CFWJ flow field. The higher momentum at the inlet enables the CFWJ to penetrate the main flow. The momentum of the CFWJ reduces gradually as it approaches the stagnation point. The main flow pushes the jet backwards, thereby creating a recirculation zone. The recirculation zone enhances the turbulence in the CFWJ, thereby improving its mixing efficiency. The distance from the nozzle exit to the stagnation point is known as the penetration length of the jet

( $x_s$ ). The dark black line in Fig. 1a shows a streamsurface, which is the loci of  $U = U_o$ . This streamsurface divides the wall jet and main flow region. The maximum height of this streamsurface gives the width ( $h$ ) of the recirculation zone. The  $U = 0$  line divides the forward and backward flow. While several experimental studies [1-4] have been conducted on CFFJ, the studies on CFWJ are relatively limited. However, the studies of CFFJ can be used to interpret the salient characteristics of a CFWJ flow field. One of the prominent aspects of the CFFJ is the fluctuating nature of the penetration length [2,4]. The stagnation point oscillates about a mean position. The presence of the wall in a CFWJ further enhances the complexity of the flow. In experimental studies, it is difficult to capture the penetration length accurately. Typically, experimental researchers have employed dye or wool turfs to identify the instantaneous location of the stagnation point [1,5], leading to uncertainties in the measurements. Also, in experiments the complete three-dimensional (3D) flow field is not available for analysis, thereby posing challenges in identifying the flow physics that are responsible for the oscillations of the penetration length.

Numerical studies of CFWJ are sparse. “Reference [6]” studied the mean characteristics of CFWJ using the Reynolds-Averaged Navier-Stokes (RANS)  $k-\epsilon$  turbulence model. They analyzed the mean characteristics of the flow for different velocity ratios  $\alpha = U_j / U_o$  where  $\alpha$  is the ratio of jet velocity ( $U_j$ ) to main flow velocity ( $U_o$ ). However, due to the limitations of RANS turbulence models, a rigorous investigation of the turbulence characteristics was not carried out. To address these limitations, 3D, unsteady, Improved Delayed Detached Eddy Simulation (IDDES) of a planar CFWJ is conducted in this study. After validating the simulation results with available experimental data, the instantaneous flow field is analyzed. The shear layer instabilities in the CFWJ flow field are identified. The flow

mechanism responsible for the penetration length fluctuations is also identified.

## II. MODEL SETUP

In the present study, a hybrid RANS-LES approach was employed to model turbulence. IDDES uses RANS near the walls and LES away from it. The complete formulation is available in several publications [7,8] and hence not repeated here. The commercial CFD solver STAR-CCM+ was used to setup and run the simulations. A two-dimensional representation of the 3D computational domain is shown in Fig. 1b. The computational domain is modeled based on the experiments of [9]. A hexahedral mesh was used, with refinements in the regions of interest. Based on the grid dependency study, the mesh selected for the present simulation consists of about 10 million cells. Fine prism layers were added near the walls. The boundary conditions used in the simulation are also shown in Fig. 1b. The side walls were treated as no-slip walls; the complete details of the simulated case are presented in Fig. 1b. Shear stress transport (SST)  $k - \omega$  is used along with LES in the present simulation. IDDES uses a blending function to switch between the RANS and LES regions; this was monitored to ensure that LES was executed in the regions of interest. The solution was considered to be converged when the residuals for continuity and momentum fell below  $10^{-6}$ . The mean quantities presented here were obtained by averaging for a time of 50s following convergence

The simulation results were validated based on the experiments of [9]. The validation procedure was based on the American institute of Aeronautics and Astronautics (AIAA) guidelines for verification and validation of CFD simulations (2002). The penetration length, width of the recirculation zone and velocity profiles were compared with the experimental results. The simulation results agreed well with the experimental results. Only after establishing sufficient confidence in the simulation results, the analysis presented here was carried out.

## III. RESULTS AND DISCUSSION

Fig. 2 shows the velocity vectors in the mean flow field of the CFWJ predicted by the simulation. The velocity vectors are colored based on the mean streamwise velocity. As the jet exists the nozzle at ( $x / h_j = 0$ ), where  $h_j$  is the size of jet, a shear layer is created between the jet and recirculation zone. The mean velocity of the jet decreasing as it approaches the stagnation point. At the stagnation point ( $x / h_j = 72$ ) the jet turns in the opposite direction due to the influence of the main flow, forming the recirculation zone. The  $U = 0$  line divides the forward and backward momentum in the flow field. Due to the interaction between the two flows, the main flow readjusts by flowing around the recirculation zone. Figs. 3(a-d) depict Instantaneous velocity at four time instances. As the jet emanates from the nozzle, the vortical structures from recirculation region interact with the shear layer and create

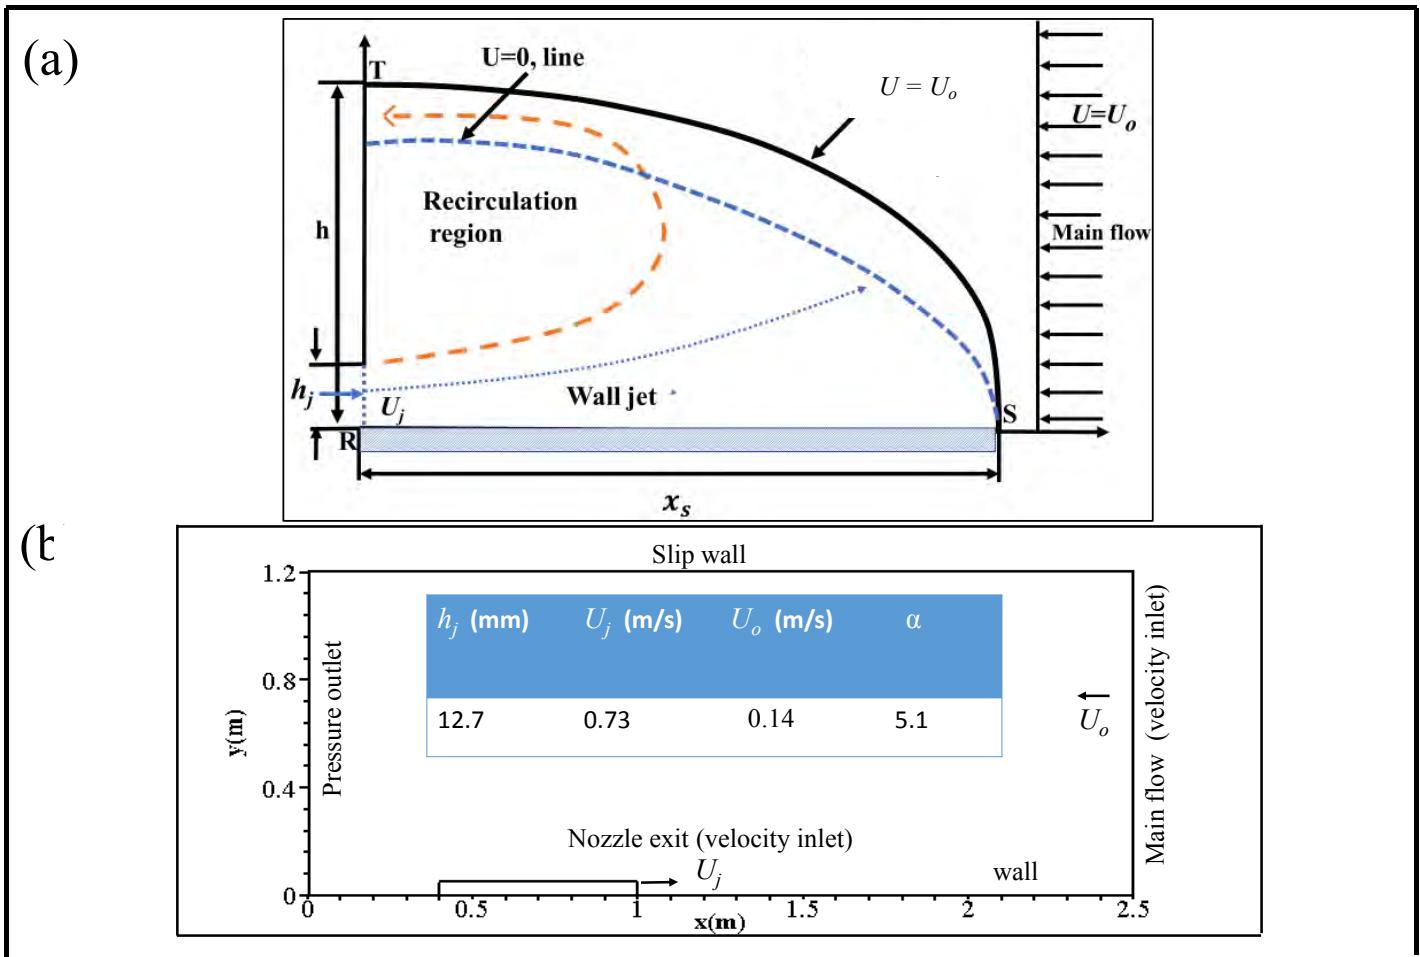

Fig. 1(a) Schematic of counter-flowing wall jet (b) Computational domain

instabilities. The vectors are also superimposed to depict this interaction. The downward motion of the fluid in the recirculation zone (marked by red arrow in Fig. 3a) interacts with the jet between  $x/h_j = 20$  to 30. This excites the jet causing instabilities making it wavy in nature. The influence of the recirculation zone and the adverse pressure gradient it encounters enables it to detach from the wall. This allows the main flow to penetrate further into the jet in the near bed region (marked by the dashed circle in Fig. 3a). As the fast moving jet negotiates the slow moving fluid particles (light blue region) arriving from the near-wall main flow, it bifurcates into an upward moving flow towards the  $U=0$  line and the wall (Fig. 3b). The fluctuating nature of the wall jet continues (Fig. 3c and Fig. 3d) and the corresponding main flow adjusts itself to the jet characteristics, reducing the penetration length of the jet. The penetration length is  $x/h_j = 55$  in Fig. 3d. The phenomenon of jet fluctuations and the corresponding change in the penetration length enhances the mixing. This analysis clearly shows the complex nature of the turbulence in the CFWJ flow field and the feedback

mechanism that exists between the recirculation zone and the wall jet. Further analysis is needed to explore this phenomena.

#### IV. CONCLUSION

A computational study of a counter-flowing wall jet is carried out using the 3D, unsteady, Improved Delayed Detached Eddy Simulation. The simulation captures the relevant flow features of the CFWJ flow field. The mechanism causing the fluctuations in the penetration length has been identified. The analysis of the instantaneous velocity field shows a feedback mechanism that exists between the recirculation zone and the jet, causing the oscillation of the jet penetration length. This mechanism contributes to the enhanced mixing in the CFWJ flow field.

**Abstract** - A tornado features kinematically combining three major co-existent components, namely, updraft, translation, and rotation, which involve all the three dimensions in space while transient in time. For numerical simulation of a tornado-building interaction scenario, it looks quite challenging to seek a set of physically-rational and meanwhile computationally-practical boundary conditions to accompany traditional CFD approaches; thus, little literature can be found, as of today, in three-dimensional (3D) computational tornado dynamics study. Inspired by the development of immersed boundary (IB) method, this study employed the re-tailored Rankine-combined vortex model (RCVM) that applies the “*relative motion*” principle to the translational component of tornado, such that the building is viewed as “*virtually*” translating towards a “*pinned*” rotational flow that remains time-invariant at the far field region. This revision renders a steady-state kinematic condition applicable to the outer boundary of a large tornado simulation domain, successfully circumventing the boundary condition updating process that the original RCVM would have to suffer, and tremendously accelerating the computation. Here, this re-tailored RCVM was extended to its 3D version with the aid of logarithm law that describes the vertical flow evolution. Eventually, this tornado model was embedded in Incompact3D, an academic high-order finite difference turbulent flow solver, resulting in a practical powerful 3D tornado-building interaction simulation tool. A case study examined the tornadic wind induced loadings on a prismatic building; over all three directions, the vertical force component was found dominant, which effectively suggests the uprooting effect as observed in many reported scenes after a devastating tornado swept over.

**Keywords:** *Re-tailored Rankine-combined vortex model (RCVM); Immersed boundary (IB); Large eddy simulation (LES); Finite difference method; Wind loadings.*

## I. INTRODUCTION

Tornadoes have been worldwide observed, and more frequently reported in United States and Canada. Compared to a straight-line wind, a tornadic flow is much more complex, since it is a type of airflow that essentially combines

translational, vertical, and rotational velocities, and all components have to be considered during the investigation. Since the study of tornado dynamics through field observations or laboratory experiments tends to be time-consuming, laborious, and expensive, more research efforts have been made in the direction of mathematical modeling and numerical simulations. Historically, Wilson [1] first applied a two dimensional (2D) tornado model to examine the effects of tornadoes on rectangular-shaped buildings. Lewellen et.al. [2-3] employed a three-dimensional (3D) large eddy simulation (LES) turbulence model to investigate the dynamics of a tornado-like vortex near the surface with particular attention paid to the turbulent flow characteristics in the corner region. Natarajan and Hangan [4] also used LES model to study the effects of surface roughness and translation on the mean tangential velocity of the tornadic wind for different swirl ratios. On the other hand, tornado-induced wind loadings exerted on constructions have been also a practical topic. Based upon the Rankine-combined vortex model (RCVM), Selvam et.al. [5-6] used the finite difference discretization of the Navier-Stokes (N-S) equations to conduct a series of studies focusing on the tornado-induced loadings on 2D sections of a cylinder and multi-cubic buildings and, more recently, some 3D cases [6] at elevated Reynolds numbers also with the aid of LES [7].

However, most aforementioned computational tornado dynamics studies mainly relied on conventional numerical methods, which need to update the time-dependent boundary conditions due to the dynamic nature of tornado. To overcome that tedious updating process, Guo et.al. [8-9] re-formulated the RCVM to model the two-dimensional (2D) tornado-building interaction with the aid of immersed boundary (IB) method and the “*relative motion*” principle, resulting in a “*virtual*” scenario in which the building “*moves*” at a velocity that is the negative of the translation velocity of the tornado, while the background airflow has only a rotational component about its “*pinned*” center. Thus, as long as the computational domain is large enough for its outer boundary to little affected by the inner flow evolution induced by the “*virtual translation*” of the building, the time-dependency and, hence, the kinematic condition updating process, can be effectively eliminated at the outer boundary of the computational domain.

This study aims to extend the 2D tornado simulation framework [8] to the 3D version by taking the vertical velocity component into account. A combination of direct forcing IB approach with a centered finite difference scheme of high accuracy is performed. Meanwhile, the LES turbulence model is coupled with the N-S solver in order to better simulate the tornadic flow at relatively high Reynolds numbers. The advantage of this framework was discussed in terms of computational efficiency, accuracy, and simplicity [10]. Considering the large computational domain along with fine grid resolution required by 3D tornado simulations, this framework has been adapted to be portable on massive parallel computing platforms via Message Passing Interface (MPI) techniques [10].

The rest of this paper will unfold as follows: the numerical method, including the tornado model, governing equations, and some other numerical treatment details, is presented in Section II. Section III provides a tornado-building interaction case with tornadic wind loadings analyzed in all directions. Finally, remarks are made in Section IV, addressing the conclusion and future extension of this study.

## II. NUMERICAL METHOD

### A. Tornado Model

The simplest model that can satisfy the Navier-Stokes equations while describing a tornadic wind field is the Rankine-combined vortex model (RCVM). In RCVM, tornado velocity profile can be decomposed into a constant-translation component,  $\vec{V}_t$ , a component of rotation with respect to the wind centre,  $\vec{V}_\theta$ , which denotes the tangential velocity component, and a vertical velocity component that obeys the logarithmic law to account for the boundary layer growth. The RCVM velocity profile along the radial direction from the tornado center consists of two distinct regions. The forced-vortex region refers to a circular area in which the radius from the tornado centre,  $r$ , is less than the  $r_c$ , the maximum radius of the forced-vortex region,  $V_\theta$  varies linearly with  $r$  and reaches the maximum tangential velocity at  $r_c$ . At radii larger than  $r_c$ , i.e., in the free-vortex region,  $V_\theta$  decreases with the radius. The detailed mathematical expression of  $V_\theta$  is as follows:

$$V_\theta = \begin{cases} r\omega, & r \leq r_c \\ r_c^2\omega/r, & r > r_c \end{cases} \quad (1)$$

where  $\omega$  is the constant angular velocity. If taking the translational velocity and counter-clockwise rotational velocity into consideration, the resultant velocity on a horizontal plane can be re-projected to the Cartesian coordinate system, resulting in [5]:

$$u = \begin{cases} (V_t - y \cdot \omega)Z_f, & r \leq r_c \\ (V_t - y \cdot r_c^2\omega/r)Z_f, & r > r_c \end{cases} \quad (2)$$

$$v = \begin{cases} ((x + V_t \cdot t)\omega)Z_f, & r \leq r_c \\ ((x + V_t \cdot t)r_c^2\omega/r)Z_f, & r > r_c \end{cases} \quad (3)$$

Remark that in Eqs. (2) and (3)  $Z_f$  denotes a vertical kinematics adjustment parameter, which is a logarithmic law based function of vertical coordinate,  $z$ , as follows:

$$Z_f = \frac{u^*}{k} \ln\left(\frac{z+z_0}{z_0}\right) \quad (4)$$

where  $k$  and  $z_0$  are constants, with  $k=0.4$ ,  $z_0=0.00375$ , respectively. When using the re-tailored RCVM in which the rotational flow component is virtually viewed as pinned, the translational velocity  $\vec{V}_t$  of the air vanishes, and Eqs. (2) and (3) reduce to:

$$u = \begin{cases} (-y \cdot \omega)Z_f, & r \leq r_c \\ (-y \cdot r_c^2\omega/r)Z_f, & r > r_c \end{cases} \quad (5)$$

$$v = \begin{cases} (x \cdot \omega)Z_f, & r \leq r_c \\ x \cdot (r_c^2\omega/r)Z_f, & r > r_c \end{cases} \quad (6)$$

### B. Governing Equations

The simulations are performed with Incompact3d, an open-source code developed mainly by Laizet & Lamballais [11]. All governing equations are solved on a collocated velocity grid via the six-order central compact finite difference scheme [12], while the pressure is on a staggered grid. A second-order Adams-Bashforth (AB) scheme is used for time-advancement and continuity is verified at the end of each sub-time step by solving a pressure Poisson equation. This Poisson equation is solved through a spectral solver to avoid the expensive cost incurred by the high-order discretization along with iterative schemes. The massively parallel version of the code was employed through an MPI implementation based on pencil domain decomposition strategy [10].

The mass and momentum conservation principles are represented by the Navier-Stokes equations, which have the following form for an incompressible fluid:

$$\rho \left( \frac{\partial \vec{u}}{\partial t} + (\vec{u} \cdot \vec{\nabla}) \vec{u} \right) = -\vec{\nabla} p + \mu \vec{\nabla}^2 \vec{u} + \vec{f} \quad (7)$$

$$\vec{\nabla} \cdot \vec{u} = 0 \quad (8)$$

where  $\vec{u}(\vec{x}, t) = (u(\vec{x}, t), v(\vec{x}, t), w(\vec{x}, t))'$  is the fluid velocity,  $p(\vec{x}, t)$  is the pressure field, and  $\rho$  is constant ( $\rho=1$ ) in the present framework.  $\vec{f}$  is the external forcing term caused by the interaction between the air and the immersed building.

### C. Time Advancement

The time integration for solving Eq. (7) is performed using a second-order Adams-Bashforth scheme. A fractional step method [13] is applied to decouple the velocity and pressure, and detailed steps are as follows:

This study is fully funded by the Discovery Grant of the Natural Sciences and Engineering Research Council (NSERC) of Canada.

$$\frac{\vec{u}^* - \vec{u}^n}{\Delta t} = -\frac{3}{2}\vec{N}^n - \frac{1}{2}\vec{N}^{n-1} - \vec{\nabla}\tilde{p}^n + \tilde{\vec{f}}^n \quad (9)$$

$$\frac{\vec{u}^{**} - \vec{u}^*}{\Delta t} = \vec{\nabla}\tilde{p}^n \quad (10)$$

$$\vec{\nabla}\tilde{p}^{n+1} = \frac{\vec{\nabla} \cdot \vec{u}^{**}}{\Delta t} \quad (11)$$

$$\frac{\vec{u}^{n+1} - \vec{u}^{**}}{\Delta t} = -\vec{\nabla}\tilde{p}^{n+1} \quad (12)$$

with

$$\vec{N}^n = -\vec{u}^n \cdot \vec{\nabla}\vec{u}^n - \mu \vec{\nabla}^2 \vec{u}^n \quad (13)$$

and

$$\tilde{\vec{f}}^{n+1} = \frac{1}{t} \int_{t_n}^{t_{n+1}} pdt, \quad \tilde{\vec{f}}^{n+1} = \frac{1}{\Delta t} \int_{t_n}^{t_{n+1}} \vec{f} dt, \quad (14)$$

where  $\vec{u}^{**}$  and  $\vec{u}^*$  are the intermediate velocities obtained between time steps  $n$  and  $n+1$

#### D. Evaluation of Forcing Term

In order to solve the Eq.(9), the forcing term  $\tilde{\vec{f}}^{n+1}$  needs to be determined in advance. This term is generated by the IB approach, and reflects the interaction between the immersed object and the fluid. In this study, a direct method is adopted to calculate the forcing term as follows:

$$\tilde{\vec{f}}^{n+1} = \varepsilon \left( -\frac{3}{2}\vec{N}^n + \frac{1}{2}\vec{N}^{n-1} + \vec{\nabla}\tilde{p}^n + \frac{\vec{u}_0^{n+1} - \vec{u}^n}{\Delta t} \right) \quad (15)$$

with  $\varepsilon=1$  in the solid body region, and  $\varepsilon=0$  elsewhere else in the computational domain. The target velocity  $\vec{u}_0$  is calibrated in order to satisfy the no-slip condition at the surface of solid body.

#### E. Entire Procedure

Details about the spatial discretization using sixth-order compact finite difference method can be found in [10]. Here, a typical solution procedure for each time step within the simulation framework is described as follows:

1. Set up a computational domain, and initialize the velocity field using the RCVM as aforementioned in Eqs. (5) and (6);
2. Based on the location of the boundary of the immersed body at time step  $n+1$ , identify the fluid, solid and solid boundary points on the Eulerian grid;
3. Calculate the target velocity  $\vec{u}_0^{n+1}$  in Eq.(15);
4. Obtain the forcing term using Eq.(15);
5. Compute the velocity field  $\vec{u}^*$  by solving Eq.(9);
6. Compute intermediate velocity  $\vec{u}^{**}$  by solving Eq.(10);
7. Compute the pressure  $\vec{\nabla}\tilde{p}^{n+1}$  by solving pressure Poisson equation Eq.(11);
8. Correct divergence-free fluid velocity  $\vec{u}^{n+1}$  at the  $(n+1)^{\text{th}}$  time step by solving Eq. (12);
9. Go back to Step 2 if time-marching is still needed; otherwise, stop the computation.

### III. NUMERICAL RESULTS

#### A. Initial condition and Boundary condition

As aforementioned in the beginning of the precedent section, this study re-tailored the original RCVM, such that the scenario of a tornado passing through a building (prism) is interpreted as a superposition of a “pinned” rotational airflow and a “virtual translation” of the building, which is opposite to the physical translation direction of the tornado. Then, the re-tailored RCVM serves to set up the initial velocity background, and note that the outer boundary condition has been rendered time-independent owing to this re-tailored model.

Figure 1 illustrates the computational domain with  $(L_x, L_y, L_z) = (24, 16, 16)$ . The length (in the  $x$ -direction) and the height (in the  $z$ -direction) of the prism are equal to 1, which is equal to the radius of the forced vortex region,  $r_c$ , and the depth (in the  $y$ -direction) of prism is set at 12. The translation velocity remains one unit. The Reynolds number based on the height of the prism is  $Re=10000$ . No slip boundary condition is applied on the bottom surface, as well as the prism walls, and the velocity on all other surfaces is governed by the re-tailored time-independent RCVM.

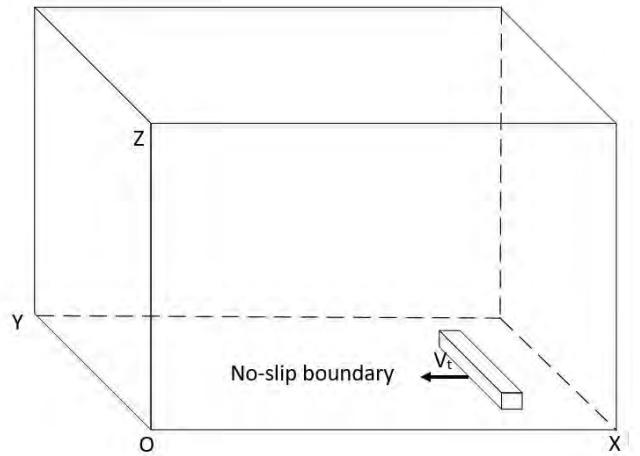

Fig.1 Schematic of the computational domain

#### B. Force Coefficient Definition

The dimensionless force coefficients in all three directions are defined as:

$$C_x = \frac{F_x}{0.5\rho V_t^2 S} \quad (16)$$

$$C_y = \frac{F_y}{0.5\rho V_t^2 S} \quad (17)$$

$$C_z = \frac{F_z}{0.5\rho V_t^2 S} \quad (18)$$

where  $F_x, F_y, F_z$  and  $S$  is the components of the resultant force in three directions and projection area, respectively. Using the

$x$ -direction as example,  $F_x = -\int_{\Omega_0} f_i d\mathbf{x}$ , and  $f_i$  is the  $x$ -component of the force density, the calculation of which is based upon the following integral form of the  $x$ -component of the momentum equations on any fluid domain  $\Omega_0$ :

$$\begin{aligned} \frac{\partial}{\partial t} \int_{\Omega_0} u_i d\mathbf{x} + \int_{\partial\Omega_0} \rho u_i \mathbf{u} \cdot \mathbf{n} ds \\ = - \int_{\Omega_0} p n_i d\mathbf{x} + \int_{\partial\Omega_0} \mu \left( \frac{\partial u_i}{x_j} + \frac{\partial u_j}{\partial x_i} \right) n_j ds + \int_{\Omega_0} f d\mathbf{x} \end{aligned} \quad (19)$$

The computations of  $F_y$ ,  $F_z$  are similar to  $F_x$ .

### C. Case Study

In this case, the initial position of the prism is placed at 3 units from right boundary of the computational domain at time step  $t=0$ , as shown in Fig.1. When employing the re-tailored RCVF, the building is “virtually moving” towards left, while the tornado central vertical line remains located at the center of the computational domain. Fig. 2 illustrates the evolution of the force coefficients in all three directions  $C_x$ ,  $C_y$ , and  $C_z$ . Note that the horizontal coordinate,  $X$ , is arranged such that, while  $X < 0$ ,  $X=0$  and  $X > 0$ , the tornado center physically approaches the prism, nominally coincides with the prism, and leaves the prism, respectively.

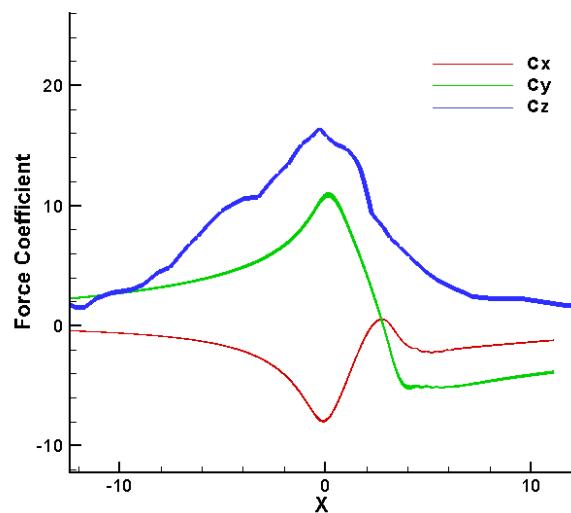

Fig.2 Evolution of force coefficients in three directions

When the translating tornado center approaches the prism,  $C_x$  keeps decreasing and stays negative, while both  $C_y$  and  $C_z$  keep positive and continuously go up. This indicates the following tornado characteristics in the approaching stage: (1) the building is attracted by the tornado in the  $x$ -direction, and the closer between the tornado center of the building, the larger attractive force; (2) the building is pushed by the tornado towards the positive  $y$ -direction due to the counter-clockwise rotation direction of the airflow, and the closer between the tornado center of the building, the larger pushing force; and (3) the building experiences an upward suction force in the  $z$ -direction, and the closer between the tornado center of the building, the larger suction force.

When the tornado is in the stage of nominally coinciding with the building, the three force coefficients consistently reach their respective extreme values, challenging the wind-resistant capability of the building to the utmost extent.

Afterwards, in the stage of tornado leaving the building, the three force components are consistent, again, in exhibiting their magnitude decreases. However, the decreasing trend for the magnitude of  $C_z$  remains unchanged all the way in this stage, tending to vanish at the end; on the other hand,  $C_x$  and  $C_y$  experience up and down in terms of their magnitudes. In detail, the  $C_x$  magnitude drops until it reaches its second extreme, which is numerically very close to zero and, locally, the tornado center is about 3 units away from the building, then rises during the period in which the distance between the tornado center and the building goes approximately from 3 units to 5 units, and then re-drops and gradually diminishes at the end; for the  $C_y$  magnitude in this stage, it steeply drops and goes to zero when  $C_x$  reaches its second extreme (at about  $X=3$ ) and, then, the direction of  $F_y$  changes to the negative  $y$ -direction, and the  $C_y$  magnitude remains increasing until approximately  $X=4$ , followed by a decreasing trend. The complex up-and-down trend for  $C_x$  and  $C_y$  is attributed to the strongly disturbed wake behind the building after the tornado sweeps it over. The three force coefficients calm down only after the core zone of the tornado has been completely away from the building.

Compared with each other, the magnitude of the  $z$ -direction force component is the highest, suggesting that the influence caused by the given logarithm law based vertical adjustment parameter  $Z_f$  is a dominant factor for the tornado dynamics study.

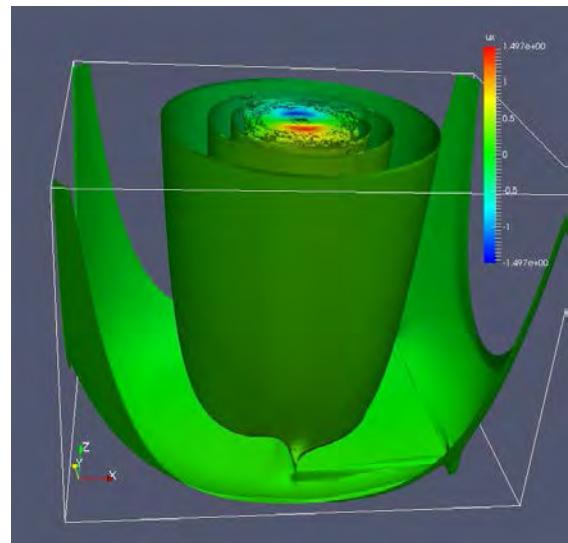

Fig.3 Velocity profile when tornado center coincides with prism

Figure 3 provides a 3D view of tornadic flow when the tornado center coincides with the building. A number of eddies are found in the tornado core area on a horizontal section near the top face of the computational domain, while beyond the core zone the streamlines overall remain circular about the center of tornado. Figure 4 zooms into the vicinity of the

building, indicating the no-slip condition on the surfaces of the prism are satisfactorily guaranteed as no penetration is observed across the interface of the prism and air.

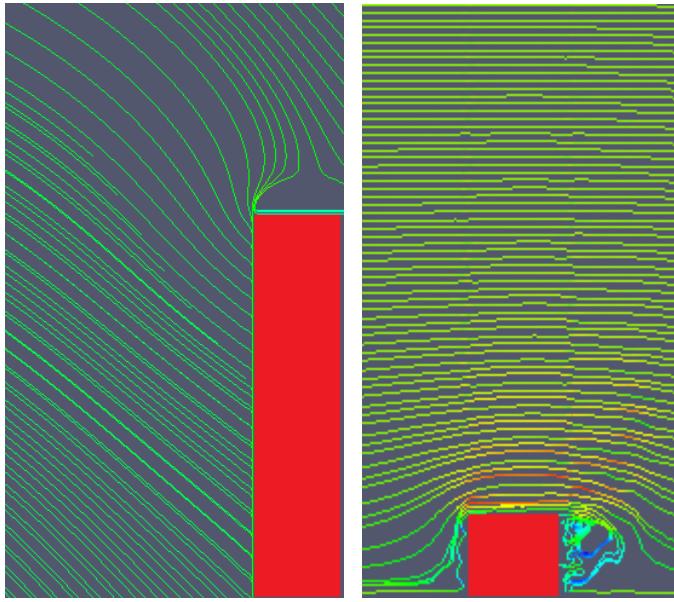

Fig.4 Streamlines near the prism on a horizontal ( $x$ - $y$ ) and a vertical ( $x$ - $z$ ) sections

#### IV. CONCLUSIONS

In this paper, a novel computational framework was established, aiming at extending previously built 2D tornado simulation model to its 3D version by introducing a vertical kinematics adjustment parameter,  $Z_f$ , for describing the boundary layer growth in the  $z$ -direction. The re-tailored Rankine-Combined Vortex Model (RCVM) was employed with the aid of the immersed boundary (IB) approach, so that the numerical investigation of tornado-construction interaction can be made without requesting kinematic condition updating process at the outer boundary of the 3D computational domain. The results obtained in the present study has shown that the vertical component of a tornado plays a significant role in the tornado dynamics study since the largest force coefficient was found in the  $z$ -direction. Extensive simulations are underway to investigate the interaction between a variety of tornadic wind scenarios and differently deployed multi-constructions owing to the embedment of the IB strategy.

#### ACKNOWLEDGMENT

In addition to the Discovery Grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada for the present study, the authors also wish to thank the Compute Canada for providing the computational facilities in support of the computations reported here.

**Abstract**— The effects of the wall temperature on the residual layer thickness of the polymers are studied numerically in the filling process in the injection molding process. A lubrication approximation model is developed to furnish a semi-analytical solution. The shear viscous heating terms are neglected to simplify the governing equations. The Cross-WLF viscosity model is used to capture the residual layer. There is a good agreement between the results of the developed model and experiments.

**Keywords**-Heat transfer; Cross-WLF model; non-Newtonian fluid; residual layer thickness; blocking time

## I. INTRODUCTION

The mold filling process is the main stage in the injection molding process, which is the most common process in manufacturing plastic goods. During the filling process, a melted polymer fills the cavity part [1]. The temperature reduction due to the heat transfer of the mold with the walls during the filling process directly affects the viscosity of the polymer and, consequently, the filling flow rate that strongly influences the quality of the molded part [2]. The probability of the residual layer formation negatively affects the quality of the final products.

Several researchers have modeled the momentum and heat transfer in the injection molding process to find the velocity and temperature profiles [3, 4]. Newtonian [5], power-law [6, 7] and the Cross-WLF models [4, 8] have been used mainly to simulate the rheological properties of the polymers in the filling stage. The Cross-WLF model offers the best fit to the most viscosity data of polymers in the filling process [9] because the effects of shear rate and temperature on the viscosity of the polymers are considered simultaneously. The combination of heat-transfer analysis coupled with non-Newtonian fluid mechanics approach, also, can predict the velocity and temperature profiles of the polymer in the filling process [10].

Formation of the residual layer depends on the balance between the main forces that involve in the movement of fluid. In a different context, Allouche et al. [11] have investigated the residual layer in the displacement of two visco-plastic fluids in a plane channel. Their study quantifies the sufficient conditions for removing the residual layer basde on the value of the

Bingham number (as the ratio yield to viscous stresses). In general, the minimum and maximum thickness of the residual layer depends on the competition of yield stress and viscous stress [12,13].

In this paper, we study the residual layer thickness following two scenarios, A. constant injection mass flux B. constant imposed pressure to simulate the formation and removing the residual layer in the filling process.

## II. MODELING

The governing equations in the Cartesian coordinates (x, y) assuming a symmetric 2D channel flow in the dimensionless form are:

$$\begin{aligned} \text{Re}\left(\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y}\right) &= -\frac{\partial p}{\partial x} + \left[ \frac{\partial}{\partial x} \tau_{xx} + \frac{\partial}{\partial y} \tau_{yx} \right], \\ \text{Re}\left(\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y}\right) &= -\frac{\partial p}{\partial y} + \left[ \frac{\partial}{\partial x} \tau_{xy} + \frac{\partial}{\partial y} \tau_{yy} \right] + \frac{1}{St}, \\ \frac{\partial u}{\partial x} - \frac{\partial v}{\partial y} &= 0, \\ \left(\frac{\partial \theta}{\partial t} + u \frac{\partial \theta}{\partial x} + v \frac{\partial \theta}{\partial y}\right) &= -\frac{1}{\text{Re Pr}} \left( \frac{\partial \theta}{\partial x} + \frac{\partial^2 \theta}{\partial y^2} \right) \\ - \frac{Ec}{\text{Re}} (\tau_{xx} \frac{\partial u}{\partial x} + \tau_{xy} \frac{\partial u}{\partial y} + \tau_{yx} \frac{\partial v}{\partial x} + \tau_{yy} \frac{\partial v}{\partial y}). \end{aligned} \quad (1)$$

Here,  $u$ ,  $v$  denote the dimensionless velocity components,  $p$  is the pressure,  $\tau$  represents the stress in the fluid. Prandtl, Reynolds, Stokes and Eckert numbers are defined as:

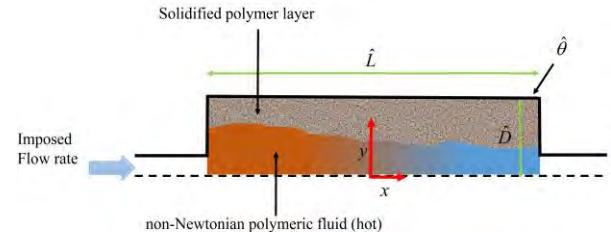

Figure 1. A schematic of problem.

$$\begin{aligned} \text{Pr} &= C\hat{p}\hat{\eta}_{00}/\hat{k}, \text{ Re } \hat{\rho}u_0\hat{D}/\hat{\eta}_{00}, \\ St &= \hat{\eta}_{00}\hat{u}_0/\rho\hat{g}\hat{D}, Ec = \hat{u}_0^2/C\hat{p}(\hat{\theta} - \hat{\theta}_w), \end{aligned} \quad (2)$$

where,  $\hat{u}_0$ ,  $\hat{D}$ ,  $\hat{g}$  are the mean imposed velocity, the half depth of the cavity and the gravitational acceleration respectively.  $C\hat{p}$ ,  $\hat{k}$ ,  $\hat{\rho}$ ,  $\hat{\theta}_i$  are the specific heat capacity, the thermal conductivity, the wall temperature and the initial fluid temperature.  $\hat{\eta}_{00}$  is the constant parameter of the Cross-WLF model. The dimensionless temperature is defined as  $\theta = (\hat{\theta} - \hat{\theta}_w)/(\hat{\theta}_i - \hat{\theta}_w)$ . We assume that the geometry is full of fluid when the molten polymer is injected to the cavity (see Figure 1). Based on the small aspect ratio of the problem ( $\delta = \hat{D}/\hat{L}$ ) we re-scale as follows:

$$\delta x = X, \delta t = T, \delta p = P, \delta V = v.$$

Applying the lubrication approximation ( $\delta \text{Re} \rightarrow 0$ ) and neglecting the viscous dissipation terms, we can rewrite the governing equations as:

$$\begin{aligned} \frac{\partial}{\partial y} \tau_{yx} &= \frac{\partial P}{\partial X}, 0 = \frac{\partial}{\partial y}, \\ \frac{\partial u}{\partial X} + \frac{\partial V}{\partial y} &= 0, \frac{\partial \theta}{\partial T} = \left( \frac{\partial^2}{\partial y^2} \right), \end{aligned} \quad (3)$$

where,  $T^* = T/\delta \text{Re} \text{Pr}$ . The Cross-WLF model interprets the rheological properties of the polymer as;

$$\begin{aligned} \tau_{yx} &= \eta \dot{\gamma}, \eta = \frac{\eta_0}{1 + (B\eta_0 \dot{\gamma})^{1-n}}, \\ \eta_0 &= \exp\left(\frac{A_1(\theta - \theta^*)}{A_2 + (\theta - \theta^*)}\right), \end{aligned} \quad (4)$$

$$\text{where, } \frac{\theta_w - \hat{\theta}^*}{\hat{\theta}_i - \hat{\theta}_w} = -\theta^*, \frac{\hat{A}_2}{\hat{\theta}_i - \hat{\theta}_w} = A_2, \eta_0 = \frac{\hat{\eta}_0}{\hat{\eta}_{00}},$$

$$\eta = \frac{\hat{\eta}}{\hat{\eta}_{00}}, B = \frac{\hat{u}_0}{\hat{\tau}^*} \frac{\hat{\eta}_{00}}{\hat{D}}.$$

$\hat{\eta}$ ,  $\hat{\tau}^*$ ,  $\hat{\eta}_{00}$ ,  $\hat{\theta}^*$ ,  $n$  are the melt viscosity, the critical stress level at the transition to shear thinning, the zero shear viscosity, the glass transition temperature and the power law index respectively.  $\hat{A}_1$ ,  $\hat{A}_2$  and  $\hat{\eta}_{00}$  are data-fitted coefficients.

### III. RESULTS AND DISCUSSIONS

Solving the momentum and energy equations considering the Cross-WLF model gives the velocity profile at different times. To calculate the temperature profile of the polymer along the filling process, we solve the energy equation ( $\frac{\partial \theta}{\partial T^*} = \frac{\partial^2 \theta}{\partial y^2}$ ) analytically. Velocity profile obtained based on

scenario A (constant injection mass flux) and scenario B (constant imposed pressure). The latter is to simulate the formation and removing the residual layer in the filling process.

#### A. Constant mass flux

In the first scenario, we considered the mass flux is constant along the process and the pressure drop is variable. We can then calculate the velocity profile during the filling process at different time.

Figure 2a and Figure 2b demonstrate the temperature and velocity profiles of a polymer during the filling process versus time. The maximum temperature gradient exists at the beginning where the dimensionless melt temperature is 1. It takes a finite amount of time for a temperature "wave" to propagate through the polymer and the melt temperature decreases. At longer times, the temperature gradient goes to zero and the polymer temperature becomes equal to the wall temperature.

The polymer layers close to the wall have small overall heat resistance and become cool faster in comparison to the layers close to the middle of the cavity. This is because the conduction heat transfer is the main mechanism in the heat transfer between the wall and melt in the filling process. Consequently, the viscosity of the polymer layers increase adjacent the wall and a residual layer appears. The temperature gradient decreases with time and the thickness of residual layer increases. The maximum velocity at the middle of the cavity increases with time since the mass flux needs to remain constant.

Figure 3 shows three different zones in which the residual layer thickness changes with time. In short times, the residual layer increases with time. Then the thickness decreases gradually and it becomes zero at longer times. This phenomenon can be explained by looking back at Cross-WLF model. The viscosity of the polymer depends on the temperature and the shear rate. In a short filling process, the temperature difference between the wall and polymer is considerable. Therefore, the viscosity of the polymer layer close to the wall increases dramatically and the residual layer thickness increases. Along the time, the temperature difference inside the polymer decreases and the shear rate effect increases. It removes the residual layer with time. In a long time process, the temperature gradient inside the polymer tends to zero and the shear rate is able to move the polymer completely.

The viscosity of the polymer increases by cooling the polymer. The pressure drop increases with time dramatically due to the constant mass flux in the filling process. The pressure drop becomes constant when the residual layer is removed completely. Note that in this stage the polymer temperature is close to the wall temperature; therefore, the viscosity does not change.

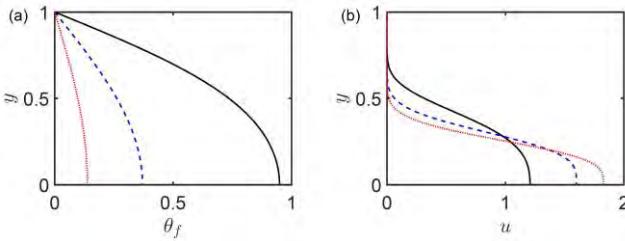

Figure 2. Temperature and velocity profiles at  $T^* = 0.1, 0.5, 0.9$  for the black solid, blue dashed and red dotted line.  $A_1 = 31$ ,  $A_2 = 0.2$ ,  $\theta^* = 0.12$ ,  $n=0.3$ ,  $B=5\times10^{11}$ .

### B. Constant imposed pressure

The results of the previous section shows that the residual layer is removable at longer times if the pressure is increased dramatically. Looking back at Figure 3b, the imposed pressure must be increased almost ten orders of magnitude to remove the residual layer completely, which is not feasible for the industry. Therefore, we are considering the second scenario (constant imposed pressure) to understand the behavior of the residual layer during a more realistic filling process.

Figure 4 shows the velocity profile evolution of the polymer during the filling process in which the imposed pressure is constant. As we have discussed, the viscosity of the polymer increases due to the heat transfer between the wall and the melt. Therefore, the residual layer thickness increases with time in the case of constant imposed pressure (compare the residual layer in the inset of Figure 4a for  $T^* = 0.01$  (blue), 0.2 (black) and 0.4 (red)). In addition, increasing the viscosity of fluid causes the maximum velocity to decrease with time. Increasing the imposed pressure augments the driving force that enhances the maximum velocity (for instance compare the blue lines in the Figures 4a and 4b). In addition, higher pressure decreases the thickness of the residual layer. The dashed lines in the insets of Figures 4a and 4b show the residual layer thickness reaching 0.52 and 0.48 at  $P$  of  $3\times10^{-12}$  and  $4.2\times10^{-12}$  respectively when  $T^* = 0.4$ .

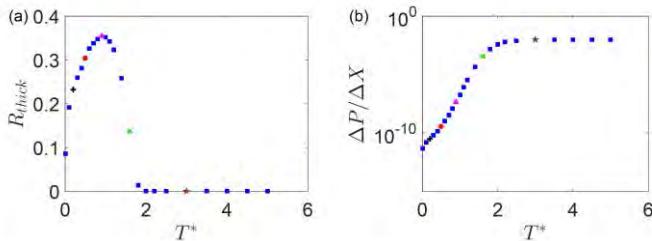

Figure 3. Dimensionless residual layer thickness and pressure drop with time for  $A_1 = 31$ ,  $A_2 = 0.2$ ,  $\theta^* = 0.12$ ,  $n=0.3$ ,  $B=5\times10^{11}$ .

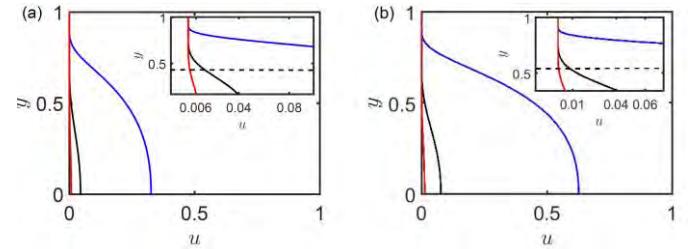

Figure 4. Velocity profile evolution along the time with the constant impose pressure.  $A_1 = 31$ ,  $A_2 = 0.2$ ,  $\theta^* = 0.12$ ,  $n=0.3$ ,  $B=5\times10^{11}$ . The imposed pressure of (b) is 40% greater than (a).

### C. Comparison with experiments

In order to evaluate the developed model, a pilot tool was made to produce sheets with dimensions of  $130 \text{ mm} \times 30 \text{ mm} \times 3 \text{ mm}$ . A gate was located in the center of the cavity as shown in Figure 5. The cavity was equipped with two Kistler 61923 thermocouples flush with the surface and 44 mm apart from each other. The presence of the thermocouples enabled not only the measurement of the temperature of the cavity wall overtime, but also monitoring the advancement of the melt front inside the cavity. The response time of the thermocouples was 1 m/s. Using a thermolator, adjustments were made to the temperature of the cooling water and hence the cavity walls.

By controlling the injection pressure, we deliberately produced short shots to monitor the melt front advancement at different injection pressures. We used the traveling time of the melt front between two thermocouples to calculate the average velocity of the melt inside the cavity and calculate the blocking time (the time that the residual layer thickness becomes half of the cavity).

Table 1 shows the comparison between the blocking time coming from the present work, the model of Chen [14] and the experimental results. The model of Chen is an empirical method for the calculation of the blocking time. In this model, the blocking time is independent of the imposed pressure and depends on the thermal diffusivity, the melt temperature, the mold temperature and the no-flow temperature. Table 1 shows that there is a good agreement between the results of the present work and the experimental one.

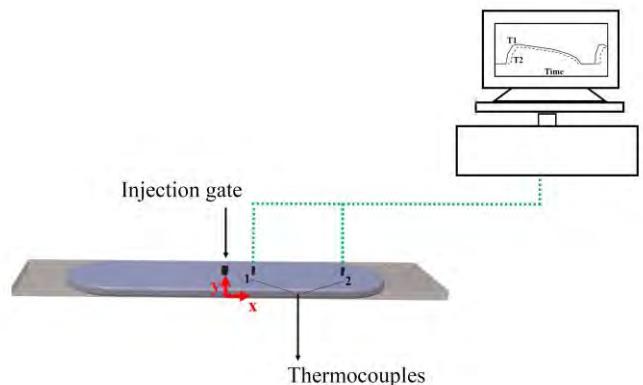

Figure 5. Schematic of the experimental setup.

TABLE I. BLOCKING TIME COMPARISION

$A_2, -\theta^*$	Blocking Time		
	Experiments	Present work	Chen [14]
[0.19, 0.08]	0.725±0.10	0.836	0.248
[0.21, 0.09]	0.907±0.10	0.915	0.215
[0.28, 0.11]	0.915±0.10	0.791	0.284

#### IV. CONCLUSIONS

Through developing a semi-analytical model, we have studied the residual layer that appear in the injection molding process. We have assumed that the geometry is full of the fluid when the molten polymer is injected to the cavity. We have relied on the Cross WLF to predict the rheological properties of the polymer. We have followed two scenarios when the momentum equation: Scenario A: constant mass flux; Scenario B: constant imposed pressure. The model is able to predict the blocking time of the cavity in the constant imposed pressure condition and there is a good agreement between the results of the model and experiments. Based on the developed model the residual layer disappears completely in the filling process if the imposed pressure increases several orders of magnitude in scenario A. However, this pressure is much higher than the pressure that is typically used in industrial cases.

#### ACKNOWLEDGMENT

This research has been carried out at Université Laval, supported financially by the NSERC Engage grant. The authors acknowledge Husky injection molding systems for the support of this work.

**Abstract**— In this paper, the displacement flow of a viscoplastic fluid by a non-Newtonian fluid in a vertical annulus is experimentally studied. The two fluids have a very small density difference. The light displaced fluid is placed below the heavy displacing fluid. Buoyancy, the imposed flow velocity and the annulus motion are the important flow parameters. In regard to the annulus motion, two scenarios are considered: first, the annulus is stationary; Second, the annulus slowly reciprocates with an amplitude of 100 mm and the frequency of 0.1 Hz. Our experimental results demonstrate that the displacement flow efficiency increases significantly when the annulus is in motion.

**Keywords-** *Miscible displacement flows; Non-Newtonian; Moving geometry; Annulus*

## I. INTRODUCTION

Primary cementing is a key operation in the construction of oil&gas wells. This operation is executed in oil&gas wells for a number of reasons, such as providing a mechanical support for the well, preventing water penetration into the well, protecting the casing from corrosive materials, to name a few. Failure in primary cementing may result in a decrease in production [1] and/or environmental consequences.

Removal of drilling mud from the annulus and its replacement with cement slurry is the foundation of the primary cementing process. The efficiency of the process depends on how successfully cement is able to displace mud out the flow geometry (i.e., an annulus). Therefore, to improve the process, displacement flows need to be studied [2].

There is currently no robust method to fully and completely displace the drilling mud in the casing and more importantly in the annulus section of the well. Recently, in the industrial setting it is becoming more common to use certain movements of the casing to improve the displacement. The current casing movements are slow reciprocation and/or rotation, aiming to increase the displacement efficiency. There exist various types of casing heads and special adaptors which make the rotation and/or reciprocation of the casing possible. Typical casing

reciprocations are between 6-12 m over a few minutes and casing (or liner) rotations vary between 10-40 rpm. Although the precise effects of these movements are not known, they are thought to be able to break the gel strength of the drilling mud to finally mobilize the slowly moving and static mud in the annulus [3, 4, 5].

Displacement flows of primary cementing are hard to fully understand due to the presence of various parameters. For example, the parameters that describe the geometry (inclined pipe and annulus), the inclination angle, gravitational acceleration and the flow rate require at least eight dimensionless groups to describe the flow. Considering two-fluid displacement flows, this increases to 10-12 dimensionless groups [2]. Rheological properties of the fluids involved also further contribute to the complexity of the system [6, 7]. To date, several studies have been conducted on different aspects of displacement flows to gain insights crucial understanding. Miscible displacement flows of Newtonian fluids in uniform pipes have been studied in detail in an inclined pipe [8, 9], a stationary vertical pipe [10] and a moving pipe [11]. Displacement flows of non-Newtonian fluids have also been studied experimentally and numerically [12, 13, 14]. Buoyant miscible displacement flows in nearly-horizontal, inclined and vertical ducts have also received attention [15, 16, 17]. Annular displacement flows have been investigated in only a few studies [18, 19]. There are even fewer studies in literature which can be directly relevant to the displacement flows in moving geometries [7, 20]. To fill an obvious lack in the literature, in this novel work, we experimentally investigate the displacement of a viscoplastic fluid in a moving annulus. In addition to providing essential scientific knowledge, this work is also technically important as it considers for the first displacement flows in a moving annulus with moving parameters similar to those used in industrial settings.

## II. EXPERIMENTAL SETUP, PROCEDURES AND DETAILS

Our experiments were performed in a 270 cm long annulus. The inner cylinder had an outer diameter of 40 mm and the outer cylinder had a diameter of 50 mm, creating a gap of 5 mm between two cylinders. The cylinders were transparent

(plexiglass clear acrylic cylinders) and they positioned vertically. They system had a manual plastic socket-weld gradual On/Off gate valve located at 40 cm from the top end (see figure 1). The gate valve initially separated the two parts of the annulus setup and completely segregated the displacing and displaced fluids. The gate valve system was designed in a way that it could be manually opened at the beginning of each experiment. All the experiments were performed at room temperature. The displacement flow setup was held on a fixed platform and it was divided into two parts: fixed and mobile sections, which enabled us to investigate the displacement flow in a stationary and moving geometry. The fixed part of the annulus setup included the outer cylinder, the clear cube vessel and all connections above the gate valve. The mobile section contained a stepper motor connected to the inner cylinder to produce the reciprocation motion. The maximum amplitude and the maximum frequency of reciprocation motion could be 15 cm and 0.3 Hz, respectively. The LabVIEW was used to control all parameters. Initially, the lower part of the annulus was filled using a peristaltic pump with a Carbopol solution (light fluid or displaced fluid) colored with a small amount of ink (Fountain Pen India black ink) for visualization purposes. Light absorption calibrations were performed in usual fashion, for which the amount of 2 g of ink per one liter of liquid was found to be a reasonable trade-off. The upper part of the annulus, above the gate valve, was filled with displacing fluid (heavy fluid). The densities of our experimental fluids were measured by a high-precision density meter (Anton Paar DMA 35). The viscosity and the yield stress of the solutions were measured in usual fashion, using AR-G2 TA Instrument digital controlled shear stress-shear rate rheometer. The maximum error in measurement of viscosity was 5%. To avoid pump disturbances and ensure a smooth steady inflow, the displacing upper fluid was fed by gravity from a large elevated tank filled with the displacing fluid. The flow rate was controlled by a needle valve and it was measured by a flow meter (Omega FTB 421, low flow plastic turbine), located downstream of the annulus setup. At the start of each experiment, the gate valve was opened and the displacement process started. Images of the displacement flow were recorded using a high-speed camera (Basler acA2040, with 4096 gray-scale levels) covering around 120 cm below the gate valve and they were subsequently post-processed using in-house Matlab codes, to quantify different aspects of the flow. To enhance quality of the images, the annulus setup was back-lit using Light-Emitting Diode (LED) strips. In addition, to improve light homogeneity, a diffusive layer was placed between the annulus setup and the LED strips.

Figure 1. Real and schematic views of experimental annulus setup.

### III. RESULTS AND DISCUSSIONS

The experiments were performed at a fixed density difference and at a small Atwood number ( $At = \frac{\hat{\rho}_H - \hat{\rho}}{\hat{\rho} + \hat{\rho}_L} = 0.0005$ ).  $\hat{\rho}_H$  and  $\hat{\rho}_L$  represent the densities of the displacing and displaced fluids, respectively. The displaced fluid was a Carbopol solution as a viscoplastic fluid with a 1.4 Pa yield stress. The displacing fluid was a Xanthan solution. Carbopol and Xanthan compositions and determined parameters from rheological measurements, assuming the Herschel-Bulkley model (Eq. 1), and power law model (Eq. 2) are listed in Table 1, respectively.

$$\hat{\tau} = \hat{\tau}_Y + \hat{\kappa}\hat{\gamma}^n. \quad (1)$$

$$\hat{\tau} = \hat{\kappa}\hat{\gamma}^n. \quad (2)$$

TABLE I. RHEOLOGICAL MEASUREMENTS FOR CARBOPOL & XANTHAN

Rheological measurements for Carbopol composition			
	Consistency	Power-law index	Yield stress
	$\hat{\kappa}(\text{Pa.s}^n)$	$n$	$\hat{\tau}_Y (\text{Pa})$
Carbopol 0.07 % (wt/wt)	1.34	0.45	1.4
Xanthan 0.25 % (wt/wt)	0.81	0.31	-----

The Herschel-Bulkley and power law models are appropriate rheological models that describes the shear behavior of the Carbopol gel and Xanthan solutions, respectively. Figure 2 shows an example of the rheometer flow curve for our Carbopol solution, in which the Herschel-Bulkley model is fitted to the datapoint.

To study the effect of the reciprocation motion on the displacement flow, the annulus setup was used to impose a reciprocation motion of 100 mm at a small frequency (0.1 Hz).

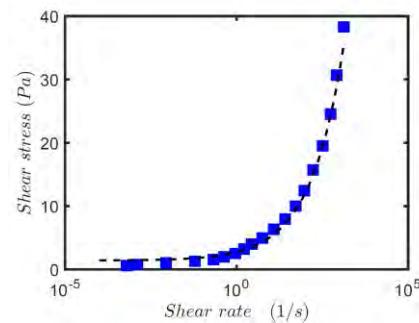

Figure 2. Rheological results for low concentration of the Carbopol solution. The dashed line indicates the Herschel-Bulkley model parameters fitted to the data.

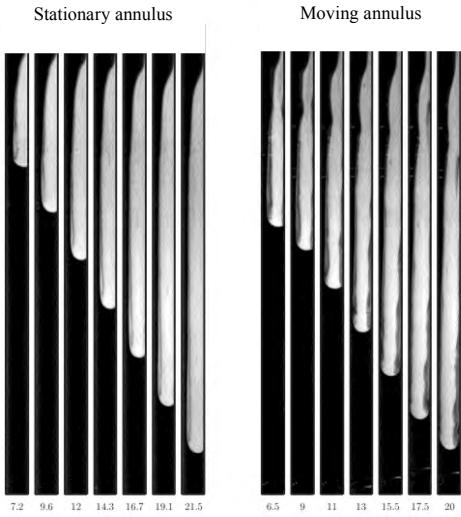

Figure 3. Sequence of images showing the displacement flow in a stationary and moving geometry (with a frequency of 0.1 Hz over 100 mm amplitude with respect to vertical). The field of view is  $46 \times 1200 \text{ mm}^2$  right below the gate valve. From left to right, the results of stationary and moving geometry are shown at  $\hat{V}_0 \approx 14(\text{mm/s})$ . The experimental times in each image sequence panel are provided in second (s), below each snapshot.

Figure 3 shows examples of our annular displacement flow results. This figure (left side) shows a sequence of images of a flow in stationary annulus at a low imposed flow rate, i.e.,  $\hat{V}_0 = 13.74(\text{mm/s})$ . As time grows, the heavy fluid displaces the light fluid in the downward direction and there is not much mixing between the two fluids. In addition, there is a static residual layer of the Carbopol solution on the wall. The same behavior is observed in figure 3 (right side) and it shows that the displacement process is not as efficient as the case without motion at short time. However, it should be mentioned that the story is different at extended times.

Figure 4 shows a sequence of experimental images with the same parameters of figure 3 but for an extended time. This figure indicates the effects of a moving geometry on the flow at longer times. It is obvious that the static residual layer is evidently stable and the amount of the Carbopol solution remains unchanged for the stationary geometry (figure 4). Figure 4 (right side) shows that by adding a reciprocation motion, the overall displacement improves: the amount of the Carbopol displaced by Xanthan solution is increased. In fact, the reciprocating motion of the inner cylinder is able to remove the static residual layers of the displaced phase, in the downward direction. Due to the shear exerted by the inner wall motion, the reciprocation enhances the removal of Carbopol from the walls and consequently the displacement flow efficiency increases.

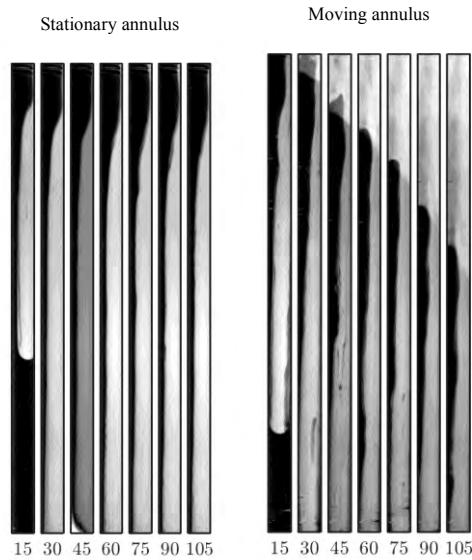

Figure 4. Sequence of images showing the displacement flow in a stationary and moving geometry (with a frequency of 0.1 Hz over 100 mm amplitude with respect to vertical) at long time. The field of view is  $46 \times 1200 \text{ mm}^2$  right below the gate valve. From left to right, the results of stationary and moving geometry are shown at  $\hat{V}_0 \approx 14(\text{mm/s})$ . The experimental times in each image sequence panel are provided in second (s), below each snapshot.

To explain this feature more quantitatively, it is necessary to introduce the depth-averaged concentration profiles of our displacements (shown by C in the following figures). Figure 5 shows an example of the evolution of the average concentration profile with time and streamwise location. Note that the experimental snapshots are calibrated between 0 (dark displaced fluid) and 1 (transparent displacing fluid). Therefore, in these diagrams, when the concentration value is around 1, the displacement is complete and there is no layer of the displaced fluid on the wall. On the other hand, when the concentration value is smaller than 1 a layer of the Carbopol solution remains on the wall.

There are interesting results delivered through analyzing depth-averaged concentration diagrams. First, the depth-averaged concentration profiles show the displacement flow is not complete and a layer of the displaced fluid remains on the wall at all times. Second at short times, the motion does not seem to affect the displacement efficiency.

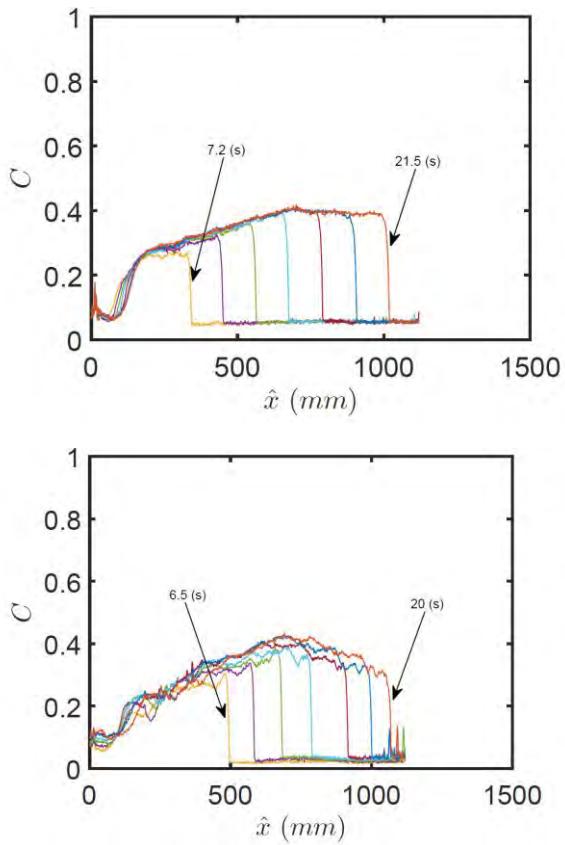

Figure 5. Evolution of the depth-averaged concentration field with time  $\hat{t}$ , and streamwise location,  $\hat{x}$  measured from the gate valve. From top to bottom, the geometry is stationary ( $\hat{t}=[7.2, 9.6, 12, 14.3, 16.7, 19.1, 21.5]$ (s)) and moving ( $\hat{t}=[6.5, 9, 11, 13, 15.5, 17.5, 20]$ (s)), respectively.

To give a global vision of the displacement efficiency at longer times, the depth-averaged concentration diagrams with the same parameters are presented in figure 6. It can be seen that when the Carbopol solution is displaced by the Xanthan solution in the moving geometry, the amount of Carbopol layer on the wall decreases, significantly. In the stationary geometry of figure 6 (top), the concentration values are approximately below 0.5 and all profiles nearly collapse. Therefore, as time grows, the efficiency of the displacement flow does not change. However, in the moving geometry of figure 6 (bottom) the concentration value is under 0.8. Therefore, the amount of the Carbopol solution on the wall decreases significantly and the displacement efficiency increases at an extended time.

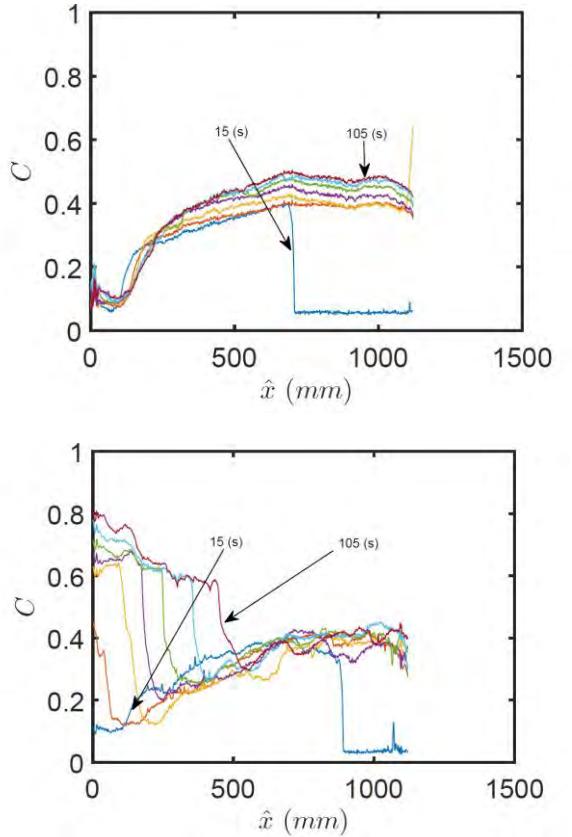

Figure 6. Evolution of the depth-averaged concentration field with time  $\hat{t}=[15, 30, 45, 60, 75, 90, 105]$ (s), and streamwise location,  $\hat{x}$  measured from the gate valve. From top to bottom, the geometry is stationary and moving, respectively.

#### IV. CONCLUSION

We experimentally studied miscible displacement flows in a long, vertical moving annulus. The experimental fluids were Xanthan solution (displacing fluid) and non-Newtonian viscoplastic (displaced fluid) and they had a very small density difference. The main finding was that the displacement flow efficiency was a function of the geometry motion. In the cases studied, the displacement flow in the moving annulus (reciprocation motion) was more efficient in comparison to the stationary annulus.

**Abstract**— An engineering model evaluates the effect of produced water in a production tubing on the reduction of asphaltene deposition on the tube (pipe) wall. We rely on an industrial hypothesis that droplets colliding with the pipe partially prevent the deposition of the asphaltene particles on the wall surface. First, we use a population balance model to calculate the droplet size evolution along a production tubing. Then, we study the fraction of the pipe wall surface dynamically coated by water droplets. To do so, we consider the wall bombardment by droplets that fluctuate in a turbulent flow. The results demonstrate that the dynamically coated area by droplets increases gradually (max by order of  $10^{-4}$ ), the effects of which on asphaltene deposition is negligible.

**Keywords**-Asphaltene precipitation; droplet breakup; population balance model

## I. INTRODUCTION

The interaction between asphaltene particles and droplets is an important problem of flow assurance in the oil industry. Asphaltenes are molecular substances, which compose crude oil along with resins, aromatic hydrocarbons and saturated hydrocarbons such as alkanes that are not soluble in straight-chain solvents. Asphaltenes precipitate from a hydrocarbon fluid when the local pressure drops below the so-called asphaltene onset precipitation pressure. Further downstream pressure decrease is accompanied with further precipitation. Complex deposition phenomenon consists of different processes. Precipitated particles interact with each other, grow due to agglomeration, are transported to the wall and stick to its surface with some probability [1, 2]. Asphaltene deposition represents a significant concern only for a vertical production tubing. Here, a substantial pressure drop required for intense asphaltene precipitation is obtained due to hydrostatic pressure difference. Asphaltene deposition has received significant attention in the literature [3, 4]. Numerous articles have considered the problem of asphaltene deposition in reservoirs [5, 6], in pipelines [1, 2] and in the Couette flows [1]. Some of published asphaltene deposition models demonstrated a reasonable agreement with experimental data. It is important to emphasize that those models were developed for a single-phase

(hydrocarbon) flow, whereas, in practice, water is usually produced along with oil. The effects of droplets on the asphaltene deposition in turbulent flow are an unanswered question due to the physical complexity of the problem.

## II. MODELING

### A. Basic concept of accounting for an effect of dispersed water on asphaltene deposition

Figure 1 illustrates asphaltene deposition on the tubing wall in the presence of dispersed water. The smaller particles and the larger spheres denote the asphaltene aggregates and the water droplets, respectively. According to the comprehensive approach to asphaltene deposition modeling, this phenomenon is a complex process, which consists of the following components: 1) precipitation of primary asphaltene particles; 2) particle agglomeration; 3) particle transport to the pipe wall; 4) interaction of particles with the wall. Eskin et al. [1,2] showed that the asphaltene deposition rate is a strong function of the particle size. Therefore, modeling of the particle size distribution evolution along a production tubing is a key deposition model element. Brownian motion as well as turbulent diffusion (dispersion) govern both agglomeration and deposition of asphaltene particles. However, Eskin et al. [2] showed that turbulent diffusion can be neglected because only very small submicron particles are able to deposit on the pipe wall.

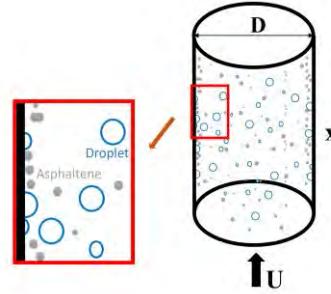

Figure 1. Diagram illustrating asphaltene deposition in a pipe in presence of asphaltene particles and water droplets.

Here, we consider the effect of water on asphaltene deposition. Water droplets absorb asphaltene molecules. It leads to a modification of droplet surfaces causing coalescence suppression, i.e., droplet stabilization. Non-coalescing droplets are intensely fragmented by turbulence and can reach rather small sizes. At high water holdups ( $\sim 50\%$ ), the droplet specific surface may reach very high values. For example, this surface can be up to 3 orders of magnitude larger than the corresponding specific surface of the pipe wall. However, a simple analysis shows the amount of asphaltene absorbed by droplets is small. Indeed, absorbed asphaltene molecules form a monolayer on a droplet surface. The thickness of this monolayer is approximately equal to the diameter of an asphaltene molecule, which does not exceed a few nanometers [3]. Because the monolayer thickness is so small, the total volume concentration of asphaltenes absorbed on droplets is always much lower ( $< 10^{-4}$ ) than the volume concentration of asphaltenes in a fluid, which can cause a significant deposition rate ( $\sim 10^{-2}$ ) [3]. Therefore, an effect of water on asphaltene deposition is limited to only droplets-pipe wall interactions. Droplets, driven by turbulence eddies, collide with the wall (deposit surface) and bounce from it. In the course of a droplet-wall interaction, a deformed droplet coats some surface area of the wall. This area can vary during the bouncing process. Evidently, the area coated by a droplet is unavailable for depositing asphaltene particles. Thus, the problem of accounting for an effect of water on asphaltene deposition can be reduced to determining the mean fraction of the pipe wall surface that is dynamically coated with water droplets. Then, the deposition flux in the presence of dispersed water is calculated as:  $a_v = q_a(1-S)$ , where,  $q_a$  is the asphaltene deposition flux and  $S$  is the mean fraction of the pipe wall surface dynamically coated by water droplets. To determine the parameter  $S$  we need to evaluate the droplet size distribution in a pipe flow and consider a process of droplet interaction with the pipe wall (deposit surface).

### B. Droplet dispersion in a pipe flow

We have relied on the population balance model (PBM) in order to predict the droplet size evolution along the time. A disbalance between the viscous stress of the fluid inside the droplets, the surface tension of the droplets and the external stress causes droplet breakup from the continuous phase. The competition of these stresses destroys the surface of the droplets and droplet breakup occurs. A transient diameter based on PBM holding the breakage and the coalescence terms can be written as follows in turbulent uniform conditions [7,8]:

$$\frac{df_i}{dt} = -B_D(i,t) + B_B(i,t) - C_D(i,t) + C_B(i,t), \quad (1)$$

where  $f_i$  is the mass based distribution of the  $i_{th}$  droplet.  $B_D, B_B, C_D$  and  $C_B$  are the breakage death, the breakage birth, the coalescence death and the coalescence birth of droplets respectively in the PBM model. The breakage death has been defined as:

$$B_D(i,t) = b(i)f(i,t). \quad (2)$$

The breakage frequency function  $b(i)$  and daughter size distribution function are investigated by different methods (e.g., Coulaloglou and Tavlarides [9]). The breakage birth is calculated as:

$$B_B(i,t) = v(i) \int_{d_i}^{d_{max}} h(i,j) b(j) \frac{f(j,t)}{v(j)} d(d_j), \quad (3)$$

where  $v(i)$  is the volume of the  $i_{th}$  droplet and daughter size redistribution function  $h(i,j)$  is calculated by Coulaloglou and Tavlarides [9]. The coalescence birth term is:

$$C_B(i,t) = \frac{d^2(i)v(i)}{2} \times \frac{C(\left[d_i^3 - d_j^3\right]^{1/3}, d_j) f(i,t)}{\left[d_i^3 - d_j^3\right]^{2/3} \rho_d v(j)} \frac{f(\left[d_i^3 - d_j^3\right]^{1/3}, t)}{v(i) - v(j)} d(d_j). \quad (4)$$

The coalescence death term is [10]:

$$C_D(i,t) = f(i,t) \int_{d_{min}}^{(d_{max}^3 - d_i^3)^{1/3}} C(d_i, d_j) \frac{f(j,t)}{\rho_d v(j)} d(d_j). \quad (5)$$

Figure 2 shows the evolution of pure droplet with time in oil,  $\rho_d = 965.3 \text{ kg/m}^3$ ,  $\mu_d = 0.3 \text{ mPa/s}$  and liquid-liquid surface tension is  $0.0056 \text{ N/m}$ . We have considered the mono-dispersed initial condition to solve PBM. The initial mass fraction of droplets is  $\phi=0.1$  (assuming a very diluted system to neglect the coalescence terms) and the initial droplet size is  $d_d = 150 \mu\text{m}$  ( $V_{i+1}/V_i = 0.5$  and  $i=1:20$ ). The results show that the droplet size is alleviated with time. Figure 2d illustrates the evolution of the mean droplet size with time in a log-log scale, showing that there are three different regions in the droplet breakage with time in case of initially mono-dispersed droplets.

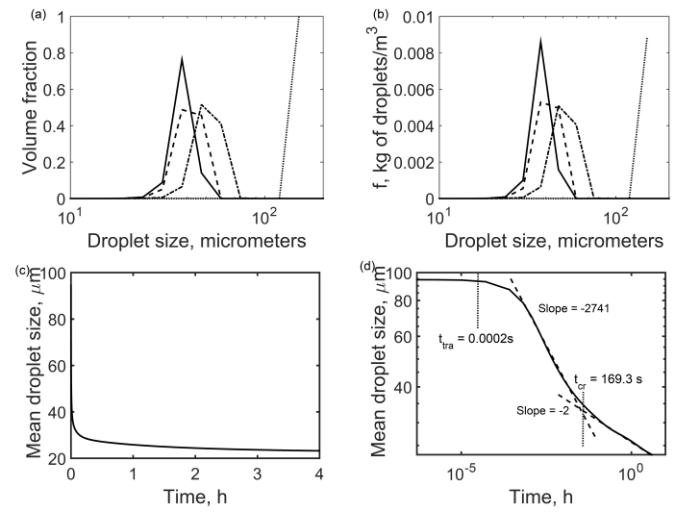

Figure 2. Size evolution of pure droplet with time in turbulent system. Subfigures in the top row show the volume fraction and mass distribution function with time from left to right (the breakage time is 0h, 0.1h, 1.5h and 4.0h in the dotted line, dash-dotted line, dashed line and solid line respectively). The bottom row shows the average droplet size with time in linear and logarithmic axis. The continuous and dispersed phases are considered as oil and water respectively.

The mean droplet size does vary much with time in the first region before reaching the transition time ( $t_{tra}$ ), which is in the order of  $10^{-4}$ s. The transition time represents the time required for the imbalance between the viscous stress of the fluid inside the droplet and surface tension to break the droplets considering the mono dispersed droplet distribution as an initial condition. Another important time is the critical time ( $t_{cr}$ ) which is quantified by the inflection point of the mean droplet size and it demonstrates the time when the droplet breakup mechanism is changed. Rapid size reduction implies that eddies have more effects on the turbulent mechanism of droplet breakup due to the large size of droplets (first zone). Brownian motion has more effects on collision of droplets in the case of the small droplet size; therefore, the rate of size reduction decreases in tiny droplets. The coalescence terms do not have a significant effect on the PBM in diluted systems because the coalescence terms are 5 orders of magnitude smaller than the breakup terms. Solsvik et al. [8] have stated the coalescence terms are negligible compared to droplet breakup in a dilute dispersed system. The results of our simulation confirm this statement.

### C. Droplet deposition on the wall

To evaluate the cumulative wall coating effect caused by multiple droplets-wall interactions, a collision of a single droplet with the wall should be considered. In practice, a pipe wall is often characterized by a rather significant roughness. This circumstance complicates the interaction analysis. However, a reasonable estimate of the interaction phenomenon could be obtained assuming that the wall is smooth. The larger the ratio between the droplet diameter and the wall roughness, the closer this is to reality. The only significant mechanism causing a droplet-wall collision is a droplet fluctuation caused by a turbulent eddy. Following Kuboi [11], we assume that droplet fluctuations are mainly controlled by eddies, whose scales are equal to droplet sizes. Usually, the droplet fluctuation is relatively low. Therefore, we assume that the droplet deformation during the interaction process is small. Obviously, after a collision with the wall the droplet should ricochet. Thus, the droplet-wall interaction process consists of the two stages: droplet compression (deformation) and relaxation (shape restoration). Due to the smallness of droplet deformation, we do not consider a hydrodynamic flow field inside the droplet at the compression stage. Then, we can formulate the momentum equation for the droplet-wall interaction, assuming that all fluid elements inside a droplet have the same velocity (see Figure 3). Also, we make additional assumptions to derive the momentum equation for a droplet interacting with the wall. We assume that the droplet interacting with the wall maintains a shape of a sphere with a cut segment. The volume of this segment is neglected due to the assumed deformation smallness. We also assume that during the compression stage, the wall reaction force acting on a droplet is comprised of the two components. First, a hydrodynamic reaction force appears because a droplet interacting with the wall loses momentum component normal

to the wall. We evaluate this force by considering an interaction of an imaginary jet of radius  $a$ . We consider that this force is absent during the relaxation stage. The second component of the reaction force is the capillary force applied also to the same droplet wall contact area. For the sake of simplicity, we neglect the drag force acting on the droplet during its interaction with the wall. Because a turbulent eddy transporting the droplet is also decelerated in the wall vicinity, this assumption should not significantly affect the droplet-wall interaction process. Thus, the momentum conservation equation for a droplet of the  $i$ -th size fraction interacting with the wall during the compression stage is:

$$(\rho_d + \frac{1}{2} \rho_o) V_i \frac{dV_{iy}}{dt} = -\rho_d V_{iy} \pi a_i^2 - \frac{2\sigma}{R_i} \pi a_i . \quad (6)$$

$V_{iy}$  is the velocity component normal to the wall for the  $i$ -th size fraction droplet. In this equation, the left-hand side represents the inertial force that is equilibrated by the forces expressed by the terms on the right-hand side, the hydrodynamics reaction force and the capillary force, respectively. Let us formulate equation 5 in the dimensionless form as follows:

$$\frac{d \tilde{y}_i}{d \tau^2} = -\frac{3}{4} \frac{1}{1+s} (1 - \tilde{y}_i^2) \left( \frac{d\tilde{y}_i}{d\tau} \right)^2 + 1, \quad (7)$$

where  $\tilde{y}_i = y_i / R_i$ ,  $\tilde{V}_i = V_i / \Omega_i$ ,  $\Omega_i = \sqrt{2\sigma / \rho_d R_i}$  and  $s = \rho_o / 2\rho$ . This equation can be solved numerically considering  $\tau_i = 0$ ,  $\tilde{y}_i = 1$  and  $\frac{d\tilde{y}_i}{d\tau} = \tilde{V}_{iy0}$ . We assume that the fluid fluctuation velocity distribution is Maxwellian. In addition, we assume that a droplet exactly follows the fluid in a fluctuation motion. The root-mean-square fluid fluctuation velocity can be calculated by the following empirical correlation [1]:

$$\sqrt{\bar{V}_y^{2+}} = \frac{0.005 y^{+2}}{1 + 0.002923 y^{+2.128}}. \quad (8)$$

Here,  $\bar{V}_y^{2+} (\frac{d_i}{2})$  is the mean-square fluid fluctuation velocity at the moment of touching the wall.  $y^+ = y / \delta^+$  is the normalized distance to the wall.

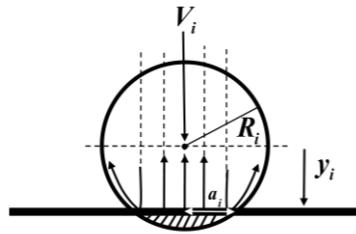

Figure 3. The schematic of the droplet interacting with the wall.

$\delta^+$  is the wall layer thickness. Then, it is considered that the initial value of normal to the wall droplet fluctuation velocity is equal to the most probable fluid fluctuation velocity at  $y = 0.5d_i$ . Equation 6 is easily integrated up to the moment when  $\tilde{V}_{iy} = 0$  indicating the end of the compression stage. The specific pipe wall area dynamically covered by droplets of the  $i$ -th size fraction due to their multiple collisions with the wall is:  $S_i = fr_i \zeta_i A_i$ , where  $A_i$  is the mean droplet-wall contact area during a single collision;  $\zeta_i$  is the mean droplet wall contact time;  $fr_i$  is the frequency of droplet-wall collisions. The frequency of droplet-wall collisions per surface area unit is determined, assuming the Maxwellian droplet fluctuation velocity distribution. The total specific area (per unit pipe surface area) covered by droplets is calculated as:

$$S = \sum_{i=1}^m fr_i \left[ \underbrace{\int_{R_i}^{y_{if}} \pi(R_i^2 - y_i^2) \frac{dy_i}{V_{iy}}}_{\text{compression}} + \underbrace{\int_{y_{if}}^{R_i} \pi(R_i^2 - y_i^2) \frac{dy_i}{V_{iy}}}_{\text{relaxation}} \right] \quad (9)$$

The problem of accounting for the effect of water on asphaltene deposition can be reduced to determining the mean fraction of the pipe wall surface that is dynamically coated with water droplets. Then, the deposit flux in the presence of dispersed water is calculated as:  $q = q_a(1-S)$  which  $q_a$  is the asphaltene deposition flux and  $S$  is the mean fraction of the pipe wall surface dynamically coated by water droplets.

Let us illustrate the results of the model developed by a few examples. We consider a dispersion of water in oil flowing in a production tubing of the diameter  $D = 0.0625$  m with the mean velocity  $U$ . The water holdup is  $\phi = 0.1$ . The oil viscosity and density are  $\mu_o = 1.3$  mPa/s and  $\rho_o = 760$  kg/m<sup>3</sup>, respectively. The interfacial tension is 0.0025 N/m. The steady-state droplet size distribution, calculated by the dispersion model developed, is employed for this analysis. Figure 4 illustrates the droplet-wall interaction process. Figure 4a shows that how the velocities of droplets of different sizes change during the droplet compression stage.

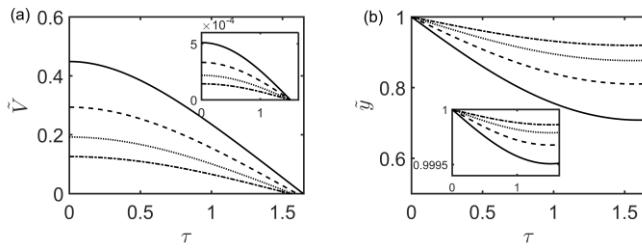

Figure 4. The dimensionless velocity (a) and the dimensionless distance from the droplet center to the wall surface (b) versus dimensionless time during the droplet compression stage. The droplet size decreases for the line, dashed line, dotted line and dash-dotted line, respectively. The results are shown for the four first larger droplets and the insets show the results of the four last small droplets.

Figure 4b shows how the distance from the droplet center to the wall changes during the compression stage. The largest deformation is observed for the droplet of the largest size. However, even in this case, the maximum deformation value does not exceed 30% of the droplet radius. Thus, the assumption on the small droplet deformation accepted for modeling is satisfactory. Moreover, the fraction of larger droplets in the entire population is relatively small, whereas the deformation rapidly decreases with a reduction in droplet size.

For the same mixture, we also calculate the specific pipe surface, dynamically coated by droplets, for the different mean flow velocities  $U = 0.8, 1, 1.5$  and  $2$  m/s. Droplets are initially assumed to be monodispersed with the size  $d_o = 150\mu\text{m}$ . Figure 5 illustrates the distribution of the sought parameters along a tubing of 4 km long. Only a negligible fraction of the pipe surface is dynamically coated with droplets. The droplet sizes decrease along a tubing due to their fragmentation. The droplet size reduction leads to an increase in the droplet number concentration causing an increase in the droplet-pipe wall collision frequency. As a result, the pipe surface area, coated with droplets, slowly increases along the tubing. In addition, the droplet coated surface expectedly increases with an increase in the mean flow velocity because of the two effects. First, droplet sizes decrease with an increase in the mean flow velocity due to a corresponding increase in the turbulence energy dissipation rate. Second, a higher mean flow velocity results in a larger droplet fluctuation velocity. An increase in the fluctuation velocity causes an enhancement in frequency of droplet-wall collisions as well as in stronger droplet deformations. These factors lead to an increase in a droplet-wall contact area. A significant increase in the water holdup (see Figure 5b) leads to a relatively slight increase in the specific wall area dynamically coated by droplets. An increase in the holdup causes a reduction in the droplet breakup rate. Therefore, an effect of water holdup on the pipe area, dynamically coated by droplets, is relatively small.

The major outcome of our modeling is a demonstration that the effect of water dispersed in oil on the process of asphaltene deposition in a production tubing is negligible.

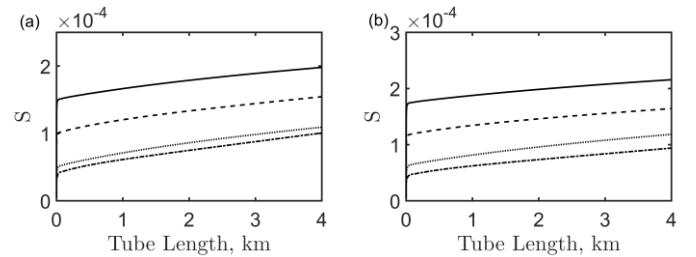

Figure 5. Distribution of the specific pipe wall area covered by droplets, along the pipe. Flow velocities:  $U = 0.8, 1.0, 1.5, 2.0$  m/s corresponding to the dash-dotted line, dotted line, dashed line and line, respectively. Water hold up:  $\phi = 0.1$  (a) and  $0.4$  (b).

### III. CONCLUSIONS

An engineering model was developed to estimate the pipe wall surface area dynamically coated by droplets, which collide with the wall due to their fluctuations in a turbulent flow. An evolution of the droplet size distribution along production tubing was modeled by a population balance equation. A droplet-wall collision process was modeled assuming that a droplet deformation in a single collision was small. It was also assumed that droplets follow the fluid in fluctuation motion caused by turbulence. The frequencies of the droplet-wall collisions were calculated assuming that the droplet fluctuation velocity distribution was Maxwellian. Calculations of the specific pipe surface area dynamically coated with water droplets, at different mean flow velocities and water holdups, showed that the coated specific area remains small and, therefore, the effect of produced water on asphaltene deposition can be ignored in practical computations of asphaltene deposition.

**Abstract**— In this paper, the equations of motion for a two-dimensional (2-D) wing encountering a gust are presented. The wing has two degrees of freedom, i.e. pitch and plunge, and its motion is restrained by nonlinear translational and rotational springs. Two different stiffness nonlinearities are examined: (i) cubic and (ii) free play. For given system parameters, the responses of the nonlinear system to the sharp-edged and 1-cosine gust profiles are obtained at different flow velocities and compared to the time response of the system with no gust input.

**Keywords:** *aeroelasticity; gust response; cubic nonlinearity; free-play nonlinearity; flutter analysis*

## I. INTRODUCTION

Aeroelasticity is an interdisciplinary field of study dealing with interactions between inertia, aerodynamic and elastic forces. Classical theories in aeroelasticity assume linear aerodynamics and structural dynamics resulting in a set of linear equations. These equations can be fairly easily solved in time or frequency domain and used for examining the aircraft stability and response to external excitation. However, linear aerodynamic theories start to break down at high airspeed. Flow separation and shock oscillations may also introduce aerodynamic nonlinearities. Moreover, structural nonlinearities may arise from, for example, large deformations, material behavior, worn hinges of control surfaces, and loose control linkages [1, 2].

Woolston et al. may be the first researchers that investigated the effects of structural nonlinearities on the flutter of a wing [1]. Two different wing models were studied: a wing capable of bending and twisting (i.e. two-degree-of-freedom (2-DOF) system) and, also, a wing with a control surface (i.e. 3-DOF system). They considered structural nonlinearities as concentrated in the torsional stiffness. Three different types of nonlinear springs, namely flat spot (representing free play), hysteresis, and cubic were examined. They found that there is a strong connection between the stability of a nonlinear system and the initial conditions - in many cases the flutter speed was decreased as the initial disturbance was increased.

A comprehensive review of different types of structural and aerodynamic nonlinearities encountered in aeronautical engineering was conducted by Lee et al. [2]. They discussed several techniques, such as finite difference and describing function, for solving equations with structural nonlinearities. They found that even a 2-DOF system with a single nonlinearity

in the pitch degree of freedom may show a complex dynamical behavior. For example, they showed that a system with a free-play nonlinearity may undergo period-1, period-2, and period-4 limit-cycle oscillations (LCO), as well as, chaotic motion, depending on the airspeed. For a more recent and quite shorter review of nonlinear aeroelasticity, the reader is referred to [3].

Several researchers have studied the response of a lifting surface to a time-dependent external excitation. For example, Poirel and Price investigated the effect of longitudinal atmospheric turbulence on the dynamics of an airfoil with a hardening cubic structural nonlinearity in pitch [4]. They found that flutter occurred at a lower velocity for the excited case than the so-called non-excited one, whereas the onset of LCO occurred at a higher velocity. Marzocca et al. investigated the aeroelastic response to a time-dependent external excitation of a 2-D rigid/elastic-lifting surface in incompressible flow field, featuring plunging-pitching coupled motion [5]. Haddadpour et al. examined the effects of the sharp-edged gust on the dynamics of a flexible high-aspect ratio wing [6]. In their model, they used linear structural dynamics and linear quasi-steady aerodynamics.

In reality, almost all lifting surfaces involve some sort of structural nonlinearity, and they may also encounter with atmospheric turbulence during a normal flight. Nevertheless, very few studies on the nonlinear aeroelastic response to a time-dependent excitation can be found in the body of the literature. This is, in fact, the principal objective of this paper, namely studying the effects of a time-dependent excitation, such as sharp-edge and 1-cosine gusts on the dynamics and stability of a 2-DOF typical airfoil section with structural nonlinearities.

## II. NONLINEAR AEROELASTIC MODEL WITH GUST EXCITATION

### A. Governing Equations Including the Gust Input

Fig. 1 shows the cross-section of a 2-D rigid wing with degrees of freedom in the plunge and pitch directions. The plunge displacement is measured from the elastic axis and is represented by  $h$  (positive downward);  $\alpha$  is the pitch angle about the elastic axis (positive nose up). The elastic axis is located at a distance  $ab$  from the mid-chord, while the mass center is located at a distance  $x_c b$  from the elastic axis,  $b$  being the semi-chord. The wing is supported by a translational and a rotational spring, attached to the elastic axis, which generally have a nonlinear stiffness.

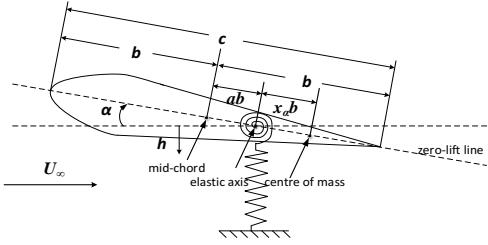

Figure 1. Schematic showing geometry of the wing section.

Here, we follow formulations presented in [2, 5]. The dimensionless aeroelastic equations featuring coupled plunging-pitching motion of a typical airfoil section exposed to a gust input are expressed as

$$\xi'' + x_\alpha \alpha'' + 2\zeta_\xi \frac{\bar{\omega}}{U^*} \xi' + \left(\frac{\bar{\omega}}{U^*}\right)^2 G(\xi) - l_a(\tau) = l_g(\tau), \quad (1)$$

$$\left(\frac{x_\alpha}{r_\alpha}\right) \xi'' + \alpha'' + 2\zeta_\alpha \frac{1}{U^*} \alpha' + \frac{1}{U^{*2}} M(\alpha) - m_a(\tau) = m_g(\tau), \quad (2)$$

where  $\xi = h/b$  is the dimensionless plunge displacement, and  $\zeta_\xi$  and  $\zeta_\alpha$  are, respectively, viscous damping ratios in pitch and plunge;  $U^* = U_\infty/b\omega_\alpha$  is the dimensionless velocity, and  $\bar{\omega} = \omega_\xi/\omega_\alpha$  is the frequency ratio,  $U_\infty$  being the freestream velocity,  $\omega_\xi$  and  $\omega_\alpha$  also being natural frequencies in pitch and plunge, respectively; also,  $l_a(\tau)$  and  $m_a(\tau)$  are the aerodynamic lift and pitching moment about the elastic axis, respectively, while  $l_g(\tau)$  and  $m_g(\tau)$  are the lift and moment about the elastic axis due to the gust;  $G(\xi)$  and  $M(\alpha)$  represent the nonlinear plunge and pitch structural stiffness terms, respectively; moreover,  $(\cdot)' \equiv \partial(\cdot)/\partial\tau$  denotes the time derivative with respect to dimensionless time  $\tau$ .

The aerodynamic lift  $l_a(\tau)$  and pitching moment  $m_a(\tau)$  may be expressed as

$$l_a(\tau) = -\frac{2}{\mu} \int_0^\infty \phi(\tau-\sigma) \left( \alpha' + \xi'' + \left(\frac{1}{2} - a\right) \alpha'' \right) d\sigma - \frac{1}{\mu} (\alpha' + \xi'' - a\alpha''), \quad (3)$$

$$m_a(\tau) = \frac{2}{\mu} \left(\frac{1}{2} + a\right) \int_0^\infty \phi(\tau-\sigma) \left( \alpha' + \xi'' + \left(\frac{1}{2} - a\right) \alpha'' \right) d\sigma + \frac{1}{r_\alpha^2 \mu} a(\xi'' - a\alpha'') - \frac{1}{r_\alpha^2 \mu} \left(\frac{1}{2} - a\right) \alpha' - \frac{1}{8} \frac{1}{r_\alpha^2 \mu} \alpha'', \quad (4)$$

where  $\mu = m/\pi\rho b^2$  is the mass ratio, and  $r_\alpha = I_\alpha/m b^2$  is the dimensionless radius of gyration;  $m$ ,  $\rho$ , and  $I_\alpha$  being, respectively, mass of the wing per unit span, air density, and mass moment of inertia per unit span. Also,  $\phi(\tau)$  is called the Wagner function and is given by

$$\phi(\tau) = 1 - A_1 e^{-b_1 \tau} - A_2 e^{-b_2 \tau}, \quad (5)$$

where the constants are  $A_1 = 0.165$ ,  $A_2 = 0.335$ ,  $b_1 = 0.0455$ ,  $b_2 = 0.3$ .

By considering  $w_G(\tau)$  as a gust variable velocity and using Duhamel's integral concept, the lift and pitching moment about the elastic axis due to the penetration into the gust,  $l_g(\tau)$  and  $m_g(\tau)$ , respectively, may be written as

$$l_g(\tau) = \frac{2}{\mu} \int_0^\tau \psi'(\tau-\sigma) \frac{w_G(\tau)}{U_\infty} d\sigma, \quad (6)$$

$$m_g(\tau) = \left(\frac{1}{2} + a\right) \frac{2}{r_\alpha^2 \mu} \int_0^\tau \psi'(\tau-\sigma) \frac{w_G(\tau)}{U_\infty} d\sigma, \quad (7)$$

where  $\psi(\tau)$  is called the Küssner function.

A widely-used approximation for Küssner's function is the following two-term exponential expression [2]:

$$\psi(\tau) = 1 - A_3 e^{-b_3 \tau} - A_4 e^{-b_4 \tau}, \quad (8)$$

where the constants are  $A_3 = 0.5$ ,  $A_4 = 0.5$ ,  $b_3 = 0.130$  and  $b_4 = 1$ .

In this paper, two different gust profiles, implying specific time variations of their velocity distribution, will be used. They are: (a) sharp-edged gust, and (b) 1-cosine gust. Their analytical expressions are:

$$\text{sharp-edged gust: } w_G(\tau) = H(\tau)w_0, \quad (9)$$

$$\begin{aligned} \text{1-cosine gust: } w_G(\tau) &= H(\tau) \frac{1}{2} w_0 \left(1 - \cos \frac{\pi \tau}{\tau_G}\right) \\ &- H(\tau - 2\tau_G) \frac{1}{2} w_0 \left(1 - \cos \frac{\pi \tau}{\tau_G}\right), \end{aligned} \quad (10)$$

where  $w_0$  is the gust maximum amplitude, and  $H(\tau)$  represents the Heaviside step function.

### B. State-space Equations

In order to deal with the integral terms in (3-4) and (6-7), we introduce six new variables or states as

$$\begin{aligned} w_1 &= \int_0^\tau e^{-b_1(\tau-\sigma)} \alpha(\sigma) d\sigma, & w_2 &= \int_0^\tau e^{-b_2(\tau-\sigma)} \alpha(\sigma) d\sigma, \\ w_3 &= \int_0^\tau e^{-b_1(\tau-\sigma)} \xi(\sigma) d\sigma, & w_4 &= \int_0^\tau e^{-b_2(\tau-\sigma)} \xi(\sigma) d\sigma, \\ w_5 &= \int_0^\tau e^{-b_3(\tau-\sigma)} \frac{w_G(\sigma)}{U_\infty} d\sigma, & w_6 &= \int_0^\tau e^{-b_4(\tau-\sigma)} \frac{w_G(\sigma)}{U_\infty} d\sigma. \end{aligned} \quad (11)$$

Using variables in (11), the aeroelastic equations (1-2) may be re-written as

$$\begin{aligned} c_0 \xi'' + c_1 \alpha'' + c_2 \xi' + c_3 \alpha' + c_4 \xi + c_5 \alpha + c_6 w_1 + c_7 w_2 \\ + c_8 w_3 + c_9 w_4 + c_{10} w_5 + c_{11} w_6 + \left(\frac{\bar{\omega}}{U^*}\right)^2 G(\xi) = f(\tau), \end{aligned} \quad (12)$$

$$\begin{aligned} d_0 \xi'' + d_1 \alpha'' + d_2 \xi' + d_3 \alpha' + d_4 \xi + d_5 \alpha + d_6 w_1 + d_7 w_2 \\ + d_8 w_3 + d_9 w_4 + d_{10} w_5 + d_{11} w_6 + \left(\frac{1}{U^*}\right)^2 M(\alpha) = g(\tau), \end{aligned} \quad (13)$$

where  $G(\xi)$  and  $M(\alpha)$  are nonlinear functions of  $\xi$  and  $\alpha$ , respectively.  $f(\tau)$  and  $g(\tau)$  are functions of initial conditions and terms in the Wagner function, which are given by:

$$\begin{aligned} f(\tau) &= \frac{2}{\mu} \left( \left(\frac{1}{2} - a\right) \alpha(0) + \xi(0) \right) (A_1 b_1 e^{-b_1 \tau} + A_2 b_2 e^{-b_2 \tau}), \\ g(\tau) &= -\frac{(1 + 2a)f(\tau)}{2r_\alpha^2}. \end{aligned} \quad (14)$$

The coefficients  $c_i$  ( $i = 0, \dots, 9$ ) and  $d_i$  ( $i = 0, \dots, 9$ ) in (12) and (13) were given in [2] and will not be repeated here for the sake of brevity; however,  $c_{10}$ ,  $c_{11}$ ,  $d_{10}$  and  $d_{11}$  are given as

$$c_{10} = -\frac{2}{\mu} A_3 b_3, c_{11} = -\frac{2}{\mu} A_4 b_4,$$

$$d_{10} = -\left(\frac{1}{2} + a\right) \frac{2}{r_\alpha^2 \mu} A_3 b_3, d_{11} = -\left(\frac{1}{2} + a\right) \frac{2}{r_\alpha^2 \mu} A_4 b_4. \quad (15)$$

After introducing a variable vector  $X = (x_1, x_2, \dots, x_{10})^T$  defined as

$$\begin{aligned} x_1 &= \alpha, x_2 = \alpha', x_3 = \xi, x_4 = \xi', x_5 = w_1, x_6 = w_2, \\ x_7 &= w_3, x_8 = w_4, x_9 = w_5, x_{10} = w_6. \end{aligned} \quad (16)$$

(12) and (13) can be written as a set of ten first-order ordinary differential equations.

### III. NUMERICAL EXAMPLES AND ANALYSIS

The dimensionless parameters of the linear system used in this paper are:  $a = -0.5$ ,  $\mu = 100$ ,  $x_\alpha = 0.25$ ,  $r_\alpha = 0.5$ ,  $\zeta_\alpha = \zeta_\xi = 0.0$ , and  $\bar{\omega} = 0.2$ . We set  $\alpha'(0) = \xi'(0) = \xi(0) = 0$ ,  $\alpha(0) = 1$  deg as the initial conditions. Using the eigenvalue solution method with the given parameters, we obtain the linear dimensionless flutter speed ( $U_L^*$ ) as 6.28, which agrees well with results in [2].

Since in this paper we consider nonlinearities only for the pitch DOF, plunging oscillations display very much expected features and are not worthy to be discussed here. Thus, throughout the paper, we only discuss the response in the pitching direction.

#### A. Gust Response with Cubic Nonlinearity

We consider a cubic nonlinearity in the structural stiffness for the pitch and a linear stiffness for the plunge degree of freedom. Thus, functions  $G(\xi)$  and  $M(\alpha)$  in (12) and (13), respectively, can be set to  $G(\xi) = \xi$  and  $M(\alpha) = \beta_1 \alpha + \beta_3 \alpha^3$ . First, we examined a system with a weak cubic nonlinearity, where  $\beta_1 = 1$  and  $\beta_3 = 10$ . Assuming a sharp-edged gust with  $w_0 = 10$  m/s, the response of the system was obtained at  $U^* = 6.27$  (not shown here because of space limitation). It was found that the oscillations gradually decay with time, and the system regains its static equilibrium. Thus, even a strong excitation at an airspeed very close to the linear flutter speed cannot change the stability of the system with a weak cubic nonlinearity.

Next, we consider a system with a strong cubic nonlinearity ( $\beta_1 = 0.01, \beta_3 = 10$ ) and keep other system parameters the same. The linear flutter speed for this system is  $U_L^* = 0.91$ . The response of the system to a sharp-edged gust and also a 1-cosine gust with the maximum amplitude of  $w_0 = 1$  m/s at  $U^* = 0.84$ ,  $U^* = U_L^* = 0.91$  and  $U^* = 2U_L^* = 1.82$  are shown in Figs. 3-5, respectively. Note that for the 1-cosine gust,  $\tau_G = 20$  throughout the paper.

As seen from Fig. 2, both the sharp-edged and 1-cosine gusts result into LCO with comparable amplitudes at  $U^* = 0.84 < U_L^*$ , while for the system without the gust input, oscillations decay with time.<sup>1</sup> This means that the nonlinear system may undergo

a Hopf bifurcation leading to LCO at a speed below the linear flutter speed, provided that a sufficiently strong gust excites it. Fig. 3 shows the dynamic response of the system with and without the gust input at the linear flutter speed,  $U_L^*$ . From the figure, one may infer that except for the transient part of the response, the gust does not make any significant changes to the dynamics of the system at  $U^* = U_L^*$ .

Fig. 4 Shows time responses of the system with and without the gust input at  $U^* = 2U_L^* = 1.82$ . As seen from the figure, the amplitude of oscillations when the system encounters a gust is obviously higher than that when there is no gust. In addition, the system undergoes period-2 motion in response to the gust input, while it performs period-1 motion when there is no gust. It is also interesting to see that the sharp-edged gust tends to increase the pitch angle in the negative direction, whereas the 1-cosine gust does the opposite.

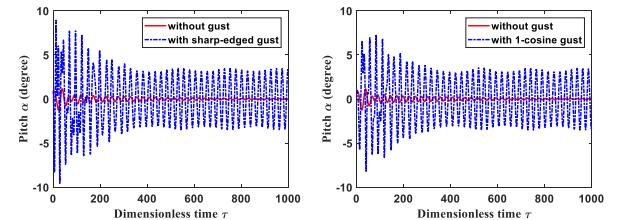

Figure 2. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the strong cubic nonlinearity in pitch at  $U^* = 0.84$ ;  $w_0 = 1$  m/s.

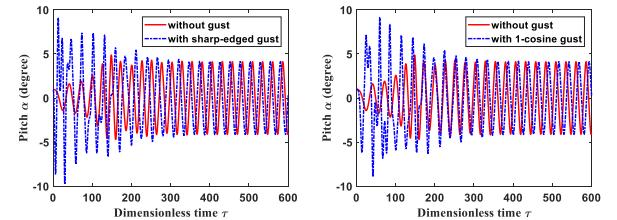

Figure 3. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the strong cubic nonlinearity in pitch at  $U^* = U_L^* = 0.91$ ;  $w_0 = 1$  m/s.

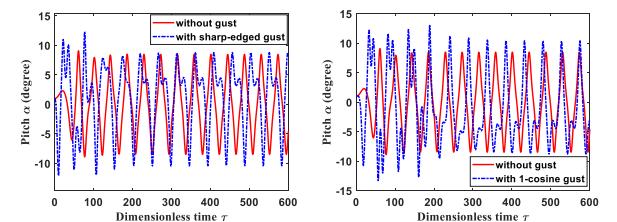

Figure 4. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the strong cubic nonlinearity in pitch at  $U^* = 2U_L^* = 1.82$ ;  $w_0 = 1$  m/s.

#### B. Gust Response with Free-play Nonlinearity

The free-play nonlinearity, in its general form, may be represented by the trilinear stiffness model, as shown in Fig. 5. In the figure,  $M_0$  represents the preload,  $M_f$  the stiffness in the free-play zone,  $\alpha_f$  the pitch angle offset, and  $\delta$  the free-play range. We examine the dynamics of a system with free-play

<sup>1</sup> The time responses to the gust inputs were obtained for a longer time range (not shown in Fig. 2) where period-1 LCO were observed.

parameters  $\delta = 0.5^\circ$ ,  $M_0 = M_f = 0$ ,  $\alpha_f = -0.25^\circ$  for the pitch stiffness. As also previously mentioned, the linear flutter speed for this system is  $U_L^* = 6.28$ .

Fig. 6 shows the bifurcation diagram for the free vibration (i.e. no gust) of a typical airfoil section with free-play type nonlinearity in pitch, where the peak values of the pitch angle,  $\alpha$ , are plotted against the normalized dimensionless airspeed,  $U^*/U_L^*$ . In the bifurcation diagram, a single dot/point represents a static equilibrium position (region I); two dots represent a period-1 motion (regions II and IX), and four dots show a period-2 motion (regions III and VIII); also, eight dots represent a period-4 motion (regions V and VII), and finally, multiple scattered dots show a chaotic motion (regions IV and VI). Table I summarizes the dynamical behavior of the system shown in the bifurcation diagram. It is noted that, as seen in Fig. 6, in region IX, the pitch amplitude increases sharply with  $U^*/U_L^*$  and goes to very large values for  $U^*/U_L^* > 1$  (not shown in the figure). These indicate the occurrence of *divergent* or *violent* flutter in region IX (for more details, see [1, 2]).

The important message of Fig. 6 is that the free-play nonlinearity may cause the system to lose the static equilibrium at a much lower flow velocity than the linear flutter speed (e.g. at 0.95 instead of 6.28 for the given system parameters). The bifurcation diagram also suggests that the route to chaos is via period-doubling, as also observed by Lee et al. [2].

Fig. 7 shows the typical phase-plane diagrams of four types of motion, which are period-1, period-2, period-4 and chaotic, respectively, at  $U^*/U_L^* = 0.8, 0.56, 0.45$ , and  $0.48$ .

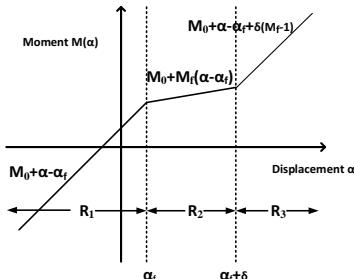

Figure 5. General free-play stiffness model;  $M_0$  represents the preload;  $M_f$  is the stiffness in the free-play zone,  $\alpha_f$  is the pitch angle offset, and  $\delta$  is the free-play range.

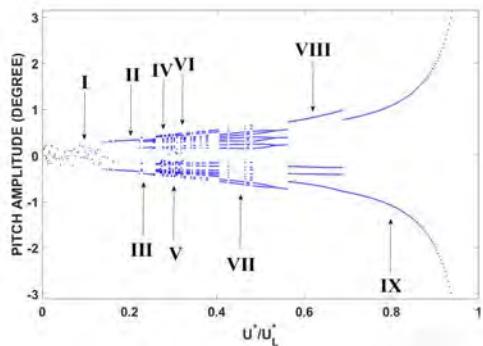

Figure 6. Bifurcation diagram of a system with a free-play nonlinearity in pitch ( $\delta = 0.5^\circ$ ,  $M_0 = M_f = 0$ ,  $\alpha_f = -0.25^\circ$ ), where the peak values of the pitch angle is plotted versus the normalized dimensionless airspeed,  $U^*/U_L^*$ .

TABLE I. DYNAMICAL BEHAVIOUR IN DIFFERENT REGIONS OF THE BIFURCATION DIAGRAM SHOWN IN FIG. 6; ( $U^*/U_L^*$ ) IS THE NORMALIZED DIMENSIONLESS AIRSPEED.

Region	$(U^*/U_L^*)$	Type of motion
Before I	(0 0.151)	Static Equilibrium
I and VIII	(0.151 0.221) and (0.688 1)	Period-1
II and VII	(0.221 0.255) and (0.529 0.688)	Period-2
IV and VI	(0.331 0.463) and (0.484 0.529)	Period-4
III and V	(0.255 0.331) and (0.463 0.484)	Chaos

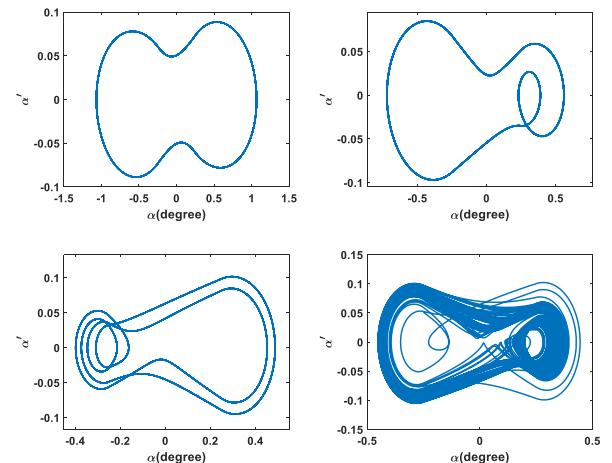

Figure 7. Phase-plane diagrams for different regions shown in Fig. 6; where  $U^*/U_L^* = 0.8, 0.56, 0.45$ , and  $0.48$  for the top-left, top-right, bottom-left, and bottom-right subfigures, respectively.

Fig. 8 shows time responses of the system in the pitch direction to a sharp-edged (left) and a 1-cosine (right) gust at  $U^* = 0.93$ . For comparison purposes, the gust response is plotted over the time response in the absence of the gust. As seen, the system undergoes LCO under the gust input, while in the absence of the gust it regains static stability. In other words, the gust input causes the system to lose its static stability at a lower airspeed, i.e. at  $U^* = 0.87$  instead of 0.95.

Fig. 9 shows the time responses at  $U^* = 1.30$  which lies in region II in the bifurcation diagram in Fig. 6. As discussed, within this region, the airfoil section undergoes period-1 LCO in the absence of a gust. However, this changes to period-2 LCO when the airfoil encounters a sharp-edged or 1-cosine gust. Thus, the gust may change the type of the oscillatory motion. In addition, it increases the amplitude of oscillation, especially in the transient part of the response.

Fig. 10 shows time responses at  $U^* = 3.06$ . Here also, the period-4 motion, which occurs in the gust absence, changes to a chaotic type motion due to the gust input. This is more evident from Fig. 11 which shows the phase-plane plots at the same airspeed without (left) and with (right) a sharp-edged gust input. Fig. 12 shows time responses at  $U^* = 6.00$ . Very large amplitudes due to gust effects are noticeable in the transient part of the responses. As seen from Fig. 13, when  $U^*$  approaches  $U_L^*$ , the amplitude of LCO due to the gust input increases rapidly to very large values (of the order of 35 deg). When  $U^*$  is greater than  $U_L^*$ , namely in the supercritical region, the time responses increase exponentially, indicating divergent flutter (see Fig. 14).

As seen from the figure, the gust response amplitude is always greater than the one in the absence of the gust.

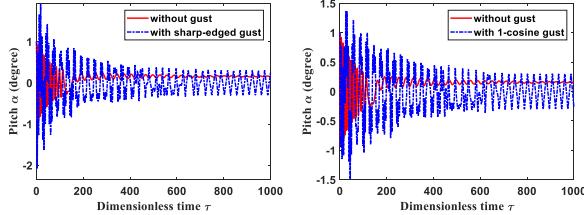

Figure 8. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the free-play nonlinearity in pitch at  $U^* = 0.93$ ;  $w_0 = 1$  m/s.

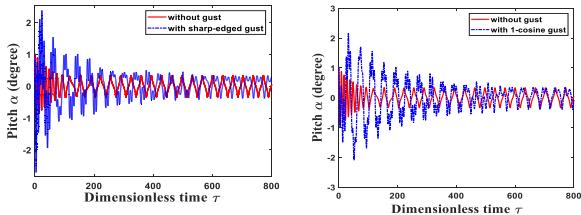

Figure 9. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the free-play nonlinearity in pitch at  $U^* = 1.30$ ;  $w_0 = 1$  m/s.

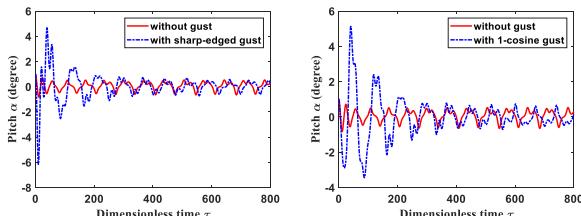

Figure 10. Sharp-edged (left) and 1-cosine (right) gust responses of a system with the free-play nonlinearity in pitch at  $U^* = 3.06$ ;  $w_0 = 1$  m/s.

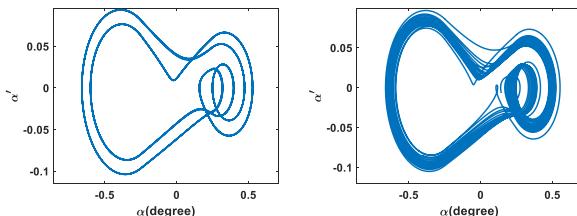

Figure 11. Phase-plane diagrams with gust and without gust (sharp-edged) at  $U^* = 3.06$ ; without (left) and with (right) a sharp-edged gust, featuring period-4 and chaotic motions, respectively;  $w_0 = 1$  m/s.

#### ACKNOWLEDGMENT

The authors are grateful to the Faculty of Engineering and Computer Science of Concordia University for the FRS funding. The second author also greatly appreciates the Faculty for a Start-Up grant.

#### IV. CONCLUDING REMARKS

The numerical results presented in this paper show that a sharp-edged or a 1-cosine gust input may influence the dynamics and stability of a two-dimensional wing with a strong cubic or free-play stiffness nonlinearity in three different ways: (1) it may alter (strictly speaking, lower) the onset of instability, (2) it may change the mode of oscillatory motion (e.g. from period-1 to period-2 motion), and (3) it may increase the amplitude of vibrations. Thus, studying the effects of time-dependent excitation on the dynamics and stability of lifting surfaces seems essential for their design. These studies are particularly crucial for the new generation of aircraft which are likely to be lighter, faster, more flexible, and more agile.

**Abstract**—Turbulent flows are fundamentally three-dimensional. Due to their inherent complexity, turbulent flow characterization is heavily relies on experimental research. A multi-color grid technique was recently proposed by the authors as a novel method for characterizing and measuring three-dimensional flows.

In this paper, further improvements of this technique are reported by implementing a new method based on color permutations. Several new advances in the experimental implementation and analysis algorithm are then presented and detailed. Results are presented using color streak images and three-dimensional particle trajectories.

**Keywords:** *3D; flow visualization; multi-color; flow measurement;*

## I. INTRODUCTION

Turbulent flows are one of the fundamental topics of classical fluid mechanics. A majority of practical engineering systems encounter turbulent flows, including the wake of buildings and flows in pumps, turbines, and heat exchangers. In these systems turbulence manifests as either a desirable trait, such as enhanced heat transfer, or non-desirable trait, such as dynamic loading on buildings. Complex three-dimensional motion and non-linear dissipative processes, two defining characteristics of turbulent flows make them extremely difficult to study numerically. This makes experimentation the primary means of turbulence research. However, this presents the challenge of developing a technique to measure all three velocity components simultaneously as all components are needed to fully define key quantities in the turbulent kinetic energy budget.

Numerous techniques have been developed in the past to measure flow velocity while few have been used quite often for turbulent flow measurement. Hot-wire anemometry is one of the simplest techniques where velocity is determined from flow passing over a very thin heated wire attached to a probe. By deploying several probes at orthogonal angles, three-dimensional velocity can be determined. This technique has the benefit of excellent temporal resolution but lacks the ability to capture the flow field with good spatial resolution. Furthermore, the probe array intrudes upon the flow. Planar Particle Image Velocimetry (PIV) is a non-

intrusive technique that generates a two-dimensional flow field by taking images of a laser-illuminated seeded flow. This produces a flow field with high spatial resolution but is limited to planar measurements. Stereoscopic PIV builds upon this by utilizing two off-axis cameras viewing the light sheet [1]. From the captured images, a 3D flow field is constructed; however, the out-of-plane velocity has been shown to have questionable accuracy and no out-of-plane gradients can be determined [2,3]. Tomographic PIV is a further advancement of the PIV technique where four or more cameras observe an illuminated volume [4]. By applying a computational scheme to the images of the seeded flow, all three velocity components can be estimated. It has been shown that the calculated third velocity component is of questionable accuracy, especially in high shear flows, due to ambiguities in identifying seed particles, called ghost particles [5,6].

Recently, wavelength-encoding techniques have been developed to measure flow velocity. Rainbow Volumic Velocimetry (RVV) is one such technique where one camera views a seeded flow passing through a volume illuminated with the polychromatic light spectrum [7]. In this method, two velocity components are found from tracking particles while the third is derived from color changes corresponding to the particles' motion in the direction normal to the cameras viewing plane. This technique produces a three-dimensional flow field but is restricted to small volumes as the out-of-plane velocity components accuracy is strongly dependent upon of the width of each color in the volume [7]. A new method of volumetric color illumination was recently proposed by the present authors utilizing a grid pattern [8]. In this grid-based technique, color changes occur over multiple planes with respect to the camera viewing plane. With many colors and permutations of those colors, high spatial resolution in the out-of-plane direction is possible. The initial implementation of this grid-based technique was able to resolve three-dimensional motion while simultaneously identifying challenges.

In this study, the limitations of the grid-based technique are presented along with progress on a series of advances both in experimental implementation and in analysis algorithm design. Findings of the grid-based technique are first reviewed and weaknesses are identified. Then, recent progress on improvements are presented with a refined

experimental method and analysis algorithm leading to a newly developed technique. The new technique is then tested and 3D particle trajectory results are presented.

## II. REVIEW OF THE MULTI-COLOR GRID TECHNIQUE

The multi-color grid technique for flow characterization divides the measurement volume into an  $N \times N$  grid where  $N$  colors are used [8]. The color pattern is designed such that each color appears only once in each row and column. Hence when a particle is observed to change color without a corresponding pixel shift in the camera view plane, it can be concluded the particle moved perpendicular to the camera view plane. Similarly, the particle would change color in addition to a pixel shift if the motion is parallel to the camera view plane. One of the advantages of the grid technique is that the number of permutations of colors, exceeds the number of colors enabling the grid pattern to be extended. This allows for improved spatial resolution in the out-of-plane direction.

The multi-color grid technique was implemented using a simple experiment of tracking particle motion underwater using a three-color grid and a basic analysis procedure [8]. Captured streaks were discretized with a simple streak technique that was able to capture many points along each streak allowing for the general shape to be well-resolved. The three-dimensional position of the streak was found using linear interpolation of color described with hue from the Hue-Saturation-Value (HSV) color model. This demonstrated that a grid technique was able to capture basic three-dimensional motion [8].

The three-color grid pattern used only contained red, green, and blue however resulted showed other colors such as pink were present [8]. This is due to neighboring colors interfering with each other. When this technique was implemented with a six-color grid, this color cross-talk effect was stronger and began to interfere with three-dimensional position determination. Hence, increasing the number of colors, thus reducing grid size, is a major obstacle in improving the possible spatial resolution of the technique due to cross-talk between neighboring colors.

The LCD projector used in experiments produced a highly divergent beam, resulting in a rectangular frustum shaped measurement volume. The calibration of the measurement volume was very simple based on a hue threshold [8]. The basic streak discretization technique had issues in accurately capturing the ends of streaks and could not handle streaks with high curvature.

## III. DEVELOPING THE COLOR PERMUTATION METHOD

Several advancements and improvements have been completed to address these limitations and to refine the technique. The first improvement is in the light beam delivery to overcome the beam divergence issue. This was

achieved by placing a planoconvex lens in front of the LCD projector. This has the effect of producing an easily modelled measurement volume in the shape of a parallelepiped. This improvement to reduce beam divergence is illustrated in Fig. 1 where the new approach is compared with the lens-free case. From observing the thickness of each colored region in the image, it is clear that the lens significantly reduces the beam divergence improving the spatial uniformity of each single-colored region.

A new calibration technique has been developed for more robust analysis. The new method fits a normal distribution to hue values using the HSV model from a single-colored volume. The region within three standard deviations of the mean hue is defined as the “core” and the region beyond this is defined as the “boundary”. An example of the core and boundary regions for a three-colored volume identified by the technique are shown in Fig. 2. Each core region is now separated by two boundary regions.

The previous streak discretization method would have issues near ends of streaks where points were mis-aligned and could not handle streaks with significant curvature. These issues have been overcome with a new discretization technique that follows the shape of a streak. In this approach, a given streak is divided into many streak subdivisions. Each subdivision is identified by a white region where segmented streak and semi-circle intersect, as shown in Fig. 3. The centroid of the subdivision, as marked by the red asterisk, and the median hue are stored for each subdivision.

The issue of cross-talk between colors has been addressed by defining the mid-plane between neighboring single-colored volumes. This leads to the case where if a particle appears as an undefined hue in the whole measurement volume, it must exist between neighboring volumes. By identifying the volumes where the particle was last found before and after transition, it is possible to determine which mid-plane the particle passed through. This approach is dependent upon proper identification of volumes before and after transition.

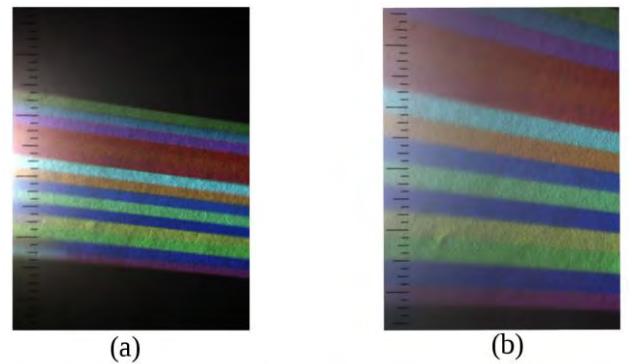

Figure 1. Comparison of illuminated volume (a) with planoconvex lens and (b) without lens showing the effect of the lens on beam divergence.

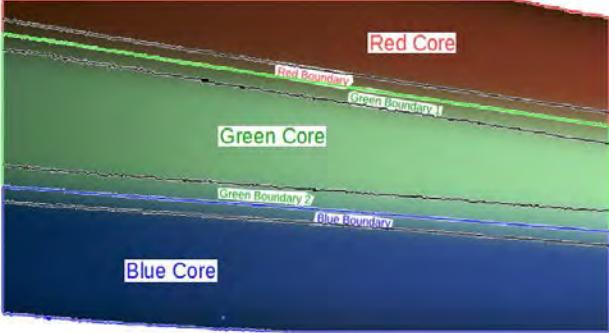

Figure 2. Cross-section of three-color grid pattern using the new calibration technique. The core and boundary regions for each color are outlined and labeled.

The robustness of volume identification and spatial resolution in the out-of-plane direction can be greatly improved via color permutations. For a selection of N colors, they can be arranged such that each color neighbors every other color only once. This allows for each color to appear several times in the volume where each appearance features unique neighbors. The result of this configuration is that once a particle changes color, e.g. a sufficiently long streak is captured by the camera, the three-dimensional position is known. As colors can repeat in the volume and mid-planes between colors are defined, this leads to a substantial increase in spatial resolution compared to the previous method for the same number of colors.

The culmination of these improvements have led to the color permutation method where color permutations drive the resolving of motion in the third dimension. For planar motion in the camera's field of view, the resolution provided by pixels far surpasses what is offered by the grid pattern. Hence, color changes are only needed in the out-of-plane direction. Moreover, this simplifies analysis as color cross-talk is limited to one direction.

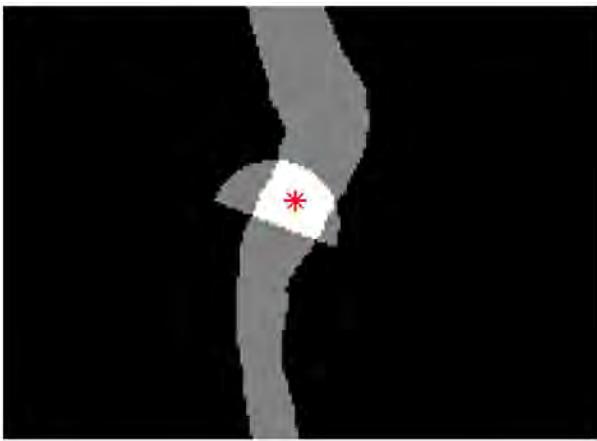

Figure 3. One step in the process of streak discretization. The subdivision is the white intersection area between semi-circle and segmented streak. The red asterisk denotes the subdivision centroid.

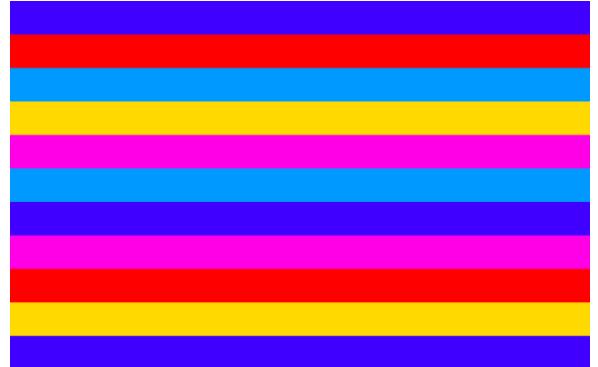

Figure 4. Five-color pattern with permutations to produce 11 layers used in experiments.

#### IV. RESULTS

The color permutation technique was tested using a five-color permutation pattern as shown in Fig. 4. This image contains one of many possible permutations of five colors. There are 11 single-colored volumes and by utilizing mid-planes, this gives 21 possible out-of-camera-plane positions, over 4 times larger than the 5 positions possible with the previous technique. The experimental setup and conditions were the same as those previously reported [8].

Fig. 5a shows a two-frame composite image of a particle traveling from left to right. The corresponding two-dimensional discretized streak is shown in Fig. 5b. Comparing the discretized streak to the original image shows the new path-following discretization method successfully captures local curvatures in the streak. This is evidenced by features such as the drop in Z position where  $Y \approx 1200$  pixels, matching the left-most orange part of the streak composite image. Similar features along the streak image are well captured by the new discretization technique. There were no mis-aligned points at the ends of each streak showing the new technique has improved over the previous method in this aspect.

Fig. 6 shows the discretized streaks in three dimensions describing the particle trajectory. The left-most part of the streak at  $Y \approx 900$  pixels was found to be in layer 11, then continuing along the streak showed the streak moving three-dimensionally up to layer 6. At this point, the second frame in the composite image begins where the streak continues from  $Y \approx 1700$  pixels and layer 6 up to  $X \approx 2500$  pixels in layer 3. The additional depth positions obtained by color permutations and mid-planes showed good resolution of the particle's motion in the out-of-camera-plane direction.

#### V. ANALYSIS OF NEW FINDINGS

Numerous changes have been made to the multi-color grid flow visualization technique. A planoconvex lens placed in-front of the projector greatly reduces beam divergence.

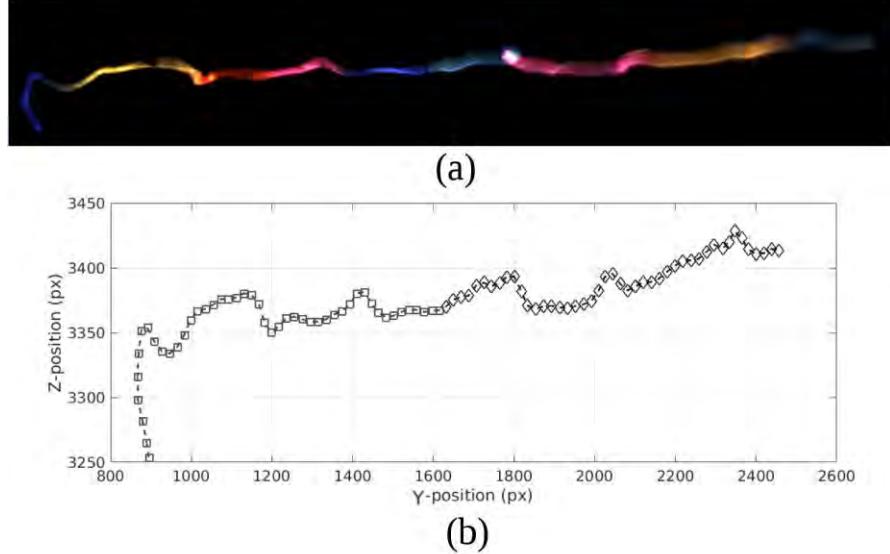

Figure 5. Two-frame composite image (a) of streak captured and two-dimensional view of discretized streak (b). The image has been rotated to match the coordinate system of the plot

This changed the shape of the illuminated volume from a rectangular frustum to a parallelepiped which is very simple to describe mathematically. Furthermore the size of each single-colored volume is smaller compared to the divergent beam setup, providing an increase in spatial resolution in one direction. With precise alignment of the planoconvex lens, a rectangular prism shaped volume is possible.

The two analysis algorithm changes, improved calibration and discretization, lay the ground work for high quality flow characterization. In the new calibration technique, using a normal distribution to define the hue threshold enables the technique to be implemented with many different projectors and clearly defines the calibration core and boundary regions. The new discretization technique

demonstrated an ability to follow the shape of a streak with somewhat complex geometry, such as local curvatures that characterizes the three-dimensionality of the flow. These advancements provide an opportunity for the future growth of the analysis algorithm.

The addition of mid-planes and color permutations together provided a very significant increase in out-of-camera-plane spatial resolution. The introduction of mid-planes mitigated the effects of cross-talk between neighboring volumes as hues not defined by the grid pattern do not need to be explicitly determined. Mid-planes also increased the out-of-plane resolution by a factor of just under two.

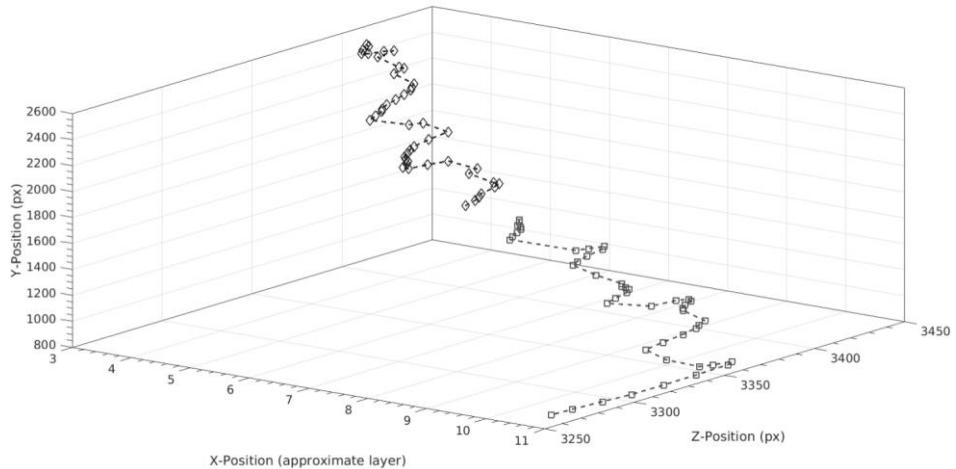

Figure 6. Three-dimensional reconstructed particle path corresponding to the two-dimensional discretized streak in Fig. 5.

Color permutations demonstrate that a large increase in spatial resolution is possible with only a few colors via permutations. As tested in the present study, 5 colors were able to produce 11 different core depth positions and with mid-planes, generated 21 possible positions. The cost for this improvement is loss of color uniqueness in the volume as a red region could end up in two different positions. This is an ambiguity that cannot be resolved until the streak changes color.

This color permutation method has shown strong potential for future growth. With additional colors, more permutations are possible, producing further improvements in out-of-plane spatial resolution. Work is currently in progress in this area of identifying valid color permutations for six or more colors.

Thus far the color permutation method has presented results from the 3D path traversed by a single particle. While this is useful to build a framework and test analysis methods in isolation, it is not practical. Multiple particles must be present for meaningful flow characterization. In a test where many particles are present, the streaks left behind by their motion may overlap or otherwise interact. Current work is focused on implementing analysis methods for cases where streaks interact.

Finally, the three-dimensional reconstruction work has been performed manually to date. Currently an automatic reconstruction technique is in development to convert hue data along streaks into depth positions. There is also ongoing work in more robust preprocessing methods to better separate streaks from background noise and select streaks with color changes to ensure compatibility with the color permutation method.

## VI. CONCLUSION

In conclusion, the multi-color grid technique was successful at resolving 3D particle motion but did reveal many flaws in the method and early implementation. The present paper serves as a progress update that identifies and resolves these limitations while advancing the technique utilizing color permutations and improved algorithm design. There are new challenges found in the updated method that join unresolved issues. Presently, work continues on addressing these issues and further refining the technique. These findings using the color permutation method will drive future research and development on this technique.

**Abstract**—Curved shocks that are locally oriented normal to the direction of the pre-shock flow vector appear on bluff and blunt bodies in supersonic flow and at the center lines of axisymmetric air intakes. There have been numerous studies to analytically approximate the shock stand-off distance associated with these curved normal shock waves; however, in view of the absence of satisfactory results across the entire range of freestream Mach numbers, further efforts are warranted. In this study, the Curved Shock Theory (CST) is used to derive analytical expressions for the pressure gradient right behind convex normal shocks in uniform upstream flow. This pressure gradient can be converted to gradients of other variables using the conservations laws and the isentropic relations. Using these gradients at the curved normal shock and an additional assumption on their variation between the shock and the blunt body it is possible to develop relations for the ratio of the shock stand-off distance to the radius of curvature of the shock surface as a function of freestream Mach number and the specific heat ratio. CST predictions are compared with experimental data from the literature and the CFD results obtained in the present study for freestream Mach numbers ranging from 1.2 to 8.

**Keywords**-shock stand-off distance; curved shock theory; blunt body; radius of shock curvature

## I. INTRODUCTION

The shock stand-off distance from blunt bodies is an important parameter to estimate the effects of shock waves on objects moving at supersonic and hypersonic speeds. The change in the shock stand-off distance can be an effective indicator of the changes in other important properties such as the drag on an aircraft or the heat flux on a re-entry vehicle. There have been continuous efforts over many decades to come up with handy expressions to quickly calculate the shock stand-off distance from blunt bodies. However, rather limited success is achieved in formulating expressions that can be applied over a wide range of Mach numbers.

Several assumptions were implemented by different researchers to simplify the problem and formulate widely applicable expressions for the shock stand-off distance as a

function of the freestream Mach number. In an earlier work by Moeckel [1], for instance, it is assumed that the detached shock wave can be represented by a hyperbola and that the sonic curve between the shock and the body is a straight line. In a recent study, Sinclair and Cui [2] made use of the variation of the size of the sonic zone bounded by the bow shock and the fore part of the body to relate the shock stand-off distance to the freestream Mach number.

In this paper, the Curved Shock Theory (CST) is used to derive an expression for the pressure gradient right behind convex bow shocks that appear in supersonic and hypersonic flows with uniform pre-shock flow. This pressure gradient relation is combined with the momentum conservation law and the isentropic relations for various flow variables, such as Mach number, density, temperature, etc. to obtain the gradients of those variables at the curved bow shock. By assuming the gradients to be constant within the shock layer between the bow shock and the blunt body or considering their average values, the ratio of the shock stand-off distance to the shock radius of curvature is obtained as a function of freestream Mach number. The aim of this study is to provide such alternative theoretical relations for the shock stand-off distance using CST and to investigate their validity. Billig's experimental correlations [3, 4], Liepmann and Roshko's experimental data [5], and our numerical simulation results are used as tools for validation.

## II. THEORETICAL FORMULATION

### A. Curved Shock Theory as Applied to Curved Normal Shocks in Uniform Pre-shock Flow

Theory that relates the pressure gradient,  $P$ , the streamline curvature,  $D$ , and vorticity,  $\Gamma$ , to the shock curvatures,  $S_a$  and  $S_b$ , on the pre-shock and post-shock sides of a doubly curved shock wave is developed in [6]. Such theories are also found in [7, 8]. When applied to a normal shock facing uniform upstream flow [8], the CST relations become:

$$0 = A'_2 P_2 + C' S_a + G' S_b \quad (1)$$

$$P = \frac{\partial p / \partial s}{\rho V^2} = \frac{\partial p / \partial s}{\gamma \rho M^2} \quad (2)$$

$$A'_2 = -\frac{M_1^2 - 1}{M_1^2} \cdot \frac{(\gamma - 1)M_1^2 + 2}{2\gamma M_1^2 - \gamma + 1} \quad (3)$$

$$C' = G' = -\frac{2}{\gamma + 1} \cdot \frac{M_1^2 - 1}{M_1^2} \quad (4)$$

where subscripts 1 and 2 correspond to the upstream and downstream sides of the bow shock at the center line, respectively;  $M_1$  is the freestream Mach number; the derivative in (2) is taken along the streamline; other notations are conventional.

For the blunt body case both shock surface curvatures,  $S_a$  and  $S_b$ , are negative and the corresponding radii of curvature,  $R_a = -1/S_a$  and  $R_b = -1/S_b$ , are positive. The total curvature is  $S_a + S_b$ , the ‘average curvature’ is  $\bar{S} = (S_a + S_b)/2$  and the ‘harmonic average radius of curvature’ is  $\bar{R}$ , where  $1/\bar{R} = (1/R_a + 1/R_b)/2$ , so that  $\bar{S} = -1/\bar{R}$ .

Substituting (3) and (4) into (1), it is possible to show that,

$$P_2 = -\frac{4\bar{S}}{(\gamma + 1)M_2^2} = \frac{4}{(\gamma + 1)M_2^2 \bar{R}} \quad (5)$$

Furthermore, applying (2) at the downstream face of the shock wave it can be written as,

$$\left(\frac{dp}{p}\right)_2 = \frac{4\gamma}{(\gamma + 1)\bar{R}} ds \quad (6)$$

### B. Shock Stand-off Distance from a Blunt Body in Uniform Pre-shock Flow

Expressions for the shock stand-off distance,  $\Delta$ , from blunt and bluff bodies in a uniform pre-shock flow can be obtained using the post-shock pressure gradient (6) from CST, along with appropriate assumptions regarding flow variables in the downstream region. One such assumption is the constant pressure gradient assumption, in other words – the linear pressure profile in the shock layer. Equation (6) can be then written as,

$$\left(\frac{dp}{ds}\right)_2 = \frac{p_0 - p_2}{\Delta} = \frac{4\gamma p_2}{(\gamma + 1)\bar{R}} \quad (7)$$

$$\frac{\Delta}{\bar{R}} = \frac{\gamma + 1}{4\gamma} \left( \frac{p_0}{p_2} - 1 \right) \quad (8)$$

$$\frac{p_0}{p_2} = \left( 1 + \frac{\gamma - 1}{2} M_2^2 \right)^{\frac{1}{\gamma - 1}} \quad (9)$$

$$\frac{\Delta}{\bar{R}} = \frac{\gamma + 1}{4\gamma} \left[ \left( \frac{M_1^2(\gamma + 1)^2}{4\gamma M_1^2 - 2(\gamma - 1)} \right)^{\frac{1}{\gamma - 1}} - 1 \right] \quad (10)$$

Here,  $p_0$  is the stagnation pressure for the post shock flow at the centerline. Equation (10) gives a relation of the ratio of the shock stand-off distance to the radius of curvature as a function of the freestream Mach number and the specific heat ratio only.

A similar equation can be obtained by using an average pressure gradient instead of the constant gradient assumption. It can be shown that the pressure gradient at the stagnation point is zero,

i.e., the pressure gradient varies across the shock layer from the value given by (6) at the shock to zero at the stagnation point. Therefore, the average pressure gradient within the shock layer can be taken as an arithmetic average, i.e., one half of the value given by (6),

$$\left(\frac{dp}{ds}\right)_{avg} = \frac{1}{2} \left[ \left(\frac{dp}{ds}\right)_2 + 0 \right] = \frac{1}{2} \left(\frac{dp}{ds}\right)_2 \quad (11)$$

It is easy to show that such an assumption is mathematically equivalent to the parabolic pressure profile in the shock layer. This leads to,

$$\frac{\Delta}{\bar{R}} = \frac{\gamma + 1}{2\gamma} \left[ \left( \frac{M_1^2(\gamma + 1)^2}{4\gamma M_1^2 - 2(\gamma - 1)} \right)^{\frac{1}{\gamma - 1}} - 1 \right] \quad (12)$$

Another estimation of  $\Delta/\bar{R}$  can be obtained by assuming a constant velocity gradient in the downstream flow and using the conservation of momentum equation for steady, inviscid, one-dimensional flow,

$$\rho V \left(\frac{dV}{ds}\right) = - \left(\frac{dp}{ds}\right) \quad (13)$$

Substituting the pressure gradient from CST into the right-hand side of (13) and applying the constant velocity gradient assumption on the left-hand side result in,

$$\frac{\Delta}{\bar{R}} = \frac{\gamma + 1}{4} \left( \frac{2 + (\gamma - 1)M_1^2}{2\gamma M_1^2 - \gamma + 1} \right) \quad (14)$$

The third flow variable that can be used to estimate the ratio of the shock stand-off distance to the shock radius of curvature is the Mach number. The equation that allow to achieve that follows from (9),

$$\left(\frac{dM}{M}\right)_2 = - \frac{2 + (\gamma - 1)M_2^2}{2\gamma M_2^2} \left(\frac{dp}{p}\right)_2 \quad (15)$$

Equation (15) used with (6), the normal shock relation for Mach number, and the constant Mach number gradient assumption results in,

$$\frac{\Delta}{\bar{R}} = \frac{(\gamma - 1)M_1^2 + 2}{2(\gamma + 1)M_1^2} \quad (16)$$

It is also possible to relate the density gradient at the downstream face of the shock wave with the pressure gradient using the fact that the flow in this region is isentropic:

$$\left(\frac{dp}{p}\right)_2 = \gamma \left(\frac{dp}{\rho}\right)_2 \quad (17)$$

Equation (17) can be used either with the constant density gradient assumption or the average density gradient assumption to find relations for  $\Delta/\bar{R}$ . The respective results are,

$$\frac{\Delta}{\bar{R}} = \frac{\gamma + 1}{4} \left[ \left( \frac{M_1^2(\gamma + 1)^2}{4\gamma M_1^2 - 2(\gamma - 1)} \right)^{\frac{1}{\gamma - 1}} - 1 \right] \quad (18)$$

$$\frac{\Delta}{\bar{R}} = \frac{\gamma+1}{2} \left[ \left( \frac{M_1^2(\gamma+1)^2}{4\gamma M_1^2 - 2(\gamma-1)} \right)^{\frac{1}{\gamma-1}} - 1 \right] \quad (19)$$

The isentropic nature of the flow in the downstream flowfield can also be used to obtain an equation that relates the temperature to the pressure gradient,

$$\left( \frac{dT}{T} \right)_2 = \frac{\gamma-1}{\gamma} \left( \frac{dp}{p} \right)_2 \quad (20)$$

Applying (20) at the downstream face of the shock wave and employing the constant temperature gradient assumption and the average temperature gradient assumption in the downstream flow field, it is possible to show that the respective equations that relate  $\Delta/\bar{R}$  to the freestream Mach number are,

$$\frac{\Delta}{\bar{R}} = \frac{\gamma+1}{8} \left( \frac{2+(\gamma-1)M_1^2}{2\gamma M_1^2 - \gamma + 1} \right) \quad (21)$$

$$\frac{\Delta}{\bar{R}} = \frac{\gamma+1}{4} \left( \frac{2+(\gamma-1)M_1^2}{2\gamma M_1^2 - \gamma + 1} \right) \quad (22)$$

### III. NUMERICAL INVESTIGATION OF RATIO OF SHOCK STAND-OFF DISTANCE TO RADIUS OF CURVATURE

Flows over a sphere, representing an axisymmetric flow case, and over a cylinder, representing a planar flow case, are numerically simulated for Mach numbers ranging from 1.2 to 8 using an adaptive unstructured total variation diminishing (TVD) finite volume Euler flow solver [9]. The shock stand-off distance and the radius of curvature for each case are obtained, and their ratio is compared against the CST results and Billig's experimental correlations.

The relations for  $\Delta/\bar{R}$  presented in Section II are adapted for different flow types by substituting the average radius of curvature,  $\bar{R}$ , with  $R$  for axisymmetric flows and with  $2R$  for planar flows, where  $R$  is the radius of shock curvature.

Experimental correlations of the shock stand-off distance and the radius of curvature with the freestream Mach number are presented in [3, 4]. These correlations, in addition to the numerical studies conducted, are used to validate the CST-based estimations of  $\Delta/\bar{R}$ . Billig's experimental correlations for spherical and cylindrical bodies, respectively, are,

$$\frac{\Delta}{R} = \frac{0.143 \exp[3.24/M_1^2]}{1.143 \exp[0.54/(M_1 - 1)^{1.2}]} \quad (23a)$$

$$\frac{\Delta}{R} = \frac{0.386 \exp[4.67/M_1^2]}{1.386 \exp[1.8/(M_1 - 1)^{0.75}]} \quad (23b)$$

#### A. Comparison of Analytical and Numerical Results

The ratios of the shock stand-off distance to the radius of shock curvature obtained for the axisymmetric and planar flow cases are presented in Fig. 1 and Fig. 2, respectively. It is seen that the theoretical curves form two distinct groups. One of the groups shows reasonable agreement with the present numerical results and Billig's experimental correlations for freestream Mach numbers higher than  $\sim 2$  for axisymmetric flow and higher

than  $\sim 3$  for planar flow. The lines of this group are for the average gradient (parabolic profile) assumption applied to the flow variables having zero gradient at the stagnation point (pressure, density, temperature) or for the constant gradient (linear profile) assumption applied to the flow variables with non-zero gradient at the stagnation point (Mach number, velocity). The second group of theoretical lines gives two times lower values of  $\Delta/R$ . The lines of this group are for the constant gradient (linear profile) assumption applied to the flow variables having zero gradient at the stagnation point (pressure, density, temperature). It is clear that the constant gradient (linear profile) assumption is not suitable for flow variables having zero gradients at the stagnation point because for gradient to become zero at the stagnation point, it should significantly deviate from its value at the shock.

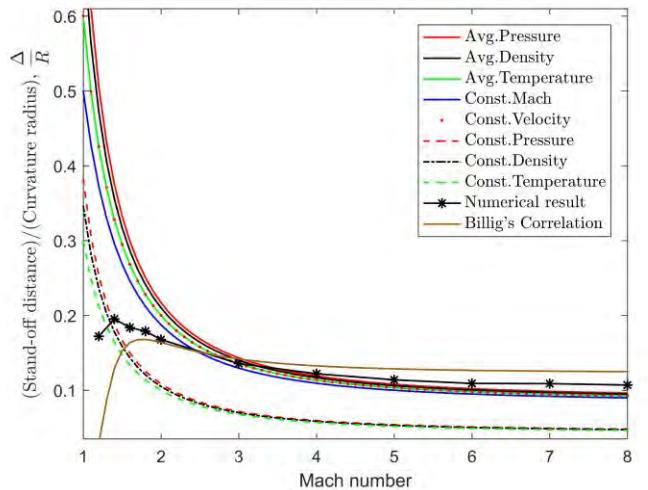

Figure 1. Ratio of the shock stand-off distance to the radius of shock curvature vs. the freestream Mach number for axisymmetric flow (over a sphere)

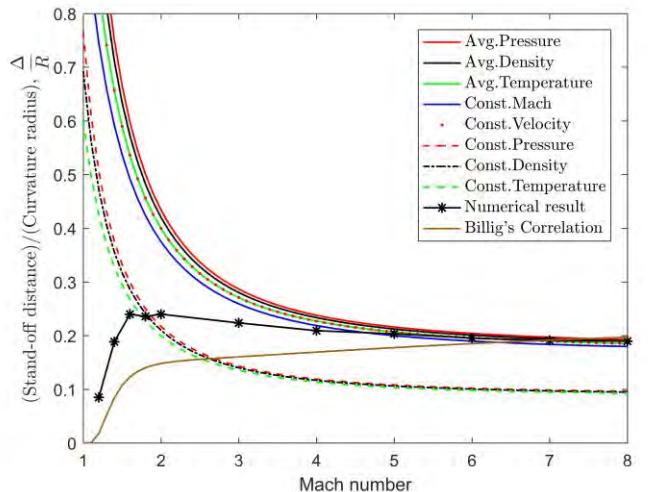

Figure 2. Ratio of the shock stand-off distance to the radius of shock curvature vs. the freestream Mach number for planar flow (over a cylinder)

## B. Evaluation of Assumptions Using Numerical Solutions

To shed some light on the accuracy of the constant pressure gradient (linear pressure profile) and average pressure gradient (parabolic pressure profile) assumptions for various Mach numbers, the average pressure gradients in the flow downstream from the bow shock at the center line are obtained from the numerical solutions. The deviation of the constant and average pressure gradient assumptions from these numerical pressure gradient values are shown in Figs. 3 and 4. It is evident from these figures that for higher Mach numbers ( $> 2$  or  $3$ ) the average pressure gradient assumption results in the pressure gradients which are much closer to the numerically determined values. On the other hand, at lower Mach numbers the constant pressure gradient assumption is more accurate. This is consistent with the results for the shock stand-off distance in Figs. 1 and 2.

## C. Weighted Average Pressure Gradient Approximation

The above discussion suggests that the CST predictions for the shock stand-off distance would be more accurate if one would come up with a better approximation of gradients in the downstream flow field. To demonstrate that, a weighting factor,

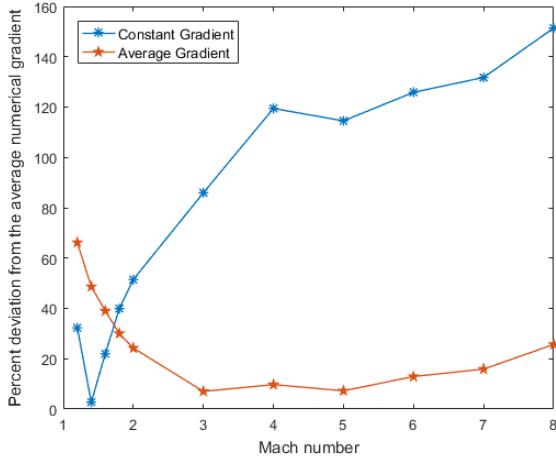

Figure 3. Percent deviation of the average and constant pressure gradient assumptions from the numerical average pressure gradient for axisymmetric flow

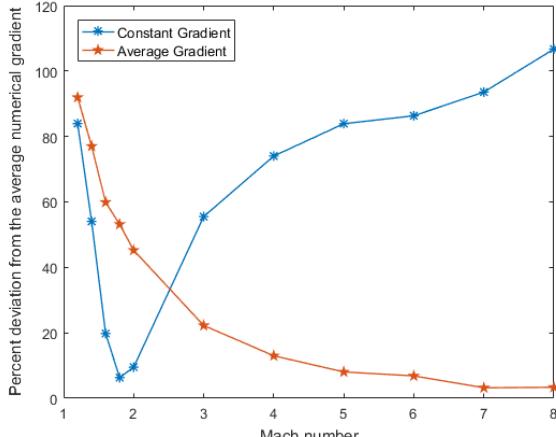

Figure 4. Percent deviation of the average and constant pressure gradient assumptions from the numerical average pressure gradient for planar flow

$W$ , is introduced in the calculation of the average pressure gradient. The weighting factor is calculated as the ratio of the average *numerical* pressure gradient downstream from the shock to the pressure gradient at the downstream face of the shock wave. The results are presented in Fig. 5.

Using the weighting factor, the averaging equation (11) is modified as follows,

$$\left(\frac{dp}{ds}\right)_{\text{avg}} = \frac{1}{2} \left[ W \left( \frac{dp}{ds} \right)_2 + 0 \right] = \frac{W}{2} \left( \frac{dp}{ds} \right)_2 \quad (24)$$

This allows to get (compare with (12)),

$$\frac{\Delta}{R} = \frac{1}{W} \cdot \frac{\gamma+1}{2\gamma} \left[ \left( \frac{M_1^2(\gamma+1)^2}{4\gamma M_1^2 - 2(\gamma-1)} \right)^{\frac{\gamma}{\gamma-1}} - 1 \right] \quad (25)$$

The values  $\Delta/R$  based on the weighted average pressure gradient approximation for axisymmetric and planar flows are shown in Fig. 6 and 7, respectively. It is seen that this approximation leads

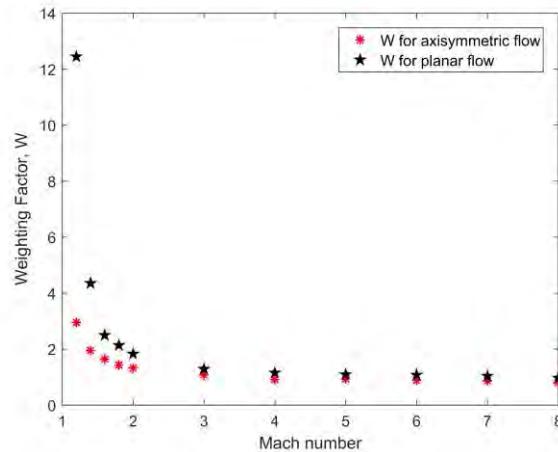

Figure 5. Weighting factor at different Mach numbers for axisymmetric and planar flows

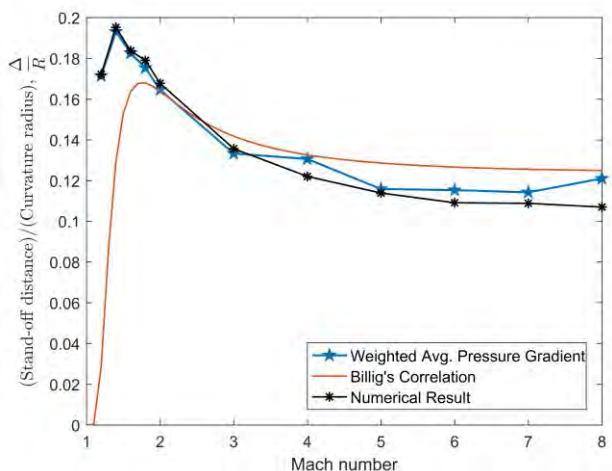

Figure 6. Ratio of the shock stand-off distance to the radius of shock curvature vs. freestream Mach number for axisymmetric flow using the weighted average pressure gradient

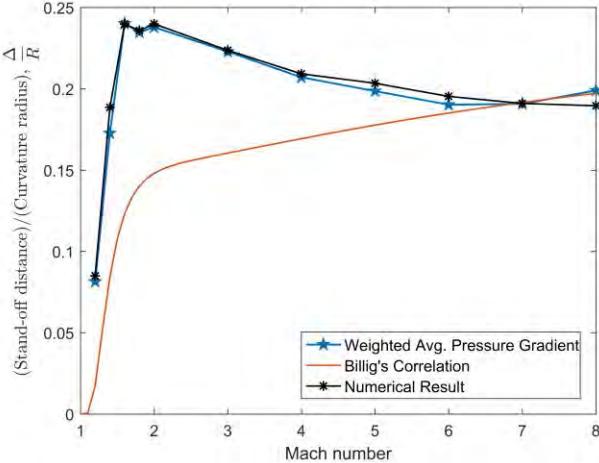

Figure 7. Ratio of the shock stand-off distance to the radius of hock curvature vs. freestream Mach number for planar flow using weighted average pressure gradient

to the results which are close to the values produced via numerical modelling (the difference is less than 10% for the whole Mach number range considered). The predictions based on the weighted average pressure gradient approximation cannot be considered as an independent theoretical treatment because numerical simulation data are used when calculating the weighting factor. However, Figs. 6 and 7 demonstrate clearly that better approximation of downstream flow gradients would certainly lead to more accurate results for  $\Delta/\bar{R}$ .

#### D. Comparison of Shock Stand-off Distance with Results in Literature Using Approximated Radius of Curvature

Most published data on the shock stand-off distance is in terms of the body radius,  $R_{body}$ , rather than the shock radius of curvature,  $R$ . Hence, an approximation of the radius of curvature is needed to facilitate the comparison of the CST results with other data. In the present work, the radius of curvature is assumed to be the sum of the body radius and the shock stand-off distance, i.e.,

$$R = R_{body} + \Delta \quad (26)$$

or

$$\frac{R}{R_{body}} = 1 + \frac{\Delta}{R_{body}} \quad (27)$$

Then the CST predictions for  $\Delta/R$  can be converted to  $\Delta/R_{body}$  as follows,

$$\frac{\Delta}{R_{body}} = \frac{\Delta}{R} \times \frac{R}{R_{body}} \quad (28)$$

As seen from Figs. 8 and 9 it is a reasonable approximation at high Mach numbers when the bow shock lies close to the body surface. At low Mach numbers, equation (27) significantly underestimates the radius of shock curvature.

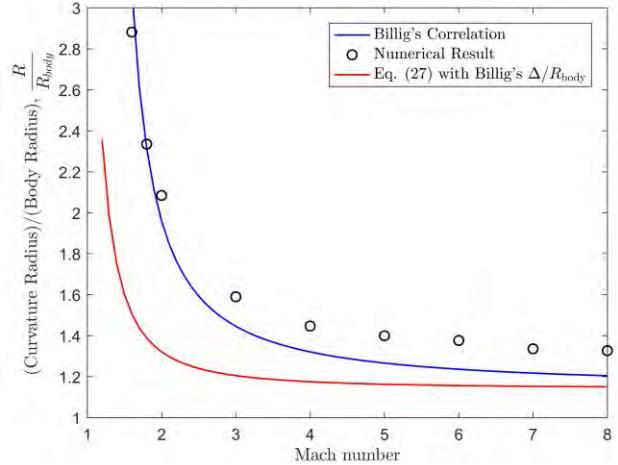

Figure 8. Comparison of the radius of shock curvature given by (27) with experimental data and numerical results for axisymmetric flow

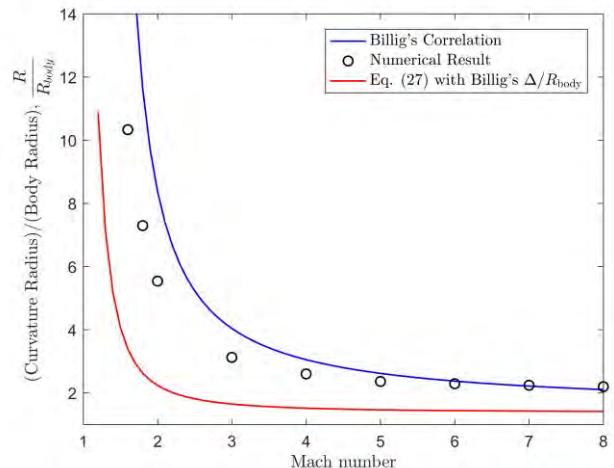

Figure 9. Comparison of the radius of shock curvature given by (27) with experimental data and numerical results for planar flow

The results for  $\Delta/R_{body}$  are shown in Figs. 10 and 11 for axisymmetric and planar flows, respectively. The CST predictions are represented by the same two groups of curves as in Figs. 1 and 2. Experimental results include Billig's correlations and data from Liepmann & Roshko [5]. Numerical results from the present work are also shown. The analytical prediction by Sinclair & Cui [2] is provided as well (for the planar case only).

It is seen in Figs. 10 and 11 that the CST relations correctly predict the overall monotonic variation of the stand-off distance (in terms of the body radius) with increasing Mach number (as opposed to Figs. 1 and 2 where non-monotonic behavior of the ratio of the stand-off distance to the radius of shock curvature is not reproduced by the CST predictions). This is because for low Mach numbers CST overpredicts the ratio of  $\Delta/R$  (see Figs. 1 and 2) while assumption (26-27) underestimates the radius of curvature  $R/R_{body}$  (see Figs. 8 and 9) so that their product (28) serendipitously exhibits correct behavior (Figs. 10 and 11).

As seen in Figs. 10 and 11, among various assumptions regarding the gradients in the post-shock flow along the center line the average pressure gradient assumption (in other words, the parabolic pressure distribution in the shock layer) leads to the best CST-based result in comparison with experimental and numerical simulation data. Nevertheless, CST somewhat underestimates the shock stand-off distance for the whole range of Mach number considered. This may be attributed to underprediction of the radius of shock curvature by (27). It is to be noted that the alternative theory by Sinclair & Cui [2] appears to overestimate the shock stand-off distance.

#### IV. CONCLUDING REMARKS

It may be concluded that the CST-based approach shows a good promise in predicting the shock stand-off distance. Further improvements might be achieved by finding better approximations for the post-shock flow gradients and the radius of shock curvature.

# An Experimental and Theoretical Investigation into the Flow Through Air Box of a Potato-rock Separator

Jacob Bobby Sagayaraj

Akash Kulshreshtha

Prabir Basu

Mechanical Engineering Department, Dalhousie University, Halifax

Lyle Gauthier

Allan Equipment, York, Prince Edward Island

## **Abstract -**

Velocity and pressure distribution in the air duct system and that over the grate of a potato-rock separator of Allan Equipment, PEI was analysed using both experimental measurements and computational fluid dynamics analysis with appropriate boundary conditions To calibrate the CFD simulations the velocity, pressure and flow rates were measured on the full-scale unit of the potato-rock separator. The effect of duct geometry on the velocity distribution through the grate was established through this exercise. Finally one design was implemented in the full scale unit. Velocity distribution obtained through this modification was checked through experimental measurements.

## **1.INTRODUCTION**

Potato harvesting is a major agricultural activity of Prince Edward Island, where the need for faster yet efficient means of harvesting is of growing importance. Potatoes are harvested from the field by large machineries. Such mechanical means of digging potato from the ground picks up from the field lots of undesired stuff like rocks, vines and dirt along with the potato. Separation of rocks from harvested potato is thus a critical step in this production cycle.

Allan Equipment is developing a new type of machine to separate rocks from potato-rock mixture. The potatoes, rocks, vines are picked up from the field and sent into a conveyor. This mixture potatoes and rocks along with the vines it falls onto a 'wave-bed' below which an air duct system is present (Figure 1). A centrifugal fan feeds air into the air plenum. The separation of potatoes from rock above the wave bed is dependent on various factors like shape and density of rock particles. The separation is achieved by a high flow of air, resulting in floatation of the potatoes. This high flow of air results in the levitation of potatoes and eventual removal through the exit because of the wave action of the wave of the wave bed. The inclined angle of the wave bed makes the rock exit the separator with the help of pinch rollers. Uniform distribution of air over the large area of its plenum of critical importance for proper operation of this potato-rock separator.

A radial fan, mounted at the inlet of the duct system provides the air to the air plenum. The fan, designed for 17,200 ACFM (29222 m<sup>3</sup>/h) and a static pressure 9.8 inches

of water (2439 Pa), is driven by a 38.9 HP motor. This particular model of fan is chosen as it is being used in most of harvesting machines at Allan equipment. This high flow fan provides enough air to levitate lighter potatoes above the wave bed. As the potatoes are levitated, the heavier rocks stay at the bottom due to its higher density. The wave action of the belt facilitates the separation of the rock at the side with help of pinch rollers. The fan is capable of functioning at different speeds with the help of programmable logic controller and a variable frequency drive. The research was carried out at an 80% load, which is the maximum load used when the harvester is used in the field.

In addition to the main fan, there is also a secondary fan (back fan) which is connected to a rear duct that sends air through ducts and into the pinch rollers present at the rock removal section. This back fan ensures that the potatoes do not come out of the pinch rollers when the separation through levitation takes place.

The Wave-bed is a unique mechanism which is developed by Allan Equipment that generates a wave motion through a cam mechanism whose speed is also controlled. The belt is made up of steel rods coated with rubber which is thinly spaced. The portion below the belt consists of disks attached to two individual rods which move along an elliptical track and meet the wave bed along its width. This produces the wave like action on the bed

Difficulty in separation was observed due to the uneven air flow distribution above the wave bed, which resulted in the clogging of potatoes in certain regions. This led to inefficient separation of the potatoes from rocks. Thus uniform flow distribution in the air plenum below the wave bed is a primary requirement of this system.

The present research was made to achieve even air flow by using theoretical and experimental means

## **2. EXPERIMENTAL**

A series of experiments were conducted in a full-scale commercial rock separator developed and used by Allan Equipment of Prince Edward Island. Primary objective of these experiments was to calibrate results of theoretical analysis and then check the results of some design improvements attempted to meet the requirements of this machine.

## 2.1 Air flow measurement above the wave bed

The flow region above the wave bed was analysed both theoretically and experimentally. Results of the theoretical analysis is discussed in section 3.1. Present section discusses the experimental results.

The purpose of this test was to understand the behavioural pattern of air flow above the wave bed. The experiment was done by placing a Pitot tube above the wave bed and measuring the velocity and pressure by connecting the pitot tube to a digital manometer. The velocity corresponding to dynamic and static pressures at each measuring location was then calculated. The measurement was done by moving the pitot tube along the length of the air plenum exit above the wave bed and recording the readings every six inches (152 mm) apart. The wave bed is shown in Fig 1.

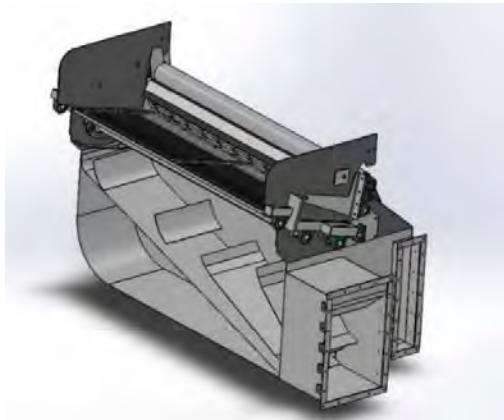

Fig 1 Design of the air plenum with baffles and wave bed

## 2.2 Introduction of a Perforated plate

Several attempts were made earlier to bring in flow uniformity by installing varied designs of flow straighteners in the air box, but they did not give the desired result. So, to achieve uniform air flow at the exit of the air plenum, a perforated sheet was introduced between the wave bed and the airbox exit. The velocity-pressure at the exit of the wave bed was measured with the help of a pitot tube and a manometer. The initially used perforated plate was made up of  $\frac{1}{4}$  inch (6.35 mm) holes equally spaced 1 inch apart throughout the entire area of 66x12 inches (1676 mm x 305 mm).

## 2.3 Adjustment of hole size in perforated plate

The velocity of the air escaping through the wave bed improved after the introduction of the perforated plate but it still appeared to uneven. So, an increase in the hole size in specific sections of low velocity was explored. The perforated plate was subdivided into 4 sections. These 4 sections were made into perforations of different sizes. (Fig 2)

### 2.3.1 Layout 1

This design option (layout 1) consists of 4 sections in which section 1 has  $\frac{3}{8}$  inch (9.52 mm) holes, the centre region has a combination of alternate  $\frac{1}{4}$  inch (6.35 mm) holes and  $\frac{3}{8}$  inch (9.52 mm) holes and the section 3 has  $\frac{1}{2}$  inch (12.7 mm) holes. There is an entire section (254 mm x 1676 mm) consisting of  $\frac{1}{4}$  inch (6.35 mm) holes.

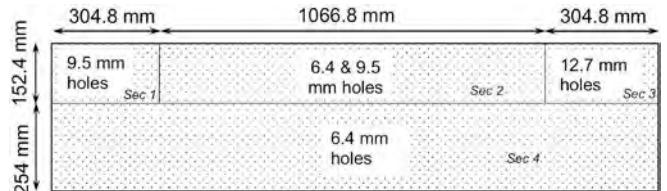

Fig 2 Layout 1 of the perforated plate

## 2.4 Removal of the wave bed

To allow access for measuring the pressure difference across the perforated plate the wave bed had to be removed from the air plenum. The testing was done along the plate in the near end (closest to air inlet), middle and far end. The far end is the inlet of the potatoes. The perforated plate had the layout 1 sized holes (Fig 3).

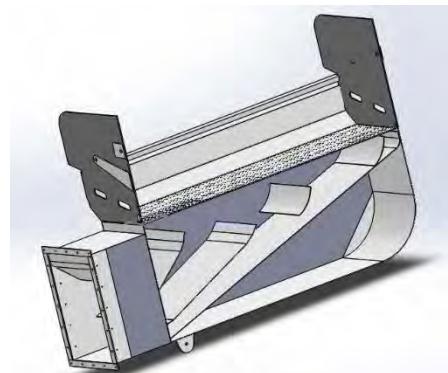

Fig 3 Perforated plate above the baffles with the wave bed removed

## 2.5 Removal of the Baffles

The desired uniformity of velocity distribution was achieved by the perforated plate. So, the role of air box baffles or flow straighteners was limited. So, they were removed to examine its impact. Experiment was carried out again after the baffles were removed (Fig 4). The layout of the perforation was the same as in Layout 1. (Fig 3)

The test was carried out in three regions; the near (To air entry) end, middle and far end. The Pitot tube was traversed across the perforated plate and the velocity pressure was measured.

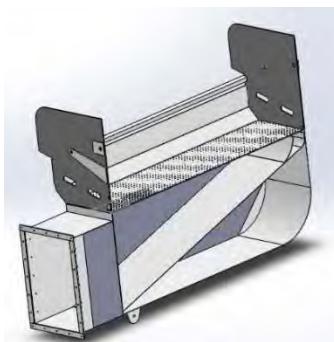

Fig 4 Perforated plate with both the baffles and wave bed removed

### 2.5.1 Fractional opening for layout 1

The fractional opening is important to understand the overall porosity of the perforated plate. This is calculated by dividing the total hole area by the total area.

Fractional opening = Total open area/ Total area

Table 1 Layout 1

Fractional opening calculation			
	Nos of holes	Hole size (mm)	Area (mm <sup>2</sup> )
Section 1	72	9.52	5127
Section 2	252	7.93	12467
Section 3	72	12.7	9124
Section 4	680	6.35	21543
Total void area		48262	mm <sup>2</sup>
Plate Length		1727	mm
Plate Width		406	mm
Total Area		701162	mm <sup>2</sup>
Total solid area		652899	mm <sup>2</sup>
<b>Fractional opening</b>		<b>0.068</b>	

## 2.6 Increase in perforated plate hole size (Layout 2)

Introduction of the perforated plate in air plenum brought about greater uniformity of velocity across the plenum but it significantly reduce the overall air flow rate into the plenum. This happened due to the additional flow resistance that the perforated plate imposed on the centrifugal fan use. To increase the flow rate of air above the perforated plate, the hole size was increased further without changing the hole pattern. The hole size was increased to 40% of the layout 1. The test was carried out in the presence of a flowmeter to measure the flow rate of air through the fan suction inlet. The flow rate through the fan had reduced much from the previous test, carried out under similar fan load conditions. This reduction in flow rate could be attributed to the high resistance in new venturi type flow meter used at the entrance of the fan.

The layout of the perforation is shown in Fig 5

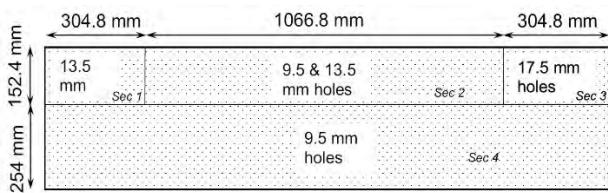

Fig 5 Layout 2

### 2.6.2 Fractional opening for layout 2

The fractional opening of the perforated plate was calculated. This calculation is important to make sure that the hole size is not increased too much.

Table 2 Increased perforation

	Nos of holes	Hole size(mm)	Area (mm <sup>2</sup> )
Section 1	72	13.5	10294
Section 2	252	11.5	26219
Section 3	72	17.4	17249
Section 4	680	9.5	48473
Total void area		102237	mm <sup>2</sup>
Length		1727	mm
Width		406	mm
Total Area		701162	mm <sup>2</sup>
Total solid area		598924	mm <sup>2</sup>
<b>Fractional opening</b>		<b>0.145</b>	

## 2.7 Attaching the wave bed

When potatoes are fed through the conveyor, they fall directly onto the wave bed shown in Fig 1. This wave bed is placed few inches above the perforated plate. So, it is desirable that we measure the velocities above the wave bed and make needed changes to the hole size in the perforated plate and thereby ensure that the flow is even in the region above the wave bed. The wave bed is mounted at an inclination and bands of different sized rubbers wound upon the bars in the wave bed. This design of different size rubbers bands made more air flow at the rear end, compared to that near end. The rear end of the wave bed is where the separation of the rocks takes place with the help of the pinch rollers. This region requires much more air compared to that near end. The movement of the potatoes to the outlet is mostly due the wave-like action of the bed, assisted by the slight bubbling provided by air.

### 2.7.1 Layout 3

The layout of the perforated plate was changed based on preliminary experiment. This change in design was to provide more air flow towards the rear end and provide an even flow of air, so that there is no clogging up of clods in the regions above the wave bed.

The layout of the modified perforated plate is shown in Fig 6

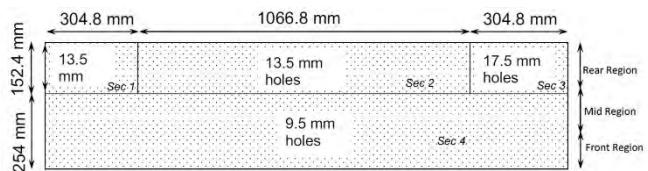

Fig 6 Layout 3

### 2.7.2 Opening fraction for layout 3

The opening fraction calculation was done for Layout 3 to make sure that the overall opening (or)Voidage does not exceed the nominal range of 20%.

Table 3. Increase in Voidage by 20%

	Nos of holes	Hole size (mm)	Area (mm <sup>2</sup> )
Section 1	72	13.49	10295
section 2	252	13.49	36032
section 3	72	17.46	17250

Width		406	mm
Total Area		701162	mm <sup>2</sup>
Total solid area		589111	mm <sup>2</sup>
Opening fraction		0.16	

### 2.8 Removing the flow meter

The velocity measurements were carried on the Layout 5 design without the flow meter at fan inlet. The isolation of the flow meter from the suction section of the fan is to record the velocity at which the harvester will function under ideal load conditions in the field.

## 3. RESULTS AND DISCUSSION

The velocities at region above the wave bed was computed using the commercial CFD code of COMSOL whose results are shown in Fig 7. These results were compared with those measured on the full scale unit. Figure 5 shows a reasonably good correlation between the flow predicted by CFD simulation and that measured. This verified validity of the present simulation.

### 3.1 Results from COMSOL CFD

The simulation was also used to find out the best possible design configuration by using appropriate boundary condition. These boundary conditions were obtained by keeping the fan setting at initial load conditions and measuring the value of velocity with air exits from the centrifugal fan. Thus, the need for hardware changes in the rock separator was avoided, thereby saving usage of raw materials and man power.

For simulation, the initial boundary conditions and the turbulence condition must be specified for the k- $\epsilon$  model. Parameters like the turbulent intensity and turbulent length scale can be determined with the help of the turbulent kinetic energy [1]. The modelling method employed was the RANS turbulence flow model. The parameters were chosen based on previous studies, showing the difference in computational cost when switching between different models for CFD analysis [2]. The figures shown here are for a few conditions in which the simulations results matched the physically conducted experiments.

Figure 7 shows the region above the bed when the baffles, the wave bed and the perforated plate are not present. This condition shows that without any resistance and the fan

attached at the inlet, the velocity with which air exits the bed is concentrated at the back and not much at the fan inlet side. This design shows uneven air flow and hence there will be inefficient separation of potato. This simulation was, however, run at a lower velocity of 33 m/s as opposed to the nominal velocity with which the fan operates.

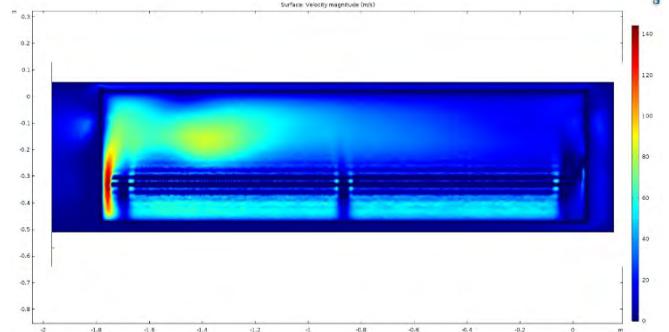

Fig 7 Velocity distribution above the air chamber with no perforated plate & baffles

The simulation was carried out with both baffles and the wave bed but without perforated plate, Fig 8. Based on the fan setting at 80%, the velocity of air coming through the inlet was kept at 43 m/s. Since there is no perforated plate, the velocity is high as indicated in the velocity scale. This pattern shows that in the centre region of the rear end, there is slight dip in the velocity.

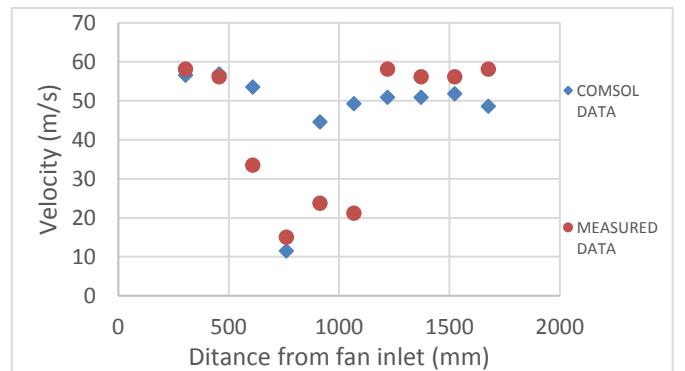

Fig 8 Simulated and experimental values of velocity above the wave bed with baffles and without the plate.

A simulation was run for the layout 3 and this is compared with the experimental results in Fig 9. which shows that the CFD result obtained, closely resembles and matches with the measured values at the rear end. The velocity pattern is shown in Fig 11. The analysis was carried out in the region above the perforated plate and hence the simulation's velocity profile is obtained at the region right above the perforated plate.

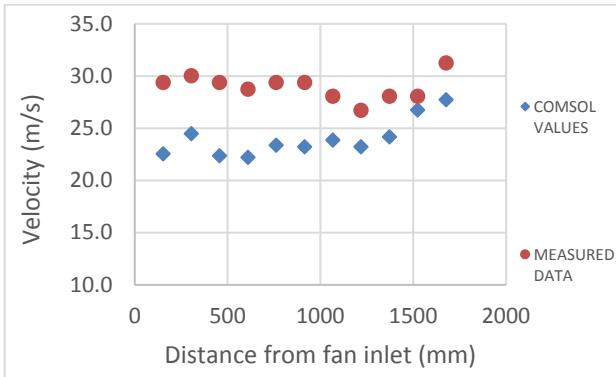

Fig 9 Simulated and experimental velocity above the perforated plate without the baffles

### 3.2 Distance vs velocity for different conditions

*Case 1: Above wave bed-with baffles-without perforated-without flow meter-layout 1*

The purpose of this test was to understand the behavioural pattern of air flow above the wave bed region in the air bed. The testing was done by placing a Pitot tube above the region and measuring the velocity pressure by connecting the Pitot tube to a digital manometer. The measurement was done by moving the instrument along the air plenum exit above the wave bed and recording the readings every six inches. The measurement was done only at the rear end. In this experiment the baffles were present inside the air chamber, as shown in Fig 1.

From the readings obtained it can be inferred that the air velocity above the wave bed was not uniform. The centre region of the air plenum appears to have a significantly low velocity, shown in Fig 10. COMSOL simulation was run with the required boundary conditions, and the obtained simulation result was close to the experimental result, as shown in Fig 8.

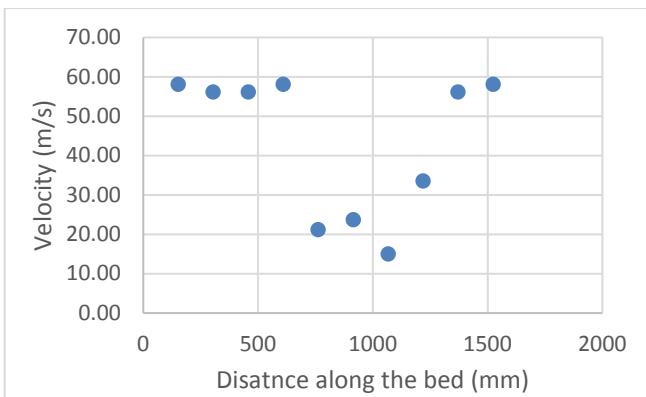

Fig 10 Experimental values of velocity plotted against distance from fan end of wave bed – case 1

*Case 2: Flow above wave bed-with baffles-with perforated-without flow meter-layout 1*

When the perforated plate of uniform holes was introduced in the air chamber, the flow was uniform in few regions but not entirely. This was influenced by the design of

the wave bed. After conducting initial testing on the air chamber, a change in design of the perforated plate was required. The initial stage of testing was carried out on the updated design shown in Fig 11. The region above the wave bed tested to find out the velocity pressure using a pitot tube. The pitot tube was moved along the wave bed and the velocity pressure was measured.

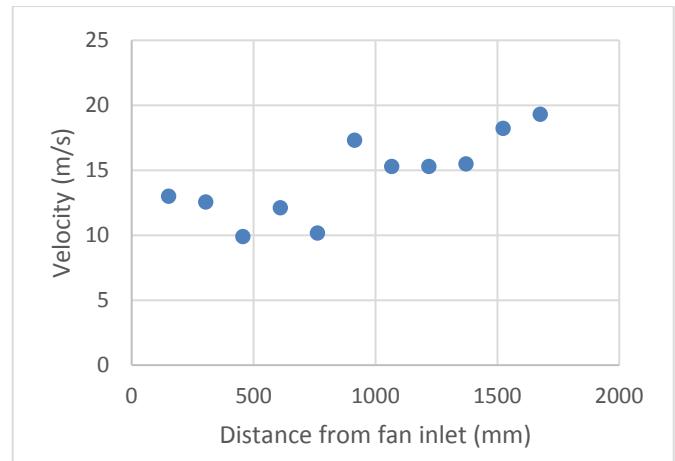

Fig 11 Measured values of velocity plotted against distance from fan end curve – case 2

*Case 3: flow above perforated-without baffles and wave bed but with flow meter -Layout 1*

A duct flowmeter of 12 inch (25.4 mm) diameter was attached at the suction section of the centrifugal fan and the flow rate was found to be 4834 CFM (8213 m<sup>3</sup>/h) and 5.2 inch of water (1294 Pa), which reduced considerably from the original value of 17,200 ACFM (29223 m<sup>3</sup>/h).

The test was carried out again after removal of the baffles inside the airbox. The pitot tube measurements were taken at a height above the perforated plate and at distances along the place. A more uniform velocity distribution was noted after removal of the wave bed and baffles. The test was carried out in three regions: the near end, middle and far end. The pitot tube was traversed across the perforated plate and the velocity pressure was measured. The pressure difference across the perforated plate was also measured and found to be 1040 Pa.

The velocity was more uniform above the perforated plate compared with that measured above the wave bed (Fig 12).

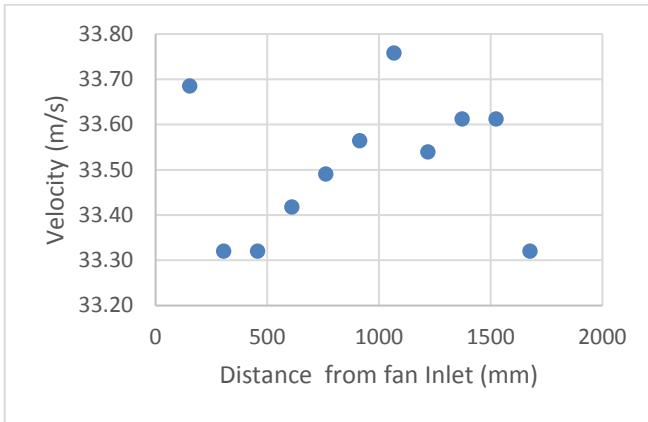

Fig 12 Distance vs Velocity above perforated plate without baffles – case 3

#### Case 4: Flow above perforated plate without baffles-with flow meter-layout 2

The analysis being focused on improving the flow distribution of air above the perforated plate, the hole size was increased further without changing the hole pattern. The hole size was increased from that of the layout 1. The bed pressure drop across the perforated plate was 600 Pa. The test was carried out in the presence of a flow meter installed at suction inlet of the fan. It measured the total flow rate of air through the fan. The flow rate through the fan had drastically reduced from the previous test, carried out under similar fan load conditions but without the flow meter. The fan was operated at the default load setting and the flow rate was measured to be 4834 CFM ( 8213 m<sup>3</sup>/h). This reduction in flow rate could be attributed to the high pressure drop of 5.2 inch WG (1294 Pa) across the flowmeter at fan inlet.

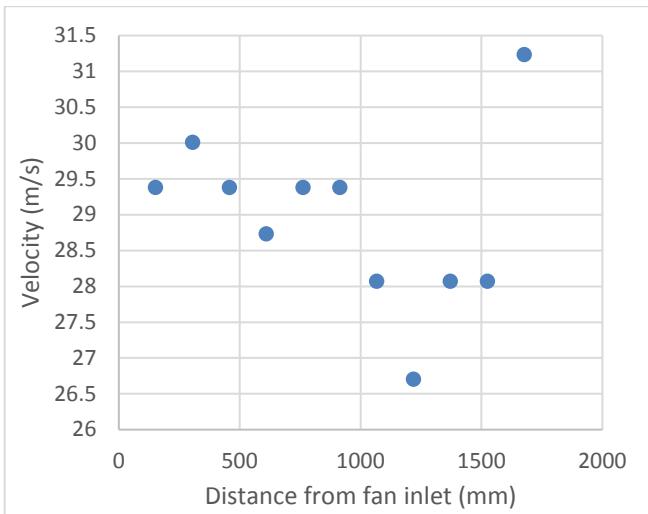

Fig 13 Distance vs Velocity above perforated plate without baffles – case 4

#### Case 5: Measurements above wave bed-without baffles-without flowmeter- Layout 3

Velocity measurements were carried on the Layout 3 design without the presence of the duct flowmeter. The flowmeter was removed from the suction of the fan to measure the flowrate the harvester will have under actual operating conditions in the field. This showed no change in velocity distribution pattern but the magnitude of the velocity had increased. Some drop in air velocity after passage through the wave bed is noted.

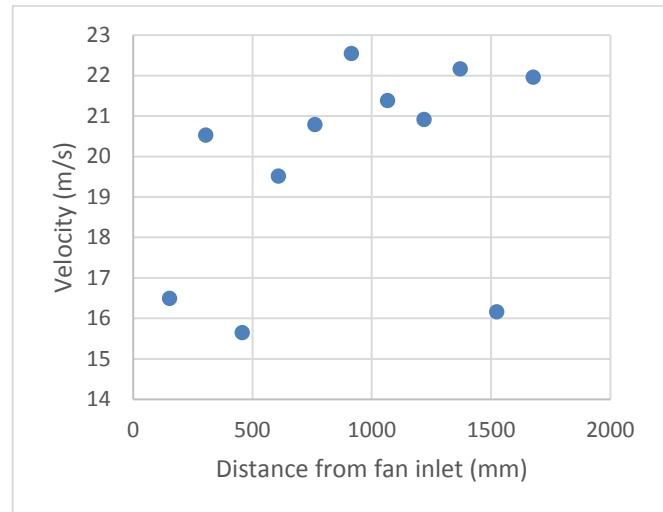

Fig 14 Distance vs Velocity above wave bed without flow meter– case 5

#### 4. CONCLUSION AND RECOMMENDATION

CFD simulations were successfully utilized to analyse the air flow through plenum of a commercial potato-rock separator. Predicted values of velocity distribution around the air distribution chamber was validated against values measured on a full scale model.

The Simulation model was used to predict flow distribution of several design configurations, but none gave the desired improvement.

To obtain the desired flow pattern a perforated plate was inserted above the plenum to get uniform flow distribution the size and percentage open areas of the perforated plate was varied and resulting air velocity distribution was checked through measurement.

**Abstract**—Continuous wave photoacoustics has been under investigation for more than a decade. Matched-filtering and pulse compression techniques, which use a chirp waveform as input light source, have been implemented into this imaging modality to improve signal to noise ratio (SNR) and resolution. However, the chirp parameters' effects on SNR are still not clear. The theory behind chirp parameters' effects on SNR is discussed in this paper. It is found that in order to get a higher SNR, chirp duration  $T$  should be maximized, chirp center frequency  $f_0$  should be controlled to make the chirp spectrum overlap with absorber spectrum, and chirp bandwidth  $\Delta$  should be smaller or equal to the absorber bandwidth.

**Keywords**-Continuous wave photoacoustics, SNR, chirp

## I. INTRODUCTION

Photoacoustic imaging, also called optoacoustic imaging, for biomedical applications has attracted a lot of interest during the past several decades. The principle of this imaging method can be found in recent work [1], [2].

The most common excitation source for photoacoustics has been a pulsed electromagnetic wave [3]–[5]. The key advantage of using a short pulse to irradiate the tissue is that the distribution of heat sources can be directly ascertained from the shape of the photoacoustic response signal [6]. However, the pulsed laser modality is limited by incident energy levels that must meet safety standards for in-vivo tissue imaging [1], as well as the difficulty in generating and detecting very short pulses.

An alternative excitation modality, which uses a continuous incident laser wave, is often referred to as Frequency Domain photoacoustics (FD-PA) where the acoustic wave is generated by periodic modulation of a laser [1], [2], [7]–[11]. More recently, the idea of implementing a pulse compression approach via matched filtering was introduced and investigated [2], [7]–[10], [12]–[14]. This is sometimes referred to as Photoacoustic Radar (PAR). The matched filter approach enables detection of a pre-known signal immersed in Gaussian white noise, therefore a long duration coded waveform with moderate power could potentially replace short high-power pulses.

Signal to Noise Ratio (SNR) is one important aspect to assess the performance of an imaging system. Many theoretical and experimental investigations have been done on the SNR of FD-PA [2], [8], [10], [12]. However, the theory behind optimizing input optical waveform parameters is still not clear. In this paper, the one-dimensional theory of FD-PA will be developed, and the incident wave parameters' effects on SNR will be discussed.

## II. 1-D THEORY OF CONTINUOUS WAVE PHOTOACOUSTICS SIGNAL TO NOISE RATIO

Diebold [15] gives a concise explanation of the governing equation for the pressure that results from launching a photoacoustic wave. The governing equation is given by

$$\left[ \nabla^2 - \frac{1}{c_s^2} \frac{\partial^2}{\partial t^2} \right] p(\vec{r}, t) = -\frac{p_0}{c^2} A(\vec{r}) \frac{\partial I(t)}{\partial t} \quad (1)$$

where  $p_0 = \frac{\beta c_s^2}{C_p} \mu_a$  and  $\beta$  is the thermal expansion coefficient,  $c_s$  is the speed of sound,  $C_p$  is the specific heat,  $\mu_a$  is the optical absorption coefficient of the chromophore absorber that has been heated by an optical pulse with fluence  $F$ .  $p(\vec{r}, t)$  is the pressure of the acoustic wave, a function of space and time.  $A(\vec{r})$  is a function of space that describes the geometry of the absorber and  $I(t)$  is a function that describes the time dependence of the incident optical pulse.

In one-dimensional model as shown in Figure 1. a), the space variable  $\vec{r}$  becomes  $z$ . The incident laser waveform  $I(t)$  is transmitted from the negative side of  $z$  axis, outside of the absorbing medium. The absorber is considered as an infinite sheet with a thickness  $l$ . The speed of sound  $c_s$  is considered to be the same in all three layers [16]. The pressure response  $p(z, t)$  is then detected by a transducer and be sent

to a receiver-filter. The output of the receiver-filter  $y(z, t)$  is the final photoacoustic signal.

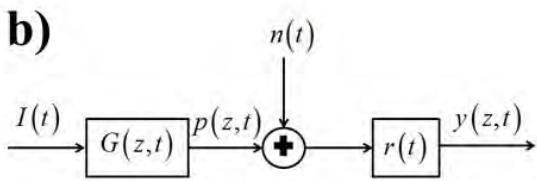

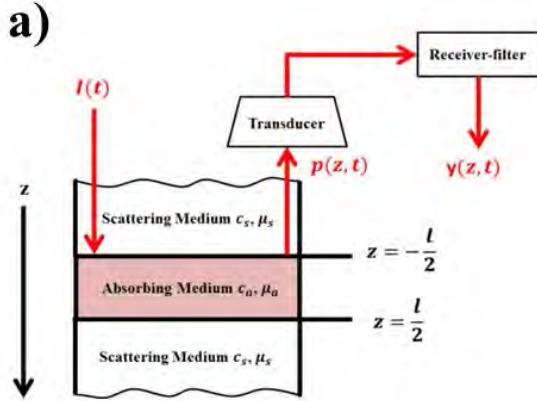

Figure 1. a) Model of absorber and surroundings; b) block diagram

When viewing the system shown in Figure 1. a) as a linear system, as shown in Figure 1. b), the transfer function concept is very useful.  $G(z, t)$  in Figure 1. b) denotes the absorber impulse response, and is given by

$$g(z, t) = \frac{p_0}{2c_s} \begin{cases} A(z, c_s t) & z > 0 \\ A(z, c_s t) & z < 0 \end{cases} \quad (2)$$

where  $A(z)$  is the spatial shape of the absorber,  $r(t)$  is the receiver-filter impulse response. The signal received at the receiver-filter also contains noise  $n(t)$  which is assumed to be a zero-mean additive Gaussian white noise [17] which is assumed to have a double-sided power spectral density of  $\tilde{S}_{nn}(\omega) = \frac{N_0}{2}$ . The output of receiver-filter  $y(z, t)$  contains the photoacoustic signal  $y_s(z, t)$  and the noise signal  $y_n(z, t)$  and is given by

$$y(z, t) = y_s(z, t) + y_n(z, t) \quad (3)$$

where

$$\begin{aligned} y_s(z, t) &= r(t)^* g(z, t)^* I(t) \\ \text{or } \tilde{y}_s(z, \omega) &= \tilde{R}(\omega) \tilde{G}(z, \omega) \tilde{I}(\omega) \end{aligned} \quad (4)$$

$$\begin{aligned} y_n(z, t) &= r(t)^* n(t) \\ \text{or } \tilde{y}_n(\omega) &= \tilde{R}(\omega) \tilde{S}_{nn}(\omega) \end{aligned} \quad (5)$$

Given a chosen waveform/receiver filter pair, the instantaneous signal-to-noise ratio (SNR) at time  $t_0$  is defined as

$$SNR = \left( \frac{S}{N} \right)_{t_0} = \frac{|y_s(z, t_0)|^2}{E|y_n(z, t_0)|^2} \quad (6)$$

where  $E|y_n(z, t_0)|$  refers to the noise expectation value.

### III. MATCHED-FILTER AND THE CHIRP

Matched-filtering is a traditional way to improve SNR in radar technology, and the transfer function of the receiver-filter for the ideal matched-filter for any arbitrary input waveform  $I(t)$  is given by [17]

$$\tilde{R}(\omega) = k \tilde{G}^*(z, \omega) \tilde{I}(\omega) e^{-i\omega t_0} \quad (7)$$

where  $k$  is a scaling constant. However, (7) is not necessarily implementable for a typical photoacoustic system since  $\tilde{G}(z, \omega)$  (determined by the absorber profile) is not known apriori. In this case, the receiver-filter is implemented as

$$\tilde{R}(\omega) = k \tilde{I}^*(\omega) e^{-i\omega t_0} \quad (8)$$

Under the condition of (8), (4) becomes

$$\tilde{y}_s(z, \omega) = k \underbrace{\tilde{G}(z, \omega) \tilde{I}(\omega) \tilde{I}^*(\omega)}_{\tilde{I}^{SD}(\omega)} e^{-i\omega t_0} \quad (9)$$

In (9),  $k$  is simply a scaling factor and the  $e^{-i\omega t_0}$  is just a time delay. Hence, (9) can be interpreted in input/output form as a pressure response to an input pulse  $\tilde{I}^{SD}(\omega)$  where  $\tilde{I}^{SD}(\omega) = |\tilde{I}(\omega)|^2$  is the spectral energy density of  $I(t)$ . The inverse Fourier transform of  $|\tilde{I}(\omega)|^2$  in time domain is known to be

$$R_H(t) = \int_{-\infty}^{\infty} I(t+\tau) \overline{I(\tau)} d\tau \quad (10)$$

which is the autocorrelation of  $I(t)$ . The SNR in (6) can then be then written

$$SNR = \frac{\frac{1}{\pi} \left| \int_{-\infty}^{\infty} \tilde{G}(z, \omega) |\tilde{I}(\omega)|^2 d\omega \right|^2}{N_0 \int_{-\infty}^{\infty} |\tilde{I}(\omega)|^2 d\omega} \quad (11)$$

By implementing matched-filtering, the SNR is improved. However,  $R_H(t)$  generally has a longer duration than  $I(t)$ , which may lead to a worse resolution. However, there exist classes of specific waveforms which possess the property of pulse compression, which means that the waveform will have shorter duration after autocorrelation. The chirp is one such waveform that can be compressed and is given by

$$I_T(t) = \begin{cases} \cos\left(2\pi f_0 t + \frac{\pi \Delta t^2}{T}\right) & |t| < \frac{T}{2} \\ 0 & |t| > \frac{T}{2} \end{cases} \quad (12)$$

where  $T$  is the duration of the chirp. During the  $T$  second interval of the pulse, the instantaneous frequency changes linearly from  $(f_0 - KT/2)$  Hz to  $(f_0 + KT/2)$  Hz. The sweep  $\Delta$  is the difference in these two values. The  $|\tilde{I}(\omega)|^2$  of the chirp shown in (11) can be approximated as a rectangular function and is given by [18]

$$|\tilde{I}_T(f)|^2 \approx \begin{cases} \frac{T}{4\Delta} & f - \frac{\Delta}{2} \leq f \leq f_0 + \frac{\Delta}{2} \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

#### IV. CHIRP PARAMETER EFFECTS ON SNR

From (11), it becomes clear that the SNR is determined by the absorber frequency spectrum that lies within the frequency interval bounded by the chirp sweep range  $f_0 + \frac{\Delta}{2}$

and  $f_0 - \frac{\Delta}{2}$ . Now consider a simple bandlimited absorber.

The bandlimited absorber is considered as a square function in the frequency domain as

$$\hat{A}(f) = \begin{cases} 1 & |f| \leq \frac{\Delta_a}{2} \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

Taking the chirp rectangular approximation shown in (13), the equation of SNR for a bandlimited absorber can be written as

$$SNR = \frac{TC}{\Delta^2} (Overlapping Area)^2 \quad (15)$$

where  $C = \frac{p_0^2}{16\pi N_0 c_s^2}$  is a constant factor which is independent of the chirp, and the overlapping area is the shaded area shown in Figure 2. It is obvious from (15) that SNR is proportional to chirp duration  $T$ .

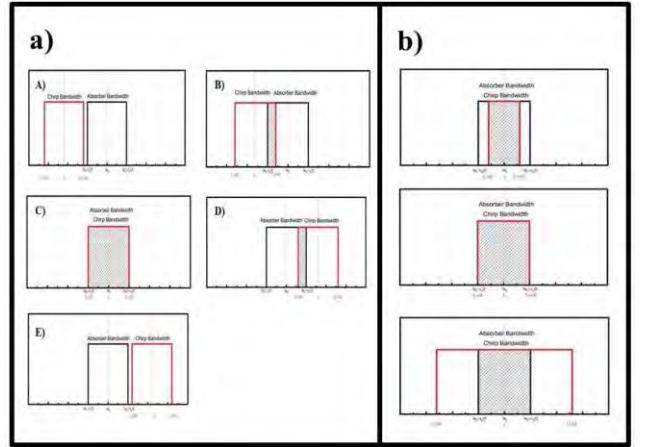

Figure 2. Bandlimited absorber and chirp frequency spectrum

In Figure 2., the black boxes denote the bandlimited absorber frequency spectrum, and the red boxes denote the rectangular approximation of the chirp spectrum. Figure 2. a) shows that the chirp bandwidth  $\Delta$  remains constant and the chirp center frequency  $f_0$  moves from left to right of the absorber. The relationship between SNR and  $f_0$  is shown in Figure 3. a). The SNR first increases with  $f_0$  until a maximum value is reached and then decreases, corresponding to the overlapping conditions. Figure 2. b) visualize the overlapping conditions when the chirp center frequency remains constant and bandwidth increases. The trend of the SNR is shown in Figure 3. b). The overall trend is that SNR decreases with increasing chirp bandwidth, and the maximum value occurs when the chirp bandwidth is smaller or equal to the absorber bandwidth,  $\Delta \leq \Delta_a$ .

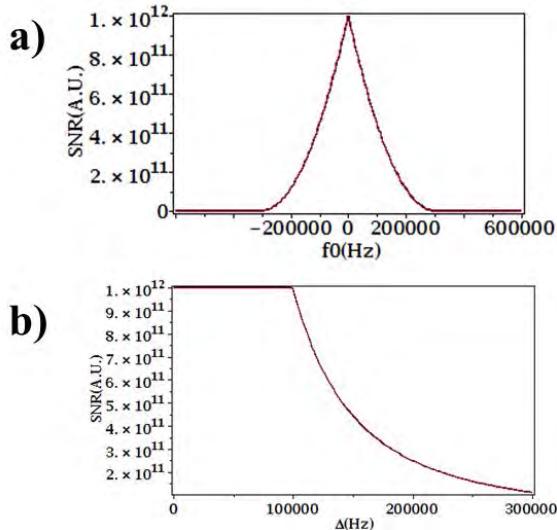

Figure 3. Bandlimited absorber and chirp frequency spectrum

In conclusion, by controlling the chirp parameters, the SNR for a photoacoustic radar signal can be optimized. In order to get a higher SNR, chirp duration  $T$  should be maximized, chirp center frequency  $f_0$  should be controlled to make the chirp spectrum overlap with that of the absorber spectrum, and chirp bandwidth  $\Delta$  should be smaller or equal to the absorber bandwidth.

**Abstract**— Oscillatory Behavior-based Signal Decomposition (OBSD) is a new technique which decomposes a signal according to oscillatory behavior, instead of frequency bands. It has been used for bearing fault signature extraction under constant speed conditions, where the bearing fault-induced vibration signal can be regarded as a low oscillatory component and the interference can be regarded as a high oscillatory component. However, its effectiveness for bearing fault signature extraction under time-varying speed conditions has not been evaluated. Theoretically, the OBSD is a frequency-independent method and should thus be effective under time-varying speed conditions. In this paper, the performance of the OBSD for bearing fault signature extraction under time-varying speed conditions is examined. The results show that the OBSD can be effectively utilized to extract the bearing fault signature under time-varying speed conditions.

**Keywords-** *Bearing fault feature extraction; Time-varying speed; Oscillatory behavior-based signal decomposition*

## I. INTRODUCTION

Bearing fault diagnosis is a useful means to prevent early bearing faults from developing into severe faults, which may lead to machine breakdown. Bearing faults can be detected and diagnosed by observing the Fault Characteristic Frequency (FCF) and its harmonics in the frequency domain of the vibration signal [1]. Each type of fault has a specific FCF, which is proportional to the rotational speed [2]. However, the collected bearing vibration signal is often contaminated by random noise and interferences transmitted from other sources, such as gears. Therefore, bearing fault signature extraction is an important step to insure the accuracy of bearing fault diagnosis.

Band-pass filtering is a commonly used method to extract the bearing fault signature [3]–[5]. The essence of this method is to remove the interference signal by using band-pass filters. However, the effectiveness of band-pass filters can be suppressed if the bearing fault-induced signal and the

inference signal have similar frequency features. Additionally, in reality bearings are often operated under time-varying speed conditions which may also reduce the effectiveness of band-pass filters. Therefore, it is necessary to implement frequency-independent methods to extract bearing fault signatures under time-varying speed conditions.

Oscillatory Behavior-based Signal Decomposition (OBSD) is a newly developed method which can be used to decompose a signal according to oscillatory behavior, instead of frequency bands [6]. It can be implemented to extract the bearing fault signature from the signal contaminated by interferences since the bearing fault-induced signal can be considered as a low oscillatory component and the inference signal can be considered as a high oscillatory component. Its effectiveness for bearing fault signature extraction under constant speed condition has been validated [7]. However, the performance of the OBSD for bearing fault signature extraction under time-varying speed conditions has not been examined. Theoretically, the OBSD should be still effective under time-varying speed conditions since it is frequency-independent.

In this paper, the performance of the OBSD for bearing fault signature extraction under time-varying speed conditions is investigated. Signals collected from experimental apparatus are used to examine the effectiveness of the OBSD.

## II. OSCILLATORY BEHAVIOR-BASED SIGNAL DECOMPOSITION

The essence of the OBSD method is utilizing two sets of wavelets with two different oscillatory behaviors to estimate a given signal [6]. The signal is decomposed into a low oscillatory component and a high oscillatory component by the OBSD. Therefore, the OBSD method can be used to extract the bearing fault signature from a signal obscured by interferences.

Compared to frequency or scale based methods for interference removal, the OBSD is superior since the signal decomposition is based on oscillatory behavior instead of frequencies. A Q-factor, defined as the ratio of the center

frequency to the bandwidth of the frequency response, is used to describe the oscillatory behavior of a wavelet [8]. A higher value of the Q-factor indicates a higher level of oscillation. Four wavelets and their frequency spectra are shown in Figure 1. The Q-factors of the waveforms are also given. It can be seen that waveform 1 and waveform 2 have different oscillatory behaviors, however, their frequency spectra share the same center frequency. The same can be observed for waveform 3 and waveform 4. Under such circumstances, frequency-based band-pass filters would not be able to separate waveforms 1 and 2, nor waveforms 3 and 4. However, they can be separated according to their Q-factors. It is calculated that waveforms 1 and 3 have a Q-factor of 1 since they exhibit low oscillatory behavior, and waveforms 2 and 4 have a Q-factor of 5 since they have relatively high oscillatory behavior. Additionally, this demonstrates that waveforms that have the same oscillatory behavior have the same the Q-factor, even if the center frequencies are different. This makes the OBSD effective for capturing the true features that are useful for bearing fault signature extraction under time-varying speed conditions.

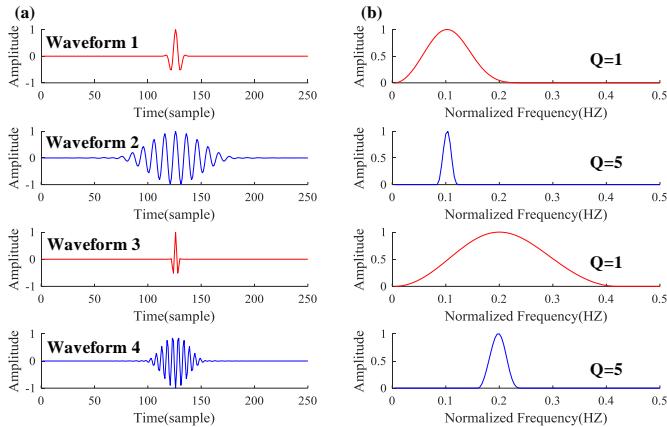

Figure 1 Wavelets and their frequency spectra

The OBSD method employs the Tunable Q-factor Wavelet Transform (TQWT) and Morphological Component Analysis (MCA) to realize the signal decomposition [6]. The TQWT is used to generate a set of wavelets that have the same Q-factor, i.e. the same oscillatory behavior. The wavelets can be obtained with the selection of three parameters,  $Q$  (Q-factor),  $r$  and  $P$ , where  $Q$  is related to the oscillatory behavior,  $r$  is related to the redundancy of the frequency responses, and  $P$  is the number of wavelets. By setting up two sets of wavelets, one with low oscillatory behavior with parameters  $Q_l$ ,  $r_l$ , and  $P_l$ , and the other set with high oscillatory behavior with parameters  $Q_h$ ,  $r_h$ , and  $P_h$ , then the signal decomposition can be completed by MCA. The wavelet coefficients are obtained via optimization [6] as

$$\begin{cases} \mathbf{w}_h^{opt} \\ \mathbf{w}_l^{opt} \end{cases} = \arg \min_{\mathbf{w}_l, \mathbf{w}_h} \|\mathbf{y} - \mathbf{S}_l \mathbf{w}_l - \mathbf{S}_h \mathbf{w}_h\|_2^2 + \lambda_l \|\mathbf{w}_l\|_1 + \lambda_h \|\mathbf{w}_h\|_1 \quad (1)$$

where  $\mathbf{w}_l$  refers to wavelet coefficients for the low oscillatory component,  $\mathbf{w}_h$  stands for the wavelet coefficients for the high oscillatory component,  $\mathbf{w}_l^{opt}$  and  $\mathbf{w}_h^{opt}$  are results after

optimization,  $\mathbf{y}$  is the signal to be decomposed,  $\mathbf{S}_l$  refers to wavelets obtained via the TWQT for the low oscillatory component,  $\mathbf{S}_h$  represents wavelets for the high oscillatory component,  $\lambda_l$  is the regularization parameter for the low oscillatory component,  $\lambda_h$  is the regularization parameter for the high oscillatory component, and  $\|\cdot\|_1$  and  $\|\cdot\|_2$  are the norm-1 operation and the norm-2 operation, respectively. This optimization problem can be solved using an iterative algorithm called the Split Augmented Lagrangian Shrinkage Algorithm (SALSA), obtained as [6]

$$_i = f(\mathbf{w}_i^{k-1}, \mu), i = l, h, k = 1, 2, \dots, K \quad (2)$$

where  $\mu$  is the penalty parameter and  $K$  is the maximum number of iterations. Details of the solution can be found in the appendix in [7]. By selecting the maximum number of iterations, the optimal wavelet coefficients are obtained as

$$\mathbf{w}_i^{opt} = \mathbf{w}_i^K, i = l, h \quad (3)$$

With the calculated wavelet coefficients, the decomposed low oscillatory and high oscillatory components can then be obtained by inverse TQWT with the optimized wavelet coefficients.

### III. IMPLEMENTATION OF OBSD ON BEARING FAULT FEATURE EXTRACTION UNDER TIME-VARYING SPEED CONDITIONS

According to the characteristics of the bearing fault-induced signal and the interference signal, the bearing fault-induced signal is more impulsive, which can be considered as low oscillatory behavior, and the interference is smoother which can be considered as high oscillatory behavior [9]. Therefore, the decomposed low oscillatory component and the high oscillatory component via the OBSD are taken to be the bearing fault signature and interference, respectively.

The bearing fault-induced signal can be simulated as impulse responses which occur at the FCF along the time span [10]. For a bearing operating under time-varying speed conditions, the equation is given as [11]

$$x(t) = \sum_{m=1}^M L_m e^{-\beta(t-t_m)} \sin[\omega_r(t-t_m) + \phi_m] u(t-t_m) \quad (4)$$

where  $M$  is the number of impulse responses which is determined by the signal length  $T$  and Instantaneous Fault Characteristic Frequency (IFCF),  $L_m$  is the amplitude of the  $m$ th impulse response,  $\beta$  is the coefficient related to damping,  $\omega_r$  is the excited resonance frequency or damped frequency of the vibration system,  $\phi_m$  is the phase of the  $m$ th impulse response, and  $u(t)$  is unit step function. In the previous equation,  $t_m$  is the occurrence time of the  $m$ th impulse response which is calculated as

$$\begin{cases} t_1 = (1+\delta_1)[1/f_c(t_0)] \\ t_m = (1+\delta_m)[1/f_c(0) + \dots + 1/f_c(t_{m-1})] \end{cases} m = 2, 3, \dots, M \quad (5)$$

where  $t_0=0$ ,  $\delta_m$  is the random slippage ratio with the average varying between 0.01 and 0.02,  $f_c(t)$  denotes the IFCF, and the time interval between the  $(m-1)$ th impulse response and the  $m$ th impulse response is  $(1+\delta)/f_c(t_{m-1})$ .

The interference signal can be simulated as the sum of sinusoidal functions of the frequency of the interference and its harmonics, given as [11]

$$h(t) = \sum_{n=1}^N B_n \sin(2\pi n f_h t) \quad (6)$$

where  $N$  is the number of sinusoidal functions,  $B_n$  is the amplitude, and  $f_h$  is the time-varying frequency of the interference, called Instantaneous Interference Frequency (IIF) in this paper.

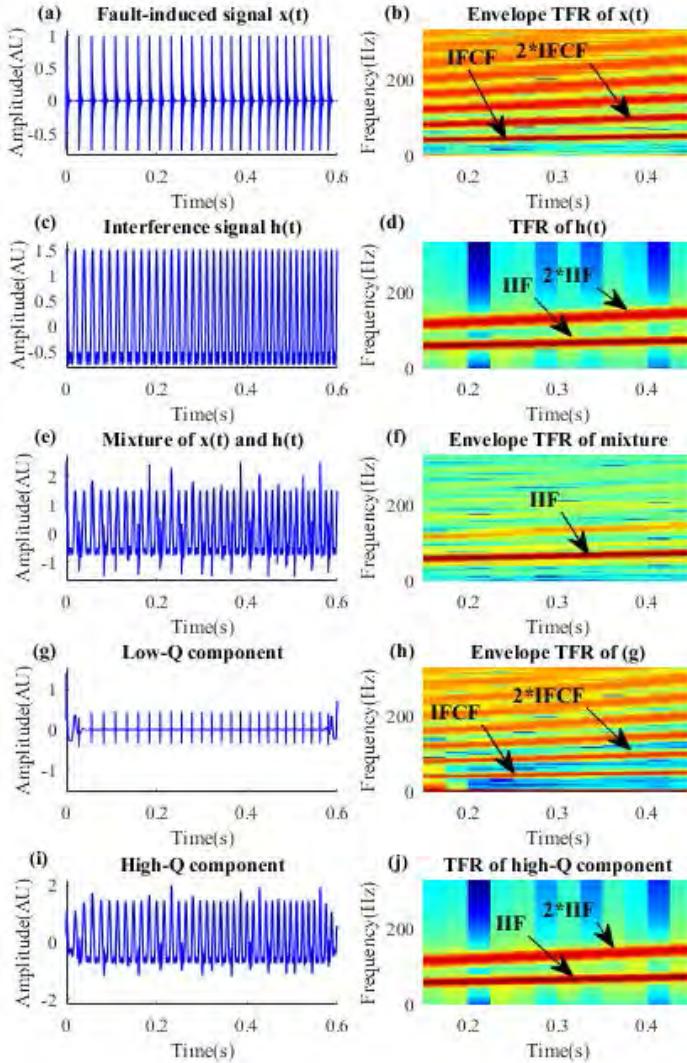

Figure 2 Implementation of the OBSD on bearing fault signature extraction under time-varying speed conditions

An example of the implementation of the OBSD on bearing fault signature extraction is illustrated in Figure 2. The original signal, shown in Figure 2(e), is a mixture of bearing fault impulses (Figure 2(a)) and interference (Figure 2(c)). The bearing fault signal is modeled by equation (4) with IFCF  $f_c(t)=35t+35$  Hz,  $L_m=1$ ,  $\beta=500$ ,  $\omega_r=4000*2\pi$  rad/s,  $\phi_m=0$ ,  $\delta_m=0.01$  and signal length  $T=0.6s$ . In addition, the interference is modeled by equation (6) with  $f_h=50t+50$  Hz,  $N=2$  and  $B_n=[1, 0.5]$ . Under constant speed, the bearing fault is generally detected by the envelope spectrum which is the spectrum of the envelope preceded by the computation of a Hilbert

transform [2]. Under time-varying speed, since the IFCF and its harmonics are time-varying, they can be observed in the Time-Frequency Representation (TFR) obtained via Short-Time Fourier Transform (STFT) [12]. As shown in Figure 2(b), the envelope TFR of the bearing fault-induced signal is composed of time-frequency curves at IFCF and its multiples, which can be used to detect the presence of a bearing fault. Similarly, the frequency of interference IIF and its 2<sup>nd</sup> harmonic show curves in the TFR of the interference signal, shown in Figure 2(d). However, it can be seen from Figure 2(f) that the envelope TFR of the original signal is dominated by the IIF, which implies that the bearing fault cannot be detected without additional signal treatment. By applying the OBSD to the contaminated original signal with OBSD parameters  $Q_f=1$ ,  $r_f=6$ ,  $P_f=40$ ,  $Q_h=6$ ,  $r_h=6$ ,  $P_h=124$ ,  $\lambda_f=\lambda_h=0.3$ ,  $\mu=2$  and  $K=150$ , the signal is decomposed into a low oscillatory component (shown in Figure 2(g)) and a high oscillatory component (shown in Figure 2(i)). The bearing fault-induced impulses, which is the fault signature, are clearly seen in the low oscillatory component (Figure 2(g)). Furthermore, the envelope TFR of the low oscillatory component, shown in Figure 2(h), is dominated by the IFCF and its harmonics which is the same case as in Figure 2(b). The bearing fault can thus be easily detected. Additionally, the TFR of the high oscillatory component shown in Figure 2(j) is dominated by the IIF and its 2<sup>nd</sup> harmonic, which is the same case as in Figure 2(d). It can be seen from this implementation that the OBSD can be effectively used to separate the bearing fault signature from a signal contaminated by interference under time-varying speed conditions.

#### IV. EXPERIMENTAL EVALUATION

To test the performance of the OBSD method for bearing fault signature extraction under time-varying speed conditions, it is applied to signals collected from an experiment. The experiment is conducted on a SpectraQuest machinery fault simulator (MFS-PK5MT) to collect the bearing vibration signal which is contaminated by interference transmitted from a gearbox and noise.

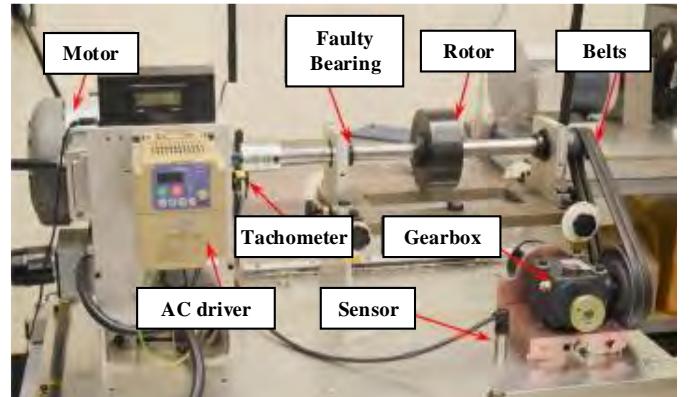

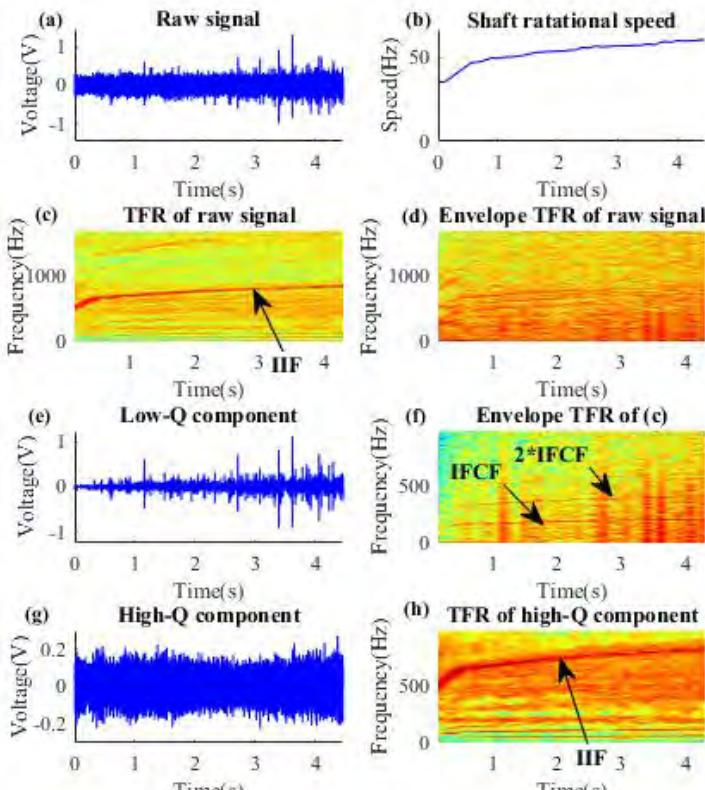

Figure 3 Experimental set-up

The set-up of this experiment is shown in Figure 3. The shaft is supported by two bearings and one of them is a faulty bearing with an outer race fault. The shaft is driven by a motor

**Abstract**— Interaural Intensity Difference (IID) in binaural sonar systems is used for echolocation and obstacle sensing. In this article, we show by simulation the optimized system's parameters in terms of frequency, sensor separation distance and the working range for an IID based binaural sonar sensing system. Our result shows that the best performances with a frequency range between 100 to 300 kHz and a separation distance, depending on the size of the microphone, in our case between 2 cm to 5 cm within the working range of 1 m. The approach developed in this paper could be useful for mobile localization and mapping, particularly in compact size mobile devices.

**Keywords-component;** acoustic sensor, binaural system, Interaural Intensity Difference.

## I. INTRODUCTION

Ultrasonic sensors are robust and low-cost, well suited for identifying objects/obstacles within a few meters, typically configured with an array of emitters and receivers to achieve an accurate mapping of the surrounding environment. Binaural ultrasonic sensors are inspired by natural hearing systems where two ultrasonic receivers flank an ultrasonic emitter. In a binaural ultrasonic the object's distance and bearing angle can be estimated from the differences in interaural time [1]–[5], amplitude [6], intensity [7]–[9] and/or phase [10], [11]. It is known that interaural time and phase difference are appreciable with low-frequency sounds. With high-frequency sounds, the interaural difference in amplitude or intensity is more convenient. For instance, bat's echolocation system uses Interaural Intensity Difference (IID) at two different frequencies as the cue to the direction of a prey [12].

In a binaural system, the degree of accuracy depends on the separation distance between the two receivers for interaural time difference cue. The sonar separation must be much larger than the wavelength of the sonic wave in use. The separation distance is usually 10's of centimeters to 10's of meters [13]. When the separation between the receiver microphones is large compared to the object's distance, there is a risk that one of the receivers does not pick up the signal. If the microphones are

too close to each other (similar to miniature animals with little separation between the two ears), both microphones record essentially the same acoustic signal. This results in very small interaural amplitude and time cues, posing substantial challenges to directional sensitivity of the auditory system [14]. To amplify the interaural difference, fly-ear inspired acoustic sensors consisting of two wings mechanically coupled at the middle have been recently developed [15].

In this article, we will show by simulation that the approach using IID makes it possible to place the receivers as close together as their size permits and thus making small size sonar system where interaural time difference measurement is not convenient. Our binaural system consists of a single emitter scanning across the range of incident angle flanked by two receivers (Figure 1). In this paper, we develop a mathematical model relating systems parameters in an IID based binaural sonar sensing system. We later utilized the model to demonstrate that the sensor performance for object identification using IID is enhanced under certain frequency and separation range. In the next sections, we will establish the concept from a theoretical perspective, and subsequently, simulate results to evaluate the model.

## II. MATHEMATICAL FORMULATION

The geometry of our binaural sonar system is depicted in **Error! Reference source not found.**, which consists of a transmitter flanked by two fixed receivers. In the model, the transmitter and receivers are assumed to be of piston shape, with the transmitter located at the origin, and the two receivers at distance  $d$  to its left and right sides. As illustrated in Fig. 1, the object coordinate with respect to the emitter placed at the center of the polar coordinate system is  $(r, \beta)$ , where  $r$  is the radial distance and  $\beta$  is the azimuth angle. The angular deviation is measured with respect to the normal line through the emitter, and it takes positive values in the clockwise direction. Likewise, the object coordinate with respect to the receiver is  $(r_r, \beta_r)$ . Note that  $\beta_r$  is measured with respect to the line that passes through the center of the object. It is parallel to the emitter's normal and is positive in the clockwise direction.

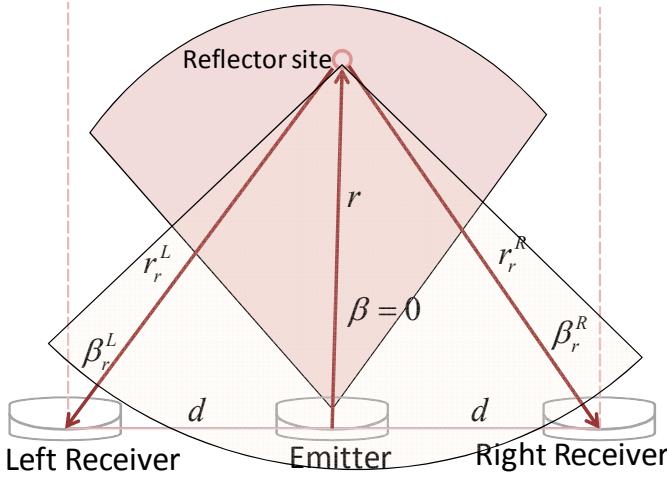

Figure 1. The geometry of the binaural sonar system with rotating emitter.

If a small object is ensonified by the emitter, it re-emits a spherical field that can be detected by a receiver. For piston-shaped emitter and receiver, the pressure field identified by the receiver can be described by [16], [17]

$$P_D(k, r, \beta, r_r, \beta_r) = \frac{\rho c \sigma}{2} U_0 \frac{k a_e^2 a_r^2}{r_e r_r} \cdot \frac{2 J_1[k a_e \sin(\beta)]}{k a_e \sin(\beta)} \cdot \frac{2 J_1[k a_r \sin(\beta_r)]}{k a_r \sin(\beta_r)}, \quad (1)$$

where  $a_e$  and  $a_r$  are, respectively, the radius of the circular emitter and of the receiver surface,  $k$  is the wavenumber relates to the frequency via  $2\pi f/c$ ,  $c$  is the speed of sound,  $\rho$  is the air density,  $J_1$  is the Bessel function of the first kind, and  $\sigma$  is the scattering coefficient, the ratio of the scattering and the incident fields. As depicted in Figure 1., the position of the object to the left or right of the receivers is obtained from

$$r_r^{L,R} = \sqrt{d^2 + r^2 - 2dr \cos(\pi/2 \pm \beta)}, \quad (2)$$

and

$$\beta_r^{L,R} = \left| \sin^{-1} \left( \frac{d \cos(\beta)}{r_r^{L,R}} \right) \pm \beta \right|, \quad (3)$$

where the superscripts L and R denote the left and the right receivers also are shown in Figure 1. Once the echo is detected by both receivers on the two sides of the emitter, the Interaural Intensity Difference (IID) is measured from absolute difference of the detected intensities that is the squared of amplitudes defined by Eq.(1).

### III. SIMULATION

The theoretical model developed in the previous section is simulated by sweeping the parameters of the system

to evaluate the performance of the model in detecting an obstacle. A typical example of the detected intensities and the IID is presented in Figure 2. In this example plot, we set  $a_e = a_r = 4.25$  mm,  $U_0 = 1000$ ,  $r = 30$  cm,  $d = 5$  cm at 50 kHz frequency.

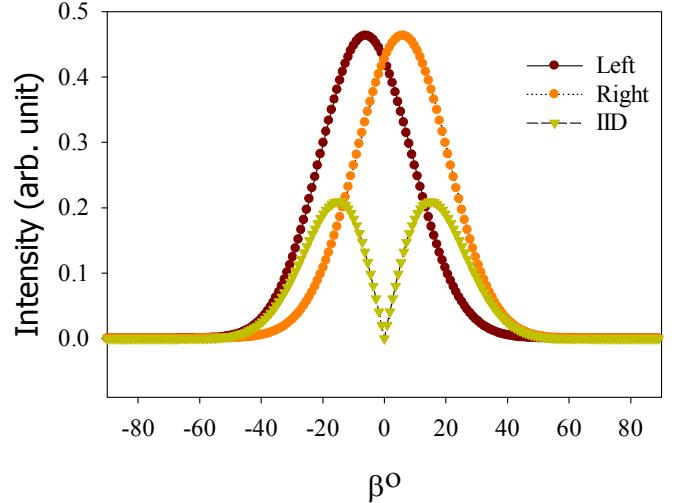

Figure 2. The detected intensities by the left and the right microphones and the IID.

In Figure 2. a point object is scanned for a range of azimuth angle from  $-\pi/2$  to  $+\pi/2$ . It is observed that the intensity captured by each microphone is largest when the object is just above the microphone. The quantity of our interest is the IID that is zero when the object is aligned with the sonar axis as the sensor scans the environment. We use this property of the IID to scan the environment searching for obstacles for various system's parameters as frequency, the separation distance between the emitter and the receiver and working range.

The crucial condition here is that the zero point of the IID must be differentiable from other parts of the signal. In other words, the contrast between the zero and the maximum of the IID signal and the slope of the curve from the maximum towards the zero point defines the performance of such system to identify the obstacle effectively. In the next section, we will evaluate necessary conditions for best performance including the system's parameters of frequency ( $f$ ), separation distance ( $d$ ) and working range ( $r$ ).

#### A. Tuning system's parameters

In this section, we identify optimal parameters for the emitter frequency ( $f$ ), the separation between the microphones and the emitter ( $d$ ), and the working range ( $r$ ). To realize this, various combinations of  $f$ ,  $d$ , and  $r$  were simultaneously explored while looking for systematic variations in the IID contrast.

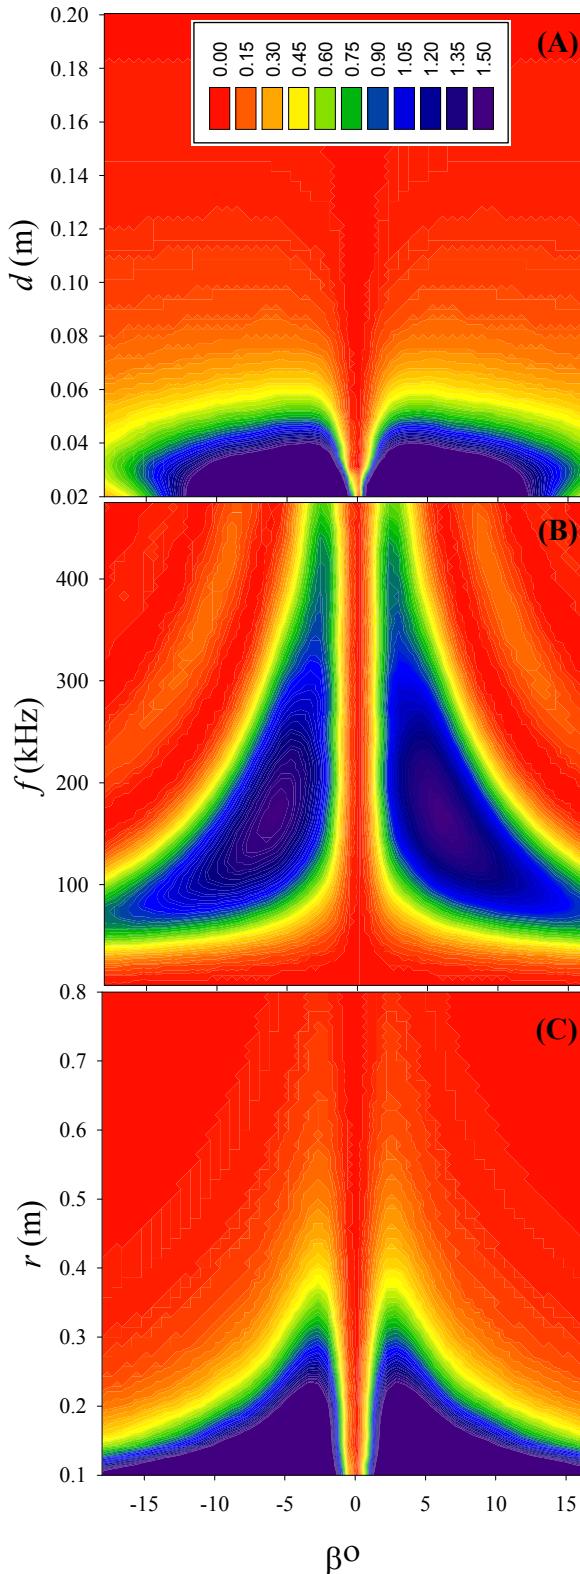

Figure 3. Color map of IID for a range of separation distance (A), frequency (B) and working range (C) respectively.

The simulation test results for the IID variation with system's parameters are plotted in Figure 3. where the horizontal axis corresponds to the scanning angle  $\beta$ . In Figure 3., red signifies low contrast, and blue denotes higher contrast desirable for better performance.

Figure 3. corresponds to the IID map with respect to varying separation distance between the emitter and the microphone ( $d$ ) that is swept from 2 cm to 20 cm. From Figure 2. Figure 3. (A) it is observed that the best performance of the sonar system corresponds to the small separation between the emitter and microphones i.e. up to 6 cm. The large separation will degrade the performance of the system especially with high-frequency ultrasonic waves where they are highly directive and therefore the IID contrast gradually fades away with increasing the separation distance. In other words, large separation is permissible with low-frequency source but will be impractical with high frequencies. This fact is shown in Figure 4. where the IID contour is plotted for a range of frequency versus separation distance. As the figure shows, with increasing the frequency, the separation distance that gives appreciable IID contrast would be limited to small distances.

In Figure 3. (B), the IID map is provided with respect to varying frequency from 1 kHz up to 500 kHz. In this figure, the suitable frequency range is observed to be between 100 to 300 kHz with the best performance around 200 kHz. The system is impractical for frequencies lower than 20 kHz since the acoustic wave loses its directivity and the microphones record almost similar pressure field regardless of the separation distance. The system also works with frequencies higher than 300 kHz; however, side lobes appear in the recorded fields as well as the IID, which may make it difficult to distinguish the main IID zero from the side lobes. One possible approach with high-frequency emitter source is to reduce the separation distance as suggested in Figure 2. Figure 3. (A).

Regarding the working range of the system in Figure 2. Figure 3. (C), the radial distance from the emitter is swept from 10 cm up to 100 cm. It is observed that the performance degrades with distance with the best performance correspond to distances lower than 50 cm. This is also due to the ultrasonic natural degradation with distance. This limitation, however, can be easily overcome by increasing the emitter's power to generate stronger pressure fields.

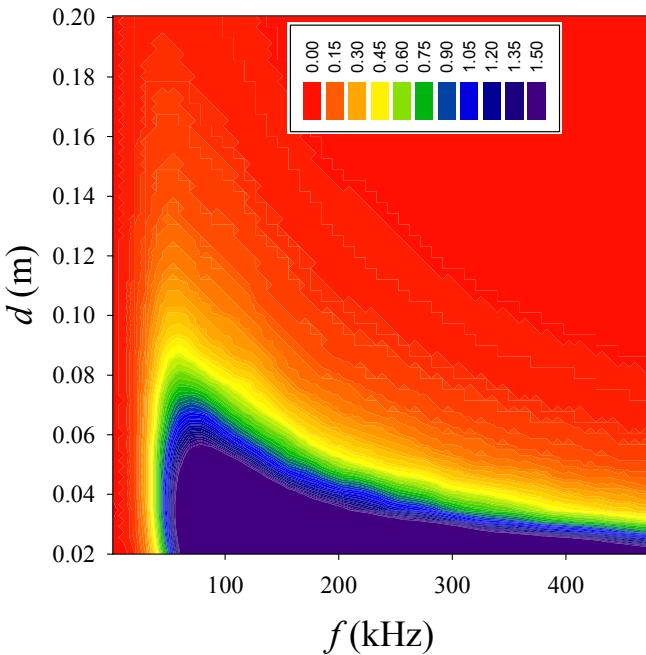

Figure 4. The IID contour for a range of frequency versus separation distance.

With respect to the above-findings, a suitable sonar system for working range within 1m would consist of a transducer that emits ultrasonic pulses of  $100 \text{ kHz} \leq f \leq 300 \text{ kHz}$ , flanked by two microphones separated by  $d < 5 \text{ cm}$ .

#### IV. CONCLUSION

In this paper, we presented the optimization of binaural sonar systems for object detection using IID measurement. This system as showed in this article is suitable for sonar systems where time of flight measurement is not practical. The simulation result showed that the performance of such system is enhanced with a frequency range between 100 to 300 kHz with the best performance around 200 kHz and the separation distance between the emitter and receiver up to maximum 6 cm within the working range of 1 m.

# Design of Electronic Stability Control (ESC) Systems for Car-trailer Combinations

Mutaz Keldani, Yuping He

University of Ontario Institute of Technology  
Department of Automotive Engineering  
Oshawa, Canada

Mutaz.keldani@uoit.net, Yuping.he@uoit.ca

**Abstract**— This paper presents the design of an electronic stability control (ESC) system based on trailer differential braking for increasing safety and improving handling performance of car-trailer combinations. Numerical simulations were performed using CarSim software to assess the performance of the proposed control strategies of the ESC system. To validate the virtual design of the ESC system for car-trailer combinations, a small scaled physical prototype (1:10) of a car-trailer combination was fabricated and tested. The prototype consists of an aluminum frame, accelerometer, and two wheels equipped with an electromagnetic differential braking. Numerical simulation and prototype testing demonstrated the effectiveness of the proposed ESC system for car-trailer combinations.

**Keywords:** *electronic stability control; lateral acceleration; differential braking; car-trailer combination*

## I. INTRODUCTION

Car-trailers are easy to own recently for several reasons, such as, their low cost, availability, and simplicity of the design. However, trailer safety systems and technology are outdated and not increasing at the same rate as passenger vehicles. For example, In Ontario, towing a trailer with a gross vehicle weight of up to 4,600 Kilograms does not require a higher driving license class. In addition, the Ministry of Transportation of Ontario does not have any regulations regarding the braking system required to ensure the safety of the trailer [1].

Car trailers usually face two of the most dangerous scenarios, known as sway and jackknifing [2]. In addition, rollovers have a huge impact on the trailer's stability. Rollovers occur due to different reasons such as; high speeds, crosswinds, road conditions and center of gravity of the trailer, which could be, affected by the way the trailer was loaded.

Understanding why each of sway, jackknifing and rollovers occur will result in an effective robust ESC controller. First, sway is defined as the unusual lateral motion that the trailers go through due to several reasons, such as; side passing wing on open roads, bow wind produced by commercial vehicles and lastly, the load distribution inside the trailer which has an effect

on the tongue load. Moving sideways will result in pendulum motion [3], which cause the car-trailer combination to lose stability. Load distribution has an impact on the braking distribution force, as the trailer could lose traction and gripping the road, which allows the trailer to swing and skid [4].

The second major hazard is the rollover, which happens due to sharp turns, high speeds and load distribution. Rollover often occurs when the lateral acceleration of the trailer is larger than the threshold value.

Jackknifing is the third major unstable motion mode. Jackknifing may be caused by several factors, such as momentum of the combination, weather condition, and low friction of road surfaces [5].

To address the aforementioned problems and avoid severe accidents, conventional braking systems may be enhanced by introducing active trailer differential braking systems. An electronic stability control system (ESC) is developed as an important safety feature in passenger vehicles. ESC is an active safety technology that improves the vehicle's stability by assisting the driver to keep the car-trailer combination on the desired path [6].

To implement the functionality of ESC, several vehicle dynamic states can be controlled, such as yaw rate of vehicle units [7], lateral motions of vehicle units [8]. Each of the above mentioned methods requires a car-trailer combination equipped with several sensors to ensure a responsive and accurate system.

Lateral acceleration control has been used for the design of active trailer differential braking system. A small-scale prototype was fabricated and examined to validate the active trailer differential braking system designed in this project, and the lateral-acceleration rearward amplification (RWA) was used as an essential lateral stability measure of the car-trailer combination [9]. Controlling the lateral acceleration of the vehicle units may effectively prevent the occurrence of rearward amplification, in which the trailer has a greater lateral acceleration than the leading unit, which can lead to rollover of the trailer [10].

## II. DESIGN OF AN ACTIVE TRAILER DIFFERENTIAL BRAKING SYSTEM

The design of the electronic stability control (ESC) system involves the modeling of the car-trailer system for controller design, a small-scaled physical prototype fabrication, and performance evaluation. The design process may be divided into two different phases. The first is the design of a virtual prototype, while the second phase is the fabrication of the small-scaled physical prototype to validate the virtual design.

### A. Mathematical Modeling

As shown in Fig. 1, 3 degrees of freedom (DOF) yaw-plane car-trailer model is generated for the ESC controller design.

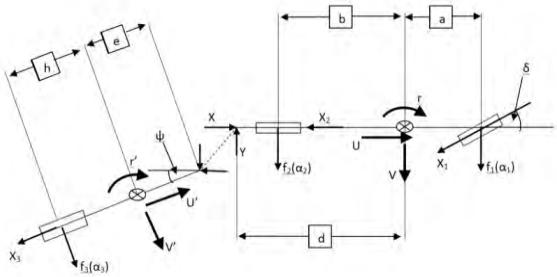

Figure 1. Schematic representation of the 3 DOF yaw-plane car-trailer model and the parameters used [11].

The equations of motion of the leading vehicle are expressed as follows [11]:

$$m_1(\dot{U} - Vr) = -X_1 \cos \delta - X_2 + X \quad (1)$$

$$m_1(\dot{V} + Ur) = f_1(\alpha_1) + f_2(\alpha_2) + X_1 \sin \delta - Y \quad (2)$$

$$I_1 \dot{r} = af_1(\alpha_1) - bf_2(\alpha_2) + aX_1 \sin \delta + dY \quad (3)$$

The trailer's equations of motion are expressed as [11]:

$$m_2(\dot{U}' - V'r') = -X_3 - Y \sin \psi - X \cos \psi \quad (4)$$

$$m_2(\dot{V}' + U'r') = f_3(\alpha_3) + Y \cos \psi - X \sin \psi \quad (5)$$

$$I_2 \dot{r}' = -hf_3(\alpha_3) - e(-Y \cos \psi + X \sin \psi) \quad (6)$$

Due to fact that the trailer is connected to the leading vehicle with an articulated joint, the forward velocity and acceleration of the leading and trailing units are assumed the same. This assumption simplifies the trailer equations of motion and helps linearize them.

In addition, the angle  $\psi$  is approximated to be small, which leads to [11]:

$$\cos(\psi) = 1 \quad (7)$$

$$\sin(\psi) = \psi \quad (8)$$

Also, the following equation is determined at zero initial conditions [11].

$$\dot{\psi} = r - r' \quad (9)$$

Using all the above assumptions and approximations, a linearized equation of motion can be expressed as [11]:

$$M\{\dot{x}\} + D\{x\} + F\delta = 0 \quad (10)$$

where the state variables are written as shown in “(11)” [11]:

$$\{x\} = \{V \ r \ \dot{\psi} \ \psi\} \quad (11)$$

Matrices M,D and F are listed in Appendix A.

The parameters listed in Table 1 are used in the mathematical modeling and CarSim model generation.

TABLE I. PARAMETERS USED TO DESIGN AND TEST A VIRTUAL PROTOTYPE.

Parameters		
Description	Symbol	Value
Leading vehicle mass	$M_L$	1521 Kg
Trailer mass	$M_T$	602 Kg
Distance between CG and front axle	$a$	0.972 m
Distance between CG and rear axle	$b$	1.807 m
Distance between vehicle CG and contact point with the trailer	$d$	4.835 m
Distance between the trailer CG and contact point with the vehicle	$e$	2.00 m
Distance between the CG and the rear axle	$h$	0.6 m
Height of vehicle CG	$H1_{CG}$	0.325 m
Height of trailer CG	$H2_{CG}$	0.676 m
Slip angle	$\delta$	
Longitudinal force on car's front wheel, rear wheel and trailer wheel respectively	$X_{1,2,3}$	
Car,trailer forward velocity	$U,U'$	
Lateral velocity of car and trailer respectively	$V,V'$	
Lateral force on car's front wheel, rear wheel and trailer's wheel respectively	$f_{1,2,3}$	
Car, trailer yaw angle respectively	$r,r'$	
Hitch angle	$\psi$	

Equations (1) to (11) show how to express a mathematical model of a car-trailer combination with some assumptions to linearize the system. However, the trailer differential braking system is designed to generate a counter moment to stabilize the car-trailer combination [10], which will result in the shwon equation [11]:

$$I_2 \dot{r}' = -hf_3(\alpha_3) - e(-Y \cos \psi + X \sin \psi) + \Delta M_z \quad (12)$$

Using the same approximations and assumptions, the governing equations of motion of the car-trailer can be linearized and simplified as the following form [11]:

$$M\{\ddot{x}\} + D\{\dot{x}\} + C_B u + F\delta = 0 \quad (13)$$

where,

$$u = -K_p * \dot{a}_y \quad (14)$$

The lateral acceleration of the trailer ( $\dot{a}_y$ ) can be formulated using mathematical manipulations and operations. However, an accelerometer sensor was used to measure the lateral acceleration of the physical prototype.

### B. ESC Controller Design

There are several types of control techniques that can be used to design an ESC system, such as, PID and LQR [12]. The purpose of this research is not only to design an ESC controller but also to fabricate a small-scaled car-trailer prototype equipped with the ESC system. Thus, a feasible ESC controller is designed. A P-control scheme is used for simplicity of tuning, proving the concept design, and fabricating a small-scaled car-trailer prototype with the ESC.

The block diagram of the controller design is shown in Fig. 2, representing the P-control scheme.

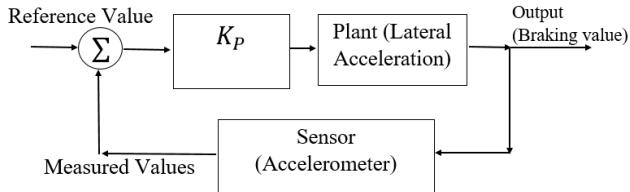

Figure 2. Block diagram representation of the designed system with a P-controller.

### C. Virtual Car-Trailer Prototype with the ESC system

The virtual car-trailer prototype with the ESC system is designed and tested using CarSim software package. CarSim provides various vehicle and trailer models that could be used to simulate selected testing maneuvers.

Since the trailer is the focus of the research, the ESC controller designed in Matlab was integrated in the car-trailer model developed in CarSim. The designed ESC is built upon the existing Anti-Locking Braking System (ABS) of trailers. The ESC controls the right and left brakes of the trailer independently. This is known as differential braking [13]. Differential braking is used to control the yaw moment, which affects the lateral acceleration of the trailer.

To ensure that the ESC is functioning as desired, several testing maneuvers are simulated, such as a double lane change maneuver.

Fig. 3, shows the integration of the ESC controller designed in Matlab/Simulink software and the car-trailer model generated in CarSim software.

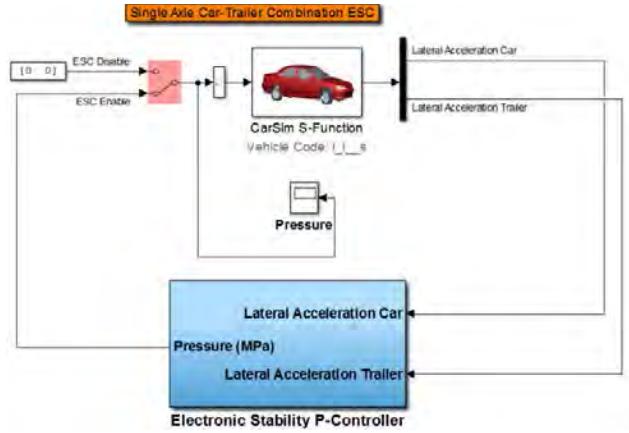

Figure 3. CarSim model of the Car-trailer combination.

The car-trailer block in CarSim exports the lateral acceleration of the leading vehicle and the trailer into the P-Controller based ESC system. The controller multiplies the input by the gain  $K_p$ , and then a generated brake pressure value is sent back to the car-trailer block to apply brakes on a specific wheel. This process continues until the error between the desired and actual lateral accelerations is minimized. The ESC controller is designed to meet the requirements of a differential braking where brakes are applied on each wheel independently. In addition, the controller applies braking force in form of brake pulsing to prevent wheels from locking.

### D. Small-Scaled Physical Car-Trailer Prototype with the ESC System

Once all the results are justified based on the numerical results of the virtual car-trailer prototype with the ESC system, a 1:10 small-scaled physical car-trailer prototype with the ESC system is designed and fabricated. The purpose of building the physical prototype is to conduct similar tests that have been done in CarSim and to compare the performance measures derived from both cases.

Since the physical prototype is equipped with a P-controller, a microcontroller is required on board. An Arduino Uno is used as the brain of the module to simulate all the data gathered by the accelerometer. The designed ESC is stored in the microcontroller to apply the required braking force based on the input of the lateral acceleration. In addition, the fabricated trailer is equipped with differential braking using two electromagnetic brakes. Fig. 4, shows the fabricated prototype with all the mentioned components needed to achieve a functional ESC.

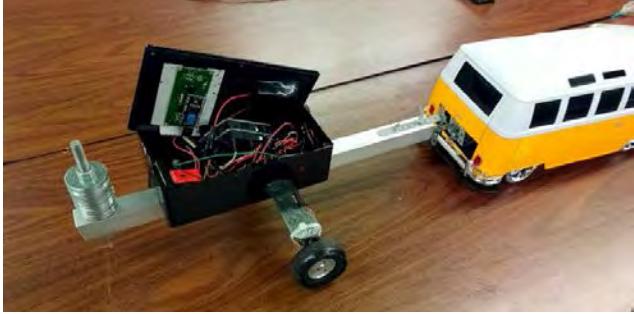

Figure 4. The fabricated 1:10 scale prototype for testing the functionality of the ESC controller.

### III. RESULTS AND DISCUSSION

As mentioned earlier, the car-trailer model developed in CarSim is used to simulate the double lane change maneuver to test the effectiveness of the designed ESC. A representation of double lane change maneuver can be seen in Fig. 5.

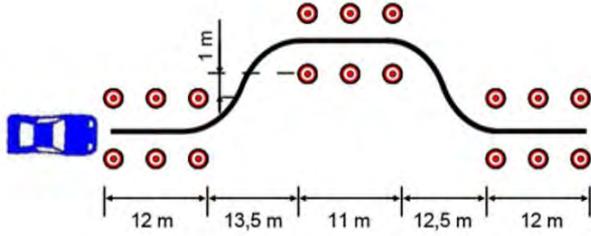

Figure 5. A representation of a double lane change maneuver [14].

The first test is done using the combination of a car towing a trailer, which is not equipped with an ESC. The Fig. 6, shows the graphs representation of the lateral acceleration over time.

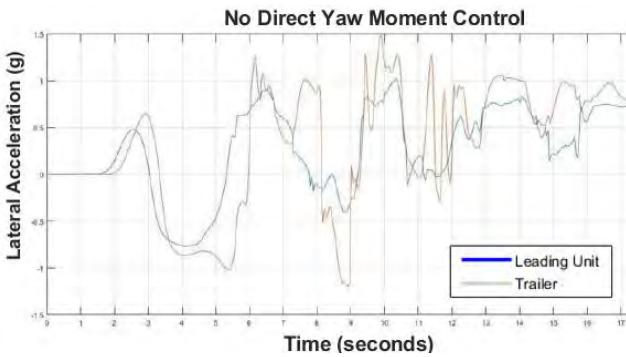

Figure 6. Graph generated from CarSim, representing the behavior of the car-trailer combination when ESC is OFF.

By looking at the graph in Fig. 6, the blue line represents the lateral acceleration of the leading vehicle which gets affected by the trailer in similar scenarios, such as double lane change maneuver, whereas the orange line represents the lateral

acceleration of the trailer. It is concluded that the trailer's reaction has a time delay and then the combination lost stability. In addition, it is also determined that the trailer has a higher lateral acceleration at all times which means the trailer has a larger sway rate than the leading car which results in losing control over the combination.

To examine the system, the same test is done. However, the car-trailer combination is now equipped with the designed ESC. Fig. 7, represents the lateral acceleration over time of the leading vehicle and trailer with the ESC controller.

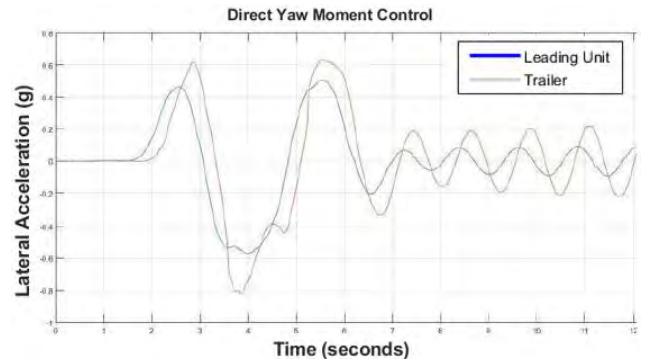

Figure 7. Graph generated from CarSim, representing the behavior of the car-trailer combination when ESC is ON.

By looking at the plots in Fig. 7, the blue curve represents the response of the leading vehicle, where the orange curve represents the trailer's behavior. It is observed that the combination has its lateral acceleration peaks at the turning points. As expected, the trailer has a larger lateral acceleration compared to the leading vehicle. However, the combination does not lose stability and sway is controlled. By looking at the graph between time intervals of 7-18 seconds, the combination has a minor oscillation and that was due to the use of P-controller.

By comparing the behavior of controlled and uncontrolled combination, we conclude that the trailer's lateral acceleration has an impact on the leading vehicle as it loses stability in the first case when the trailer loses stability. In addition, the lateral acceleration of leading vehicle and trailer have a larger amplitude when the combination is not equipped with a controller.

As stated previously, the testing phase for the physical prototype defers from the virtual prototype. To compare the results of the virtual and physical prototype, two test have been done using the physical prototype. Both tests have the same scenario where the vehicle would accelerate to a certain speed using a treadmill until it loses stability. To exert graphs from the physical prototype, a gyroscope is used to calculate the articulation angle between the leading vehicle and the trailer with reference to the leading car. Fig. 8, shows the representation of the articulation angles over time in both controlled and uncontrolled situations based on the testing results using the small-scaled physical car-trailer prototype.

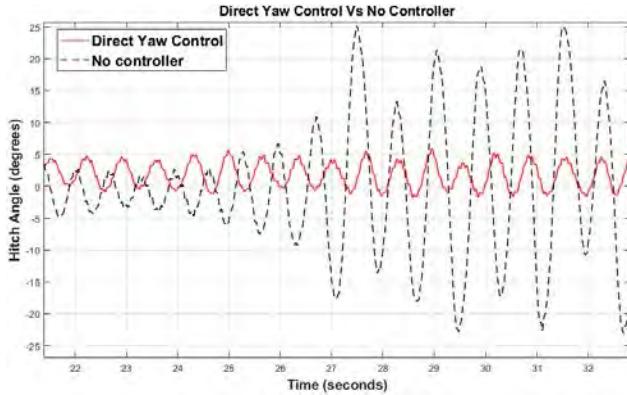

Figure 8. Comparison between the responses of the controlled and uncontrolled car-trailer combination based on the test with the small-scaled car-trailer prototype.

#### IV. CONCLUSION

An active trailer differential braking controller is designed using the P-control technique based on a 3-DOF yaw-plane car-trailer model. The ESC controller designed in Matlab is then integrated with the car-trailer model generated for co-simulation. Built upon the virtual car-trailer with the ESC, a 1:10 small scaled physical car-trailer prototype with the ESC is fabricated. In both virtual and physical prototype tests, the ESC improves the stability by controlling the yaw moment of the combination. Although the results based on the P-control scheme are promising, an advanced control scheme for the ESC could be used to further improve the performance of the ESC. Since the project is done under limited resources and time, there is room to improve in a few aspects, such as building a full-scale car-trailer prototype and implementing an advanced control strategy for the ESC.

**Abstract**—Precise micromanipulation tasks are typically performed using micromanipulators that require an accessible workspace to reach components. However, many applications have inaccessible or require sealed workspaces. This paper presents a novel magnetically-guided, and untethered, actuation method for precise and accurate positioning of microcomponents on dry surface within a remote workspace using a magnetic microrobot. By use of an oscillatory and uniform magnetic field, the magnetic microrobot can traverse on a dry surface with fine step size and accurate open-loop vector following, 3% and 2% of its body-length, respectively (step size of 7  $\mu\text{m}$ ). While maintaining precise positioning capability, the microrobot can manipulate and carry other microcomponents on the dry surface using direct pushing or grasping using various attachments, respectively. We demonstrate and characterize the untethered micromanipulation capabilities of this method using a 3 mm cubic microrobot for use in applications such as microassembly and cargo transport.

## I. INTRODUCTION

Industrial robotic systems, such as robotic arms, part positioners, and sorters, have enabled rapid and precise manufacturing of large-scale assemblies. Extension of such systems into centimeter-scale manufacturing, such as in part pick-and-place for printed circuit board assembly, has also proven to be practical. However, significant challenges exist for manufacturing at the microscale level (characteristic dimensions of less than 10 mm). Flexure-based mechanisms, such as the delta [1] and MEMS-based [2] positioners, can position microcomponents within a few micrometer and nanometer accuracies, respectively. High speeds and precise operation make tethered and traditional manufacturing methods suitable for widespread use. Tethered systems require an entry area for access to the workspace, which may not be possible in some applications requiring sealing. Tethered assembly of microcomponents, such as the 200  $\mu\text{m}$  optical prism used in [3], require a cleanroom environment. On the other hand, untethered microassembly can be

performed within a smaller and sealed workspace, which is a cost-effective approach as the workspace can meet the requirements of a clean environment.

Due to the small scale of untethered microrobots, onboard power and actuation is impractical and thus, most designs in the literature rely on external actuation such as using magnetic fields [4], [5], and [6]. Most in-liquid micromanipulation methods use magnetic gradient pulling to perform micromanipulation tasks [7], [8], and [9]. In-liquid pick-and-place operations, using bubbles [10] and a magnetic microgripper [7], have proven effective in performing autonomous tasks and are well studied. However, micromanipulation on dry surface is required for many applications and it is challenging due to the strong friction and adhesion present on the small scale [5]. To avoid the stiction phenomenon altogether, levitated micromanipulation techniques, using diamagnetic [11] and acoustic [12] levitations, are used. However, to overcome the stiction forces on the surface, methods such as the stick-slip [13] and tumbling motions [14], use varying magnetic fields to induce torque instead of direct gradient pulling. Magnetic torque enables lifting and rolling of the magnetic microcomponents which indirectly result in step-wise motion on a surface.

Dry surface micromanipulation methods in the literature either have coarse stride step sizes (at least a body-length) [14], [15], and [16] that are imprecise or are uncontrolled during some portion of their stride cycle [13]. In addition, a pushing force cannot be applied using these for direct micromanipulation. Accuracy, precision, and speed are the core requirements for applications involving dry surface microassembly, where assembly force, as well as precise and efficient positioning and orienting are necessary. Most methods require complex actuation and control schemes and thus, become sensitive to external disturbances. Use of closed-loop controllers can alleviate the positioning inaccuracies, however; ability of applying pushing force is insufficient or lacking. Dry surface micromanipulation tasks, in inaccessible workspaces, require untethered, precise, and accurate locomotion with strong force application, which have not been achieved so far.

In this work, we introduce a novel method for precise positioning of a magnetic microrobot on dry surface. Unlike

previous work, which aim to overcome the surface stiction forces, the new method of walking takes advantage of friction forces to apply strong pushing forces required for microassembly. The open-loop operation of this walking method provides accurate path following (within 2% of body-length) and has walking step sizes as small as 3% of the microrobots largest dimension, which enable precision micromanipulation and handling of various microcomponents.

## II. CONCEPT

In this section, we introduce the new principle behind the actuation, the stepwise, and precise locomotion of a cubic magnetic microrobot on a dry surface. By taking advantage of high surface friction force, the microrobot can manipulate other microcomponents either by carrying or direct pushing.

### A. Method of Walking

Walking is achieved via remote magnetic actuation which is a uniform and oscillatory field. A torque,  $\tau_B$ , is induced on the magnetic microrobot resulting in change of its kinematic state. As shown in Fig. 1(a), the external magnetic field vector,  $\mathbf{B}$ , rotates at a frequency,  $f$ , about an axis defined by angles  $\theta$  and  $\beta$  which are the heading and the tilt angles, respectively. This field profile cone, as shown in Fig. 1(a), has an opening angle of  $\phi$  degrees. The microrobot, with its volume magnetization vector,  $\mathbf{M}$ , follows this field orientation because of the induced torque, which is defined by

$$\tau_B = \mathbf{M} \times \mathbf{B}. \quad (1)$$

This two-degree-of-freedom (2-DoF) actuation, along with the dynamic interaction of the microrobot with the dry surface, result in a stepwise motion with a full-cycle stepping shown in Fig. 1(a). The motion characteristics (i.e. step precision, speed, and path accuracy) are finely tunable by varying the field parameters. To achieve a consistent stepping motion, a suitable pose must be established such that the microrobot contacts the surface with exactly two defined points. This is the case for most flat-edged contacts where the line contact can be approximated with two points dictated by surface roughness profile. However, for accurate and repeatable motion, the two points can be physically fabricated to be more prominent to ensure repeatable contact over successive stepping cycles and during micromanipulation tasks such as pushing. In this work, an attachment, with two sharp corners, is glued underneath the microrobot for use in the experiments. Unlike tumbling and rolling methods for locomotion of flat-edged geometries, [14] and [15], the point contact reduces the contact friction, however; it enables pushing of microcomponents with precision using sharp-point anchorage, controllable steering, and precise positioning.

### B. Method of Force Application

Two significant parameters of interaction between the microrobot and the surface, especially at the microscale level, are: the friction,  $\mathbf{F}_N$ ; and the surface adhesion,  $\mathbf{F}_a$ , forces. These correlated forces enable the microrobot to use the

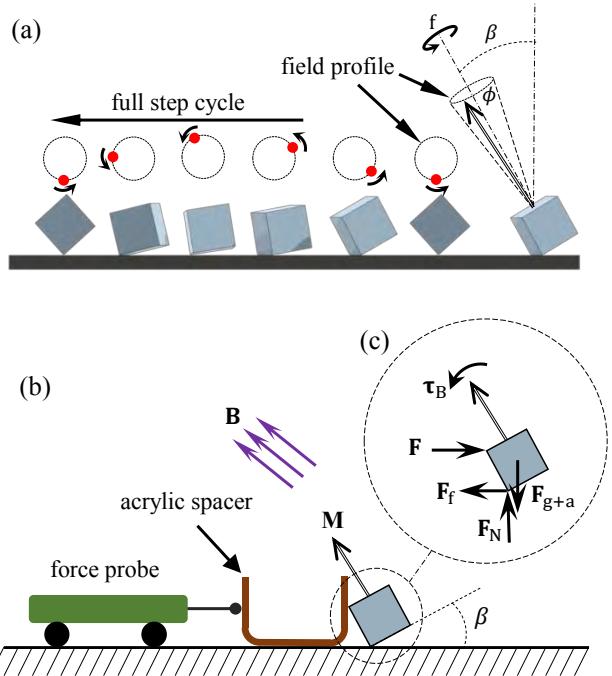

Figure 1. Conceptual schematic of walking and pushing tasks: (a) walking motion sequence during a full step cycle; (b) schematic of the force measurement setup; and (c) free-body diagram showing the forces and torque induced on the block at an instant of a pushing task.

friction force,  $\mathbf{F}_f$ , to apply an equal and opposite force,  $\mathbf{F}_p$ , to other microcomponents. A free-body diagram showing forces during a pushing task (Fig. 1(b)) is shown in Fig. 1(c). By adjusting the heading angle, the microrobot can push microcomponents around on a surface on a specific path, or towards a goal pose in a semi-holonomic fashion.

## III. MODELLING AND CHARACTERIZATION

In this section, we present the magnetic field actuation scheme, and show the characteristics of a pushing task.

### A. Time Varying Magnetic Field

A uniform magnetic field (field with no gradient) is necessary for the 2-DoF actuation of the microrobot. The smooth rotation of this field along the circular profile shown in Fig. 1(a), is necessary to prevent jerks, which would result in undesired movement or jumping of the microrobot. Thus, a central controller, with accurate time keeping capability, is essential to ensure the smooth actuation. The magnetic field is defined by

$$\mathbf{B} = B \left( R_z(\theta) R_y'(\beta) \right) \begin{bmatrix} \sin(\phi/2) \cos(2\pi ft) \\ \sin(\phi/2) \sin(2\pi ft) \\ \cos(\phi/2) \end{bmatrix}, \quad (2)$$

where  $t$  is time,  $B$  is the magnitude of the magnetic flux density,  $R_z$  is the rotation matrix about the Z axis for the world frame, and  $R_y'$  is the rotation matrix about the Y axis for the new rotated frame. From (1), given an object with a fixed magnetization, a strong magnitude field is necessary for full rolling motion because a higher magnetic torque is

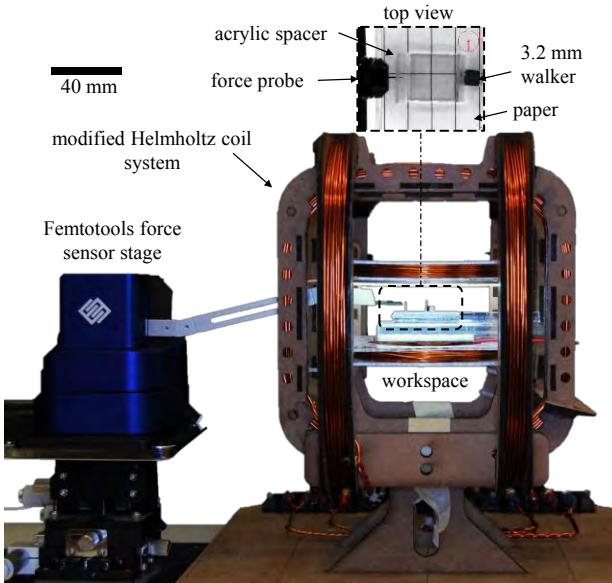

Figure 2. Experiment setup: the microrobot, the acrylic spacer, and the force sensor are placed on a paper surface within the workspace which is in the middle of custom-designed 3-axis Helmholtz coil system.

required to overcome the torque due to the weight and the surface adhesion forces from a lay-flat pose. However, with this method, since the microrobot needs to follow only the direction of the varying field with a short span, lower-magnitude field can be used. This becomes apparent for the case when a cubic microrobot is used and when  $\beta = 45^\circ$  where the magnetic torque is mostly overcoming the inertia (minimal at the microscale level and low frequency) as the weight is balanced by  $F_N$ . Therefore, unlike positioning achieved by rolling, a lower magnitude magnetic field can be used in certain configurations.

### B. Pushing Force Characterization

Using the same magnetic field actuation in (2), the microrobot can exert a pushing force on microcomponents with a flat and vertical surface. The friction and adhesion forces anchor the contact point of the microrobot to the surface and thus, an equal and opposite force can be applied to the microcomponent. This force is applied during a portion of a full-step cycle corresponding to the configuration shown in Fig. 1(b), where the pushing force  $F_p$  is achieved because of the magnetic torque  $\tau_B$ . As the microrobot relies on the point of contact to apply a force, the magnitude of the force is limited by the friction force between the microrobot and the surface. A pushing experiment was performed, and the results are presented in section IV(B).

## IV. RESULTS AND DISCUSSION

### A. Experimental setup – Magnetic Field and Force Sensing

A custom-designed setup was fabricated to actuate, sense, and measure the performance of the microrobot. The prototype coil system is comprised of three pairs of nested and mutually-orthogonal square Helmholtz coils which can generate a nearly uniform magnetic field of up to 3 mT in a workspace with dimensions of  $30 \times 40 \times 40$  mm. The

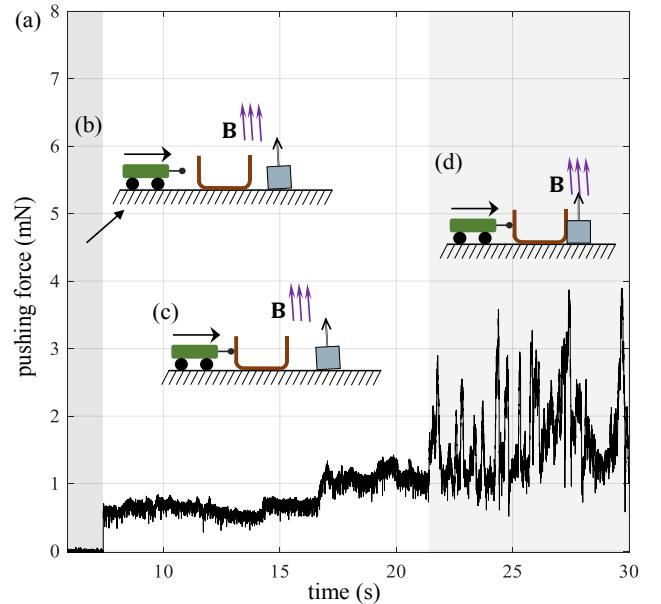

Figure 3. Friction force measurement between the microrobot and the paper surface, measured by a moving force sensor: (a) pushing force raw data; (b) interval of no contact, force sensor approaching the spacer; (c) interval of force sensor contact with the spacer; and (d) interval of microrobot contact with the spacer.

magnitude of the field is directly proportional to the current flowing in the coils which are controlled by six amplifiers (Advanced Motion Controls, 30A8) and commanded by a digital-to-analog converter card (Sensoray, Model s826). The commands are sent from a custom C-code executed on a Linux-based PC. A top-view camera (FOculus, FO123TB) is used to record position information of the microrobot. The proof-of-concept microrobot is composed of a cubic N52 magnet with side length of 3.22 mm. A two-point attachment is glued on the bottom surface of the magnet to ensure consistent contact with the surface. To measure the pushing and friction forces, a microforce sensing probe (Femtotools FT S10000) was mounted on a moving stage with a constant feed rate.

### B. Pushing Friction Test Results

To test the pushing capability of the microrobot, it was necessary to first determine the friction force present between the microrobot and the surface. This friction force was measured indirectly by using the acrylic spacer placed in between the force probe and the microrobot. The acrylic spacer provided two vertical surfaces for accurate transfer of force. Using a 3 mT constant magnetic field, the microrobot was tilted  $5^\circ$  towards the acrylic spacer as shown in Fig. 3(b). The force probe is moving to the right with a constant federate. During the initial approach (Fig. 3(b)), a small amount of noise is observed. Upon reaching the acrylic spacer, the sensor measured an averaged friction force of about 0.5mN which is the friction of the acrylic spacer with the surface. At around 17 seconds, the acrylic spacer contacted the top edge of the microrobot which corresponds to the increase in force value at that time. After the microrobot was rotated to a flat pose by the acrylic spacer, the magnetic field was turned off and the microrobot was

pushed on the surface by the force probe (Fig. 3(c)). An average force of 1.70 mN was measured during this interval. By subtracting the acrylic friction force, the average friction force of the microrobot was calculated to be 1.2 mN.

The highly varying friction force profile, as shown in Fig. 3(c), is due to the stick-slip characteristic of friction on dry surfaces. Thus, unlike sliding by gradient pull, a step-wise motion is preferred on dry surface. Further, the high impulse and oscillatory force application of the microrobot on other microcomponents enables the reliable micromanipulation.

### C. Open-loop Dead Reckoning Experiment and Locomotion Characterization

To characterize the motion, the microrobot was placed on a piece of copy paper inside the coil system and the position of the microrobot was tracked over time using vision analysis post-experiment. The tilt angle, opening angle, and frequency parameters were varied to characterize the effects of each on the walking accuracy and speed. The result of the first experiment, with  $\beta = 20^\circ$ ,  $\phi = 8^\circ$ , and  $f = 1$  Hz, is shown in Fig. 4(a). A heading angle of  $0^\circ$  (travelling to east) was set and the experiment was conducted for a duration of 34.8 s, effectively corresponding to about 35 full stepping cycles. A distance of 24.81 mm was covered during this duration in which, the effective per-step resolution is 0.7 mm (22% of body-length). The on-course path deviation error was characterized by RMSE, as shown as an inset in Fig. 4, which is 0.059 mm (1.8% of body-length). The end position of the microrobot was too close to the expected position for characterizing the offset using vision. Despite an open-loop actuation, the vector following is precise and accurate. This is as a result of the oscillatory and fine stepping of the microrobot on the dry surface. A separate experiment, using 0.25 mm cubic magnet on glass, was performed with step size and path deviation of 2% and 3% of body-length, respectively.

To characterize the speed, three opening angles ( $\phi = 8^\circ$ ,  $10^\circ$ , and  $15^\circ$ ) were selected and a magnetic field of 3 mT was applied. The speed depends on all field parameters, however; the most notable dependability is on the frequency and the opening angle. The distance of the CoM was measured using post-experiment vision analysis and the results are shown in Fig. 4(b). Linear fits were calculated, and the average speeds were found to be 0.714, 1.004, and 1.542 mm/s for  $\phi = 8^\circ$ ,  $10^\circ$ , and  $15^\circ$ , respectively. These sub-body length speeds and walking steps are finely adjustable making them suitable for precision positioning and locomotion. Using this microrobot, a maximum linear speed of 4.23 mm/s (131% of body length) was achieved with  $\phi = 45^\circ$ ,  $\beta = 30^\circ$ , and  $f = 1$  Hz. The speed can also be increased by increasing the frequency. However, at high frequencies, a higher magnitude magnetic field is required because of the inertia of the microrobot. The distance plot, shown in Fig. 4(b), shows the reliability of open-loop actuation on a uniform surface. Presence of external disturbances will affect the performance, however; it can be compensated by using active feedback.

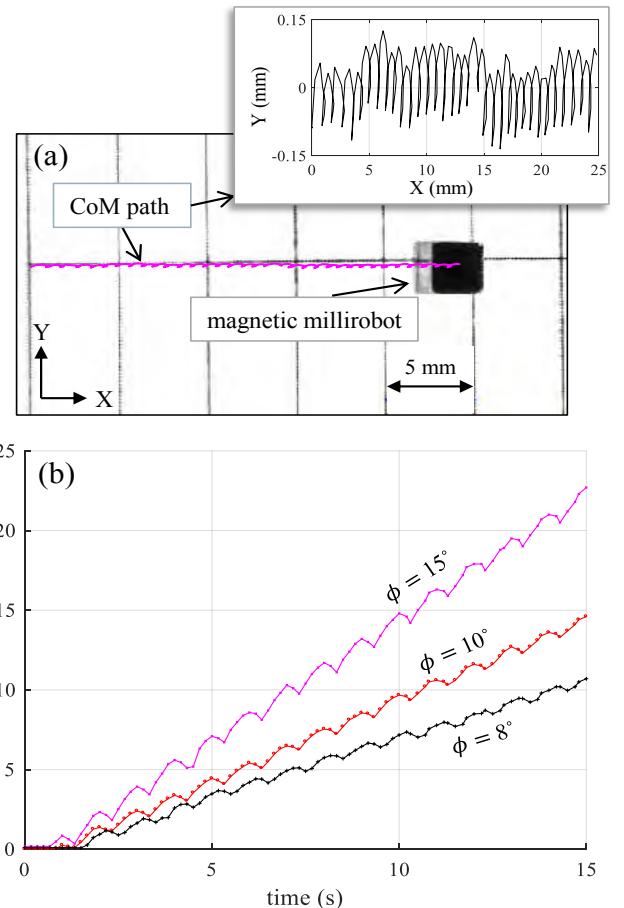

Figure 4. Precision open-loop walking characteristics of the magnetic walker: (a) top view of the microrobot at the end position with the walking path traced,  $\beta = 20^\circ$ ,  $\phi = 8^\circ$ ,  $f = 1$  Hz; and (b) plot of distance of center of mass from the starting location for span angles,  $\phi = 8^\circ$ ,  $10^\circ$ , and  $15^\circ$  where  $f = 1$  Hz.

## V. CONCLUSION AND FUTURE WORK

The new micromanipulation method presented in this paper allows for simple yet, precise open-loop and untethered positioning and micromanipulation of various microcomponents on a dry surface actuated by an external magnetic field. Unlike previous work, the presented microrobot can push other components while maintaining a reasonable positioning accuracy, and it can accurately traverse on a dry surface with different stepping size and speeds, which are finely tunable. In-place change of heading is possible by using some tilt angle giving this microrobot a holonomic characteristic to its otherwise nonholonomic motion. Due to the precise nature of the locomotion, high-speed travel is limited to 1-2 body lengths per second. For high speeds, rolling motion can be used by trading off stepping resolution and precision pushing capability. In addition, a reasonably flat surface is required for repeatable and open-loop path following, however; significant potential exists for integrating a closed-loop controller for making this method suitable for use in many industrial applications such as microassembly and cargo transport at the milli- and microscale levels.

# Adaptive Yaw Control of Three-axle Road Vehicles Based on Mass, Yaw Inertia and CG Position Identification

Yubiao Zhang\*, Ami Woo, Baris Fidan, Amir Khajepour

Department of Mechanical and Mechatronics Engineering  
University of Waterloo  
Waterloo, Ontario, Canada

**Abstract**—This paper introduces an adaptive yaw control scheme based on the estimation of the vehicle mass, yaw inertia and center of gravity (CG) position. The control designs for three-axle road vehicles, which can be trucks, buses, or even three-axle passenger cars. System parameters of these vehicles vary significantly due to varying conditions, such as unloading and fully-loading of payloads. As a result, control references and fixed-model-based controller lose efficacy. The proposed adaptive yaw control compensates these issues, utilizing the integration of a least-square based parameter identification algorithm and a Model Reference Adaptive Control (MRAC) law. Simulation test results verify the effectiveness of the proposed adaptive control scheme.

**Keywords**-three-axle vehicle, vehicle dynamics, parameters identification, adaptive yaw control

## I. INTRODUCTION

Advances in low cost sensors and computation technology expedited the progress on the performance and control of modern vehicles. One of the active areas of automobile research so far has been vehicle stability and handling characteristics. A practical and proven solution to improve the vehicle dynamics during critical driving conditions has been to produce corrective yaw moment to the vehicle. Various control methods to direct yaw-moment control (DYC) has been proposed in literature including electronic stability program based on differential braking [1, 2] and differential traction or torque vectoring [3, 4]. Indirect yaw moment control systems such as active steering control, which produces corrective steering angle to the wheels, have been alternative way to stabilize yaw moment [5, 6].

In vehicle control designs, the vehicle dynamics are often estimated using single track model. To simplify the controller design process, assumptions such as the negligible effect of the vehicle parameter variations on the dynamics and the performance region of the tire forces in the linear range are often imposed. Therefore, the performance of many existing control designs are promising specifically on two axle vehicles travelling within the linear range of the tires. However, when the effect of the vehicle parameter variations on the performance becomes substantial, the controller becomes less effective even under the same operating conditions.

One of the important parameters to take into consideration in control design is the vehicle mass. With varying mass, the center of gravity and inertia of vehicle vary, which has direct effect on the overall vehicle dynamics. For some vehicles such as passenger cars where the variation of the payload compared to the mass of the vehicle is insignificant, such changes may be tolerable. These variations are more critical in situations when the variation of the loading conditions and configurations impacts more on the overall dynamics [7-9]. The three axle heavy load trucks and commercial buses typically involve in multiple loadings and unloading of payloads more significantly compared to two axle passenger cars. These variations affect the stability and performance of the overall vehicle motion even with the appropriate control design. A controller which adapts to such changes and responds accordingly is desired. The apparent difficulty with variation of parameters in the process of control design is that these parameters are not directly measurable.

In this paper, an adaptive DYC is proposed on three-axle vehicles utilizing least-square (LS) estimation of unknown parameters of the vehicle, for improving the trajectory tracking of yaw dynamics. Section II explains the three-axle vehicle system dynamics. A single track model is developed to describe the DYC system. In section III, parameter identification and control design are developed. The mass, inertia, and center of gravity of vehicle are treated as unknown parameters and estimated indirectly in the section. The model reference adaptive control design is proposed with the reference model. The performance and effectiveness of the control strategy is proposed in Section IV. Finally, the paper is summarized and concluded in Section V.

## II. VEHICLE MODELING

### A. Single Track Model

The vehicle dynamics, in general, is non-linear and is difficult to formulate precisely. For vehicle state estimation and motion control design, linearized models are preferred. A three-axle vehicle single track model [10, 11], depicted in Fig. 1 is used in this paper. The equations for lateral dynamics and yaw motion are expressed by

$$ma_y = F_{yf} + F_{yc} + F_{yr}, \quad (1)$$

$$I_z \dot{r} = F_{yf} l_f - F_{yc} l_c - F_{yr} l_r + M_e + M_d, \quad (2)$$

\*email: gary.zhang@uwaterloo.ca

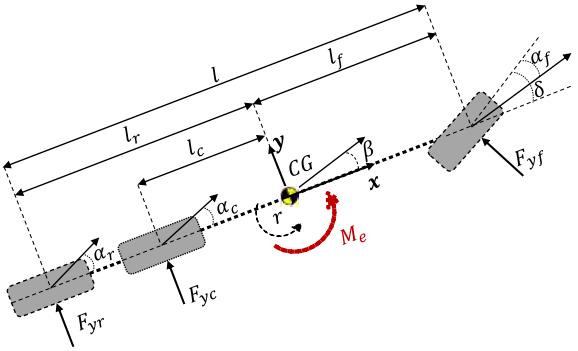

Fig. 1 The single track model  
and the lateral acceleration is given by

$$a_y = \dot{v}_y + v_x r = v_x (\dot{\beta} + r), \quad (3)$$

where, assuming the slip angles are small, tire lateral forces have a linear relationship to the tire slip angle as

$$F_{yf} = C_f \delta - \beta - \frac{l_f r}{v_x} \quad (4)$$

$$F_{yc} = C_c \beta - \frac{l_c r}{v_x} \quad (5)$$

$$F_{yr} = C_r (-\beta + \frac{l_r r}{v_x}) \quad (6)$$

The terms in (1)-(6) are defined as follows:

$m$ ,  $I_z$  - the vehicle mass and the moment of inertia about z axis;

$v_x$ ,  $v_y$ ,  $v$  - vehicle longitudinal speed, lateral speed and vehicle resultant speed;

$a_y$ ,  $\beta$ ,  $r$  - lateral acceleration, body slip angle and yaw rate at vehicle's CG (center of gravity);

$F_{yf}$ ,  $F_{yc}$ ,  $F_{yr}$  - lateral force of front, central and rear tires;

$l_f/l_c/l_r/l$ - the distance from CG to front/central/rear axle, the distance between front axle to rear axle;

$C_f/C_c/C_r$  - the front/central/rear wheels cornering stiffness,

$\delta$  - the front wheels steering angle;

$M_e$ - the extra yaw moment from the controller;

$M_d$  - the disturbance moment, the side wind causes this disturbance moment and affect to the vehicle's stability in cornering maneuver, It is assumed to be zero in this research.

Rearranging (1)-(6), the yaw dynamics at a certain operating point can be represented by the following state space

$$\dot{x} = Ax + Bu \quad (7)$$

$$y = x$$

where  $x = [\beta \ r]^T$ ,  $u = [\delta \ M_e]^T$ , and the output  $y$  is as the same as the system state;

$$A = \begin{bmatrix} -\frac{C_f + C_c + C_r}{mv_x} & -1 - \frac{l_f C_f - l_c C_c - l_r C_r}{mv_x^2} \\ \frac{l_f C_f - l_c C_c - l_r C_r}{I_z} & \frac{l_f^2 C_f + l_c^2 C_c + l_r^2 C_r}{I_z v_x} \end{bmatrix}, \quad B = \begin{bmatrix} \frac{C_f}{mv_x} & 0 \\ \frac{l C_f}{I} & \frac{1}{I_z} \end{bmatrix}.$$

### B. Model Validation

The derived model (7) was simulated for verification with the high-fidelity model of TruckSim with step-steer input (constant speed of 80km/h) with bus parameters presented in Table 1. The result in Fig. 2 shows that the vehicle dynamics has a fast response and small overshoot. But they are quite similar with the results of the TruckSim model, which verifies the reliability of the derived model for control design.

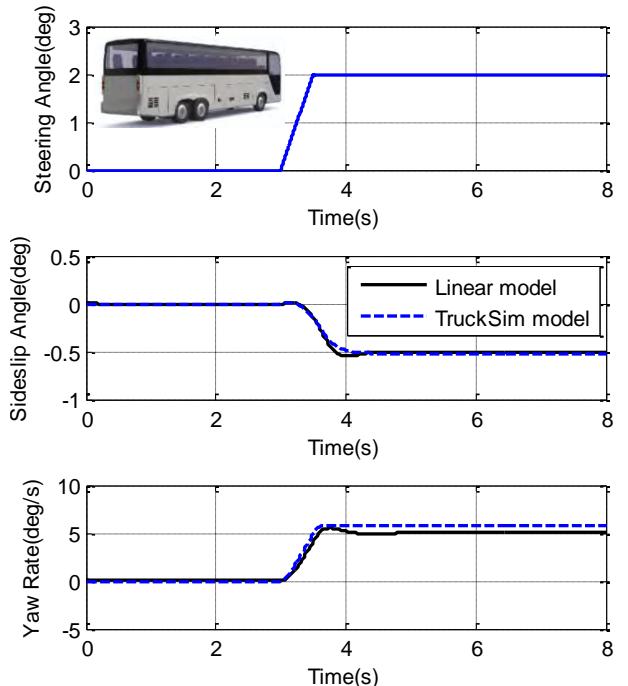

Fig. 2 Validation of the derived model by step steer

TABLE I PARAMETERS FOR A GENERIC THREE-AXLE VEHICLE

Parameter	Description(units)	Value
$m$	Vehicle mass(kg)	9415
$l_f$	Distance of front axle from CG(m)	3.5
$l_r$	Distance of rear axle from CG(m)	3.47
$l_c$	Distance of central axle from CG(m)	2.29
$l$	Distance of front axle from rear axle(m)	6.97
$l_{rc}$	Distance of central axle from rear axle(m)	1.22
$I_z$	Yaw moment of inertia(kgm <sup>2</sup> )	34685
$C_f$	Total front wheels stiffness(N/rad)	3.35e5
$C_c$	Total central Wheels stiffness (N/rad)	2.75e5
$C_r$	Total rear wheels stiffness (N/rad)	2.45e5

### III. PARAMETER IDENTIFICATION AND CONTROL DESIGN

#### A. Parameter Identification

The parameter identification (PI) of the unknown parameters is performed using an LS estimator. The estimator uses the measurements of steering angle  $\delta$ , extra yaw moment  $M_e$ , and yaw rate  $r$ , assuming available. In reality, these parameters are available for vehicles with advanced vehicle sensing technologies such as vehicles with GPS/IMU. Although these advanced sensing systems are not widely available for commercial cars yet, they could be equipped on other specific applications such as autonomous and military surveillance vehicles [12-13]. As for the vehicle side slip angle, it is usually estimated by other measurements such as the lateral acceleration and longitudinal speed of the vehicle from (1). In this research, we assume the side slip angle is available for measurement. Detailed explanations of the following basic procedures can be found in [14].

##### 1) Parametric Model

The model (7) is in the form,

$$\begin{bmatrix} \dot{\beta} \\ \dot{r} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} \beta \\ r \end{bmatrix} + \begin{bmatrix} b_{11} & 0 \\ b_{21} & b_{22} \end{bmatrix} \begin{bmatrix} \delta \\ M_e \end{bmatrix} \quad (8)$$

where  $b_{11} = k_{11}a_{11}$ ,  $k_{11} = -\frac{C_f}{C_f + C_c + C_r}$ ,  $l_c = l - l_f - l_{rc}$ ,

$l_r = l - l_f$ ,

$$\begin{aligned} a_{21} &= -\frac{l_f C_f - l_c C_c - l_r C_r}{I_z} \\ &= -\frac{l_f (C_f + C_c + C_r)}{I} + \frac{(C_c + C_r)l - C_c l_{rc}}{I} \\ &= k_{21} b_{21} + k_{22} b_{22} \end{aligned} \quad (9)$$

where  $k_{21} = -\frac{C_f + C_c}{C_f}$ ,  $k_{22} = (C_c + C_r)l - C_c l_{rc}$ .

Separating the known terms from the unknown ones and applying the Laplace transform to  $\beta$  and  $r$  yields (10) and (11), respectively,

$$s\beta = a_{11}\beta + a_{12}r + k_{11}a_{11}\delta = a_{11}(\beta + k_{11}\delta) + a_{12}r \quad (10)$$

$$sr = a_{22}r + b_{21}(\delta + k_{21}\beta) + b_{22}(M_e + k_{22}\beta) \quad (11)$$

Filtering both sides of the equation with the filter  $\frac{1}{\Lambda(s)} = \frac{1}{s+1}$ , we can express the system in the form of the static parametric model (SPM) as

$$z_1 = \theta_1^{*T} \phi_1$$

$$z_2 = \theta_2^{*T} \phi_2$$

where  $z_1 = \frac{s}{\Lambda(s)}\beta$ ,  $\theta_1^* = [a_{11} \quad a_{12}]^T$ ,

$$\begin{aligned} \phi_1 &= \left[ \frac{1}{\Lambda(s)}\beta + \frac{k_{11}}{\Lambda(s)}\delta \quad \frac{1}{\Lambda(s)}r \right]^T; \\ z_2 &= \frac{s}{\Lambda(s)}r, \quad \theta_2^* = [a_{22} \quad b_{21} \quad b_{22}]^T, \\ \phi_2 &= \left[ \frac{1}{\Lambda(s)}r \quad \frac{1}{\Lambda(s)}\delta + \frac{k_{21}}{\Lambda(s)}\beta \quad \frac{1}{\Lambda(s)}e + \frac{k_{22}}{\Lambda(s)}\beta \right]^T. \end{aligned}$$

In this case,  $z_i$  and  $\phi_i$  ( $i = 1, 2$ ) are available for measurement or estimation since then can be generated by filtering the measurements  $u$  and  $x$ .

##### 2) Estimation Model and Adaptive Law

The estimation model has the same form as the SPM with the exception that the unknown parameter  $\theta^*$  is replaced with its estimate at time  $t$ , denoted by  $\theta(t)$ , i.e.,

$$\begin{aligned} \hat{z}_1(t) &= \theta_1^T(t)\phi_1(t) \\ \hat{z}_2(t) &= \theta_2^T(t)\phi_2(t) \end{aligned}$$

and the estimation errors,

$$\varepsilon_i(t) = \frac{z_i(t) - \hat{z}_i(t)}{m_{si}}, \quad (i = 1, 2)$$

where  $m_{si}$  is the normalizing signal designed to bound  $\phi$  from above. A straightforward choice for  $m_{si}$  is  $m_{si}^2 = 1 + \alpha_i \phi_i^T \phi_i$  for any  $\alpha_i > 0$ .

We use the recursive least-squares algorithm with forgetting factor to minimize the cost function,

$$\begin{aligned} \dot{\theta}_i(t) &= P_i(t) \varepsilon_i(t) \phi_i(t), \quad \theta_i(0) = \theta_{i0} \\ \dot{P}_i(t) &= \beta P_i(t) - P_i(t) \frac{i \phi_i^T}{m_{si}^2} P_i(t), \quad P_i(0) = P_{i0} = Q_{i0}^{-1}, \quad (i = 1, 2) \end{aligned}$$

##### 3) Stability and Convergence

To guarantee the convergence of  $\theta_i(t)$  to their actual values  $\theta_i^*$ , the input (for this application the steering angle) should include at least two different frequencies to ensure it is sufficiently rich signal and  $\frac{\phi_i}{m_{si}}$  is persistently exciting [14]. Although the scenario of varying vehicle mass and yaw inertia which affects the CG position of the vehicle is considered for the paper, the varying range of the two parameters are relatively fixed small range. Table 2 shows the range of the unknown parameters to be estimated. This is used as a parameters projection for a better estimation of convergence.

TABLE II RANGES OF UNKNOWN PARAMETERS

Parameters	Mass(kg)	Yaw inertia(kgm2)	lf(m)
minimum	9415	34685	3
maximum	11415	37486	4

### B. Adaptive Reference Model

The desired vehicle behavior is can be described by a reference model. The desired vehicle performance from the reference model is to have zero vehicle sideslip angle at the center of gravity in steady state and the desired yaw rate to be determined by the front steering angle and vehicle speed.

In steady state, variables can be solved in terms of the control input as

$$\begin{bmatrix} \beta_{ss} \\ r_{ss} \end{bmatrix} = -A^{-1} \begin{bmatrix} C_f & I_f C_f^T \\ mv_x & I \end{bmatrix} \delta \quad (12)$$

$$r_{ss} = G_r \delta \quad (13)$$

where,  $G_r = -\frac{-a_{21}b_{11} - a_{11}b_{21}}{a_{11}a_{22} - a_{21}a_{12}}$  is the steady-state gain of yaw rate, which leads to an under-steering behavior of the vehicle's stability. The reference model proposed is assumed to be a first-order system [15] as follows,

$$r_d = W(s)\delta = \frac{G_r}{1 + \tau s} \delta \quad (14)$$

where  $\tau$  is the desired time constant of yaw rate. This low-pass filter is used to filter out the noise in the yaw rate signal [16]. Applying the adaptive reference model from the parameters estimation results in  $\hat{G}_r = -\frac{-\hat{a}_{21}\hat{b}_{11} - \hat{a}_{11}\hat{b}_{21}}{\hat{a}_{11}\hat{a}_{22} - \hat{a}_{21}\hat{a}_{12}}$ .

### C. Controller Design

The overall system including PI and control scheme is shown in Fig. 3. For yaw control, a model reference adaptive control (MRAC) is proposed. The desired vehicle behavior which is an LTI first order transfer function (15) is described by a reference model and is driven by a reference input. The control law is then developed so that the closed-loop plant has a transfer function equal to the reference model.

Consider the yaw rate of the plant,

$$\dot{r} = a_{21}\beta + a_{22}\gamma + b_{21}\delta + b_{22}M_e \quad (15)$$

where  $a_{21}, a_{22}, b_{22}$  are constants but unknown. The control objective is to determine a bounded function  $M_e = f(t, \beta, r, \delta)$  such that the yaw rate is tracking the desired yaw rate from the reference model of (14). Rewriting the reference model yields

$$(1 + \tau s)r_d = G_r \delta \rightarrow \dot{r}_d = -\frac{1}{\tau}r_d + \frac{G_r}{\tau}\delta \quad (16)$$

If the plant parameters are known, control law can be considered as

$$M_e = k_1\beta + k_2\gamma + k_3\delta \quad (17)$$

Substituting (17) into (15), results in the closed-loop system as

$$\begin{aligned} \dot{r}_c &= a_{21}\beta + a_{22}r_c + b_{21}\delta + b_{22}(k_1\beta + k_2r_c + k_3\delta) \\ &= (a_{21} + k_1b_{22})\beta + (a_{22} + k_2b_{22})r_c + (b_{21} + k_3b_{22}) \end{aligned} \quad (18)$$

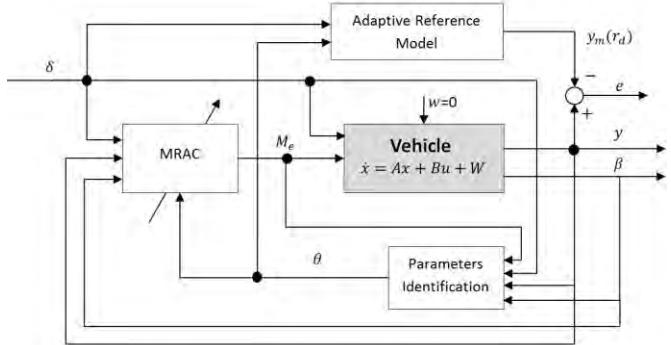

Fig.3 The PI and control scheme of whole system

The control objective is satisfied if controller parameters  $k_1, k_2, k_3$  are carefully chosen, in a way that the closed-loop poles are stable and  $\frac{v_c}{\delta} = \frac{v_d}{\delta}$ , as follows:

$$k_1 = -\frac{a_{21}}{b_{22}}, k_2 = -\frac{a_{21}}{b_{22}}, k_3 = -\frac{a_{21}}{b_{22}} \quad (19)$$

Replacing the unknown plant parameters with their estimates, the adaptive control law is established as follows:

$$\begin{aligned} \hat{G}_r &= -\frac{-\hat{a}_{21}\hat{b}_{11} - \hat{a}_{11}\hat{b}_{21}}{\hat{a}_{11}\hat{a}_{22} - \hat{a}_{21}\hat{a}_{12}}, \\ \hat{k}_1 &= -\frac{\hat{a}_{21}}{\hat{b}_{22}}, \hat{k}_2 = -\frac{1}{\tau \hat{b}_{22}} - \frac{a_{22}}{\hat{b}_{22}}, \hat{k}_3 = \frac{\hat{G}_r}{\hat{b}_{22}} - \frac{\hat{b}_{21}}{\hat{b}_{22}}. \end{aligned}$$

## IV. SIMULATIONS

To verify the proposed MRAC, simulations are performed in MATLAB and Simulink. The simulation results include vehicle responses with different parameters sets (Fig. 4), parameters identification (Fig. 5). The behavior of yaw rate, and side slip angle using adaptive yaw control is also presented (Fig. 6).

### A. Different Parameter Sets

To demonstrate the influence of varying parameters, different sets of mass, yaw inertia and CG position (lf) are simulated and the vehicle dynamics response and reference model are observed. Table 3 presents two possible parameters sets and were applied to the same bus. Fig. 4 shows a significant offset for both vehicle sideslip angle and yaw rate responses due to parameters changes. For the reference of yaw rate, the similar error happened between Para. Set 1 (reference 1) and Para. Set 2. This implies that the reference model will continuously change the values for reference output resulting in the controller to track inaccurate reference. However, an adaptive reference model is an on-line estimation and will adapt to the change of vehicle parameters.

TABLE III TWO PARAMETERS SETS

Para. Set	Mass(kg)	Yaw inertia(kgm2)	lf(m)
1	9415	34685	3.5
2	10945	36185	3

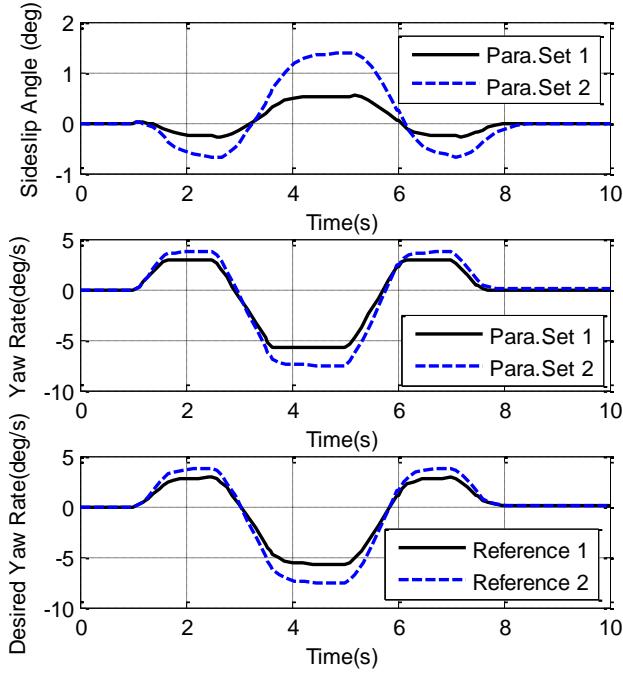

Fig.4 Vehicle responses with different parameters sets

### B. Results of PI and Adaptive Control

Persistently exciting signal is desired to ensure that the unknown parameters converge to the actual values using the adaptive scheme. In practical driving condition, the driver's steering input is not a simple step input or sinusoidal input, but a combination of complex shaped inputs. For the sake of simulation, we apply the front wheel a slight steering angle as follows,

$$\delta = 0.05 + 0.05 \sin 0.5t + 0.1 \sin t \text{ (deg)} \quad (20)$$

The unknown parameters were estimated using the steering input (20), which contains two different frequencies. Estimation results show that all parameters converge to their actual values within or around 35 seconds. Hence, the accuracy of the reference model is guaranteed. In Fig. 6, the first 10 seconds of the actual yaw rate behavior shows large fluctuations. This is due to the large fluctuations from parameters estimation module. They could be constrained within reasonable bounds in real application. However, after the 10th second, the actual yaw rate tracks the desired yaw rate precisely. From 36<sup>th</sup> to 43<sup>rd</sup> second, a steering input of double lane change is applied to the vehicle integrating with (20). Results show the actual yaw rate tracks the reference as well by generating an active yaw moment as the control action.

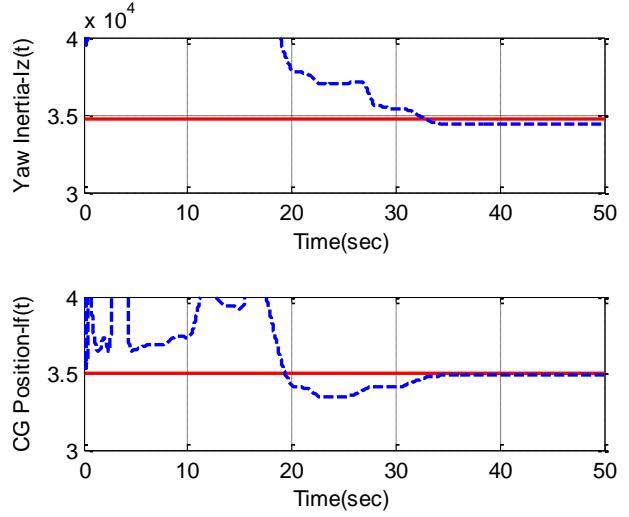

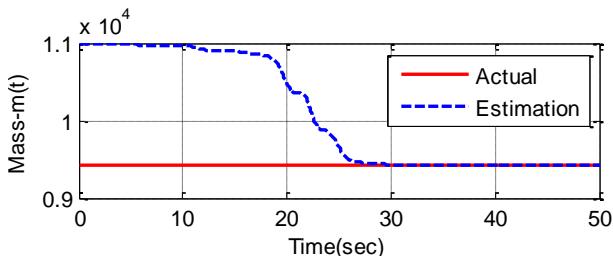

Fig.5 Parameters identification

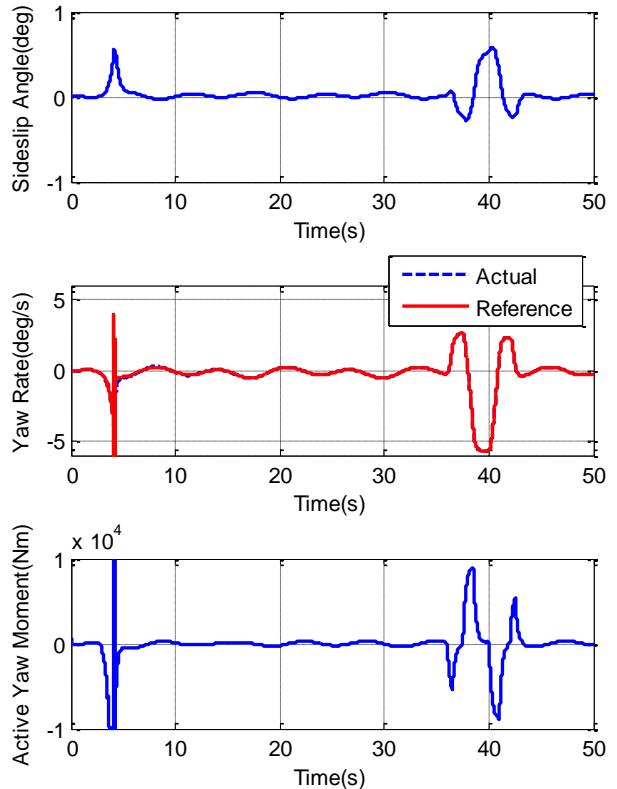

Fig.6 Adaptive yaw control

### V. CONCLUSIONS

In this paper, the vehicle mass, yaw inertia and CG position identification and a MRAC with DYC were proposed, modeled and verified. By comparison, a reference model without adaptive parameters estimation is not accurate.

To estimate the unknown parameters and verify the MRAC, an interrelated system model was built and simulated with MATLAB and Simulink. The estimation results and time response of the yaw rate and vehicle sideslip show that the proposed method was effective in improving vehicle's yaw

stability. For further study, a more comprehensive and realistic vehicle dynamic model is recommended and the plant should be tested in a real car or commercial software like TruckSim. Deeper merits of adaptive control strategy, along with robustness with parameter changes, i.e. tire nonlinear effects, will be also investigated and compared with the previous DYC<sub>s</sub>, i.e optimal control.

**Abstract** — The discrete Fourier transform in Cartesian coordinates has proved to be invaluable in many disciplines. However, less theory has been developed for functions that are best described in polar coordinates. In this paper, a discrete 2D-Fourier transform in polar coordinates is proposed and tested by numerical simulations with respect to accuracy and precision. Guidelines for choosing sample size are developed.

**Keywords**-2D Fourier Transform, discrete, polar coordinates

## I. INTRODUCTION

The Fourier transform is a powerful analytical tool and has proved to be invaluable in many disciplines such as physics, mathematics and engineering. The development of the Fast Fourier Transform (FFT) algorithm [1], which computes the discrete Fourier transform with a fast algorithm, established the Fourier transform as a practical tool in diverse areas, most notably signal and image processing.

In two dimensions, the FFT can still be used to compute the discrete Fourier transform in Cartesian coordinates. However, in many applications such as photoacoustics [2] and tomography ([3], [4], [5]), it is often necessary to compute the Fourier transform in polar coordinates. Moreover, for functions that are naturally described in polar coordinates, a discrete version of the 2D Fourier transform in polar coordinates is needed.

There have been some attempts to calculate the Fourier transform in polar coordinates. Nonequally spaced FFTs (NUFFT, see [6], [7], [8], [9]) is one of the methods that can be implemented to compute the FFT in polar coordinates. However, due to local interpolations, the NUFFT can be prohibitively slow for large input sizes and is not easily inverted. Averbuch et al. [10] proposed a new discrete polar Fourier transform, where the original function was sampled on a near-polar grid called a pseudo-polar grid followed by 1D equispaced FFT and 1D interpolations. Based on Averbuch's work, this new method was more accurate than the NUFFT method.

It should be noted that prior work has focused on numerically approximating the continuous transform. This

stands in contrast to approaches that have been taken with the continuous/discrete Fourier transform in two aspects: 1. both functions in the space and frequency domain of the DFT are in the same coordinates. 2. The DFT is defined as a transform in its own right, which means the existence of the DFT is valid even if without the existence of the continuous Fourier transform. In this paper, a new discrete 2D-Fourier transform in polar coordinates is proposed and tested by numerical simulations with respect to accuracy and precision.

## II. DEFINITION OF THE DISCRETE 2D FOURIER TRANSFORM IN POLAR COORDINATES

### A. Kernel of the discrete 2D Fourier transform in polar coordinates

To propose and work with a 2D polar DFT, the following kernels are proposed

$$\begin{aligned} E^-(ql; pk) &= \frac{2}{N_2} \sum_{n=-M}^M \frac{J_n \left( \frac{j_{nk} j_{nl}}{j_{nN_1}} \right)}{j_{nN_1} J_{n+1}^2(j_{nk})} i^{-n} e^{-in \frac{2\pi p}{N_2}} e^{+in \frac{2\pi q}{N_2}} \\ E^+(ql; pk) &= \frac{2}{N} \sum_{n=-M}^M \frac{J_n \left( \frac{j_{nl} j_{nk}}{j_{nN_1}} \right)}{j_{nN_1} J_{n+1}^2(j_{nl})} i^n e^{+i \frac{2\pi np}{N_2}} e^{-i \frac{\pi nq}{N_2}} \end{aligned} \quad (1)$$

where  $p, k, q, l, n, N_1$  and  $N_2$  are integers such that  $-M \leq n \leq M$ , where  $2M+1=N_2$ ,  $1 \leq l, k \leq N_1-1$  and  $-M \leq p, q \leq M$ .  $J_n(\cdot)$  is the Bessel function of  $n$ th order and  $j_{nk}$  is the  $k$ th zero of the Bessel function of order  $n$ . The integers  $N_1$  and  $N_2$  represent the size of the spaces in which we work, with  $N_2$  representing the dimension in the angular direction and  $N_1$  represents the dimension in the

radial direction. Since  $N_2 = 2M + 1$ ,  $N_2$  must be an odd integer.

### B. Definition of the discrete transform

The 2D-Discrete Fourier Transform in polar coordinates is defined as the discrete transform that transforms the matrix (or double-subscripted series  $f_{pk}$ ) to the matrix (double-subscripted series) to the matrix  $F_{ql}$  according to

$$\begin{aligned} F_{ql} &= \mathbb{F}(f_{pk}) \\ F_{ql} &= \sum_{k=1}^{N_1-1} \sum_{p=-M}^M f_{pk} E^-(ql; pk) \\ &= \sum_{k=1}^{N_1-1} \sum_{p=-M}^M f_{pk} \frac{2}{N_2} \sum_{n=-M}^M \frac{J_n \left( \frac{j_{nk} j_{nl}}{j_{nN_1}} \right) i^{-n}}{J_{nN_1} J_{n+1}^2(j_{nk})} e^{-in\frac{2\pi p}{N_2}} e^{+in\frac{2\pi q}{N_2}} \end{aligned} \quad (2)$$

The notation for  $E^-(ql; pk)$  and  $E^+(ql; pk)$  are the discrete kernels for the forward and inverse transform, respectively. The subscript (+ or -) indicates the sign on the exponent containing the  $p$  variable; the  $q$  variable exponent then takes the opposite sign. From a matrix point of view, both  $f_{pk}$  and  $F_{ql}$  are  $N_2 \times (N_1 - 1)$  sized matrices. The inverse transform is then given by

$$\begin{aligned} f_{pk} &= \mathbb{F}^{-1}(F_{ql}) \\ f_{pk} &= \sum_{l=1}^{N_1-1} \sum_{q=-M}^M F_{ql} E^+(ql; pk) \\ &= \sum_{l=1}^{N_1-1} \sum_{q=-M}^M F_{ql} \frac{2}{N_2} \sum_{n=-M}^M \frac{J_n \left( \frac{j_{nl} j_{nk}}{j_{nN_1}} \right) i^n}{J_{nN_1} J_{n+1}^2(j_{nl})} e^{+i\frac{2\pi np}{N_2}} e^{-i\frac{\pi nq}{N_2}} \end{aligned} \quad (3)$$

### C. Approximation to the continuous Fourier transform

To approximate the continuous Fourier transform, the function needs to be sampled at some specific points. For a space limited function defined over continuous  $(r, \theta)$  space where  $0 \leq r \leq R$  and  $0 \leq \theta \leq 2\pi$  and the function is effectively zero elsewhere (that is the function can be made as close to zero as necessary, elsewhere in the plane), the sampling points are defined in the spatial domain as

$$r_{pk} = \frac{j_{pk} R}{j_{pN_1}} \quad \theta_p = \frac{p2\pi}{N_2} \quad (4)$$

And in the spatial frequency domain as

$$\rho_{ql} = \frac{j_{ql}}{R} \quad \psi_q = \frac{q2\pi}{N_2} \quad (5)$$

Equations (4) and (5) give the sampling grid in regular  $(r, \theta)$  and frequency  $(\rho, \psi)$  space. Clearly, the density of the sampling points depends on the numbers of points chosen, that is on  $N_1$  and  $N_2$ . Also clear is the fact that the grid is not equi-spaced in the radial variable. It can be shown that the approximate relationship between sampled values of the continuous function  $f(r, \theta)$  and sampled values of its continuous forward 2D transform  $F(\rho, \psi)$  is given by

$$F\left(\frac{j_{ql}}{R}, \frac{2\pi q}{N_2}\right) \approx 2\pi R^2 \sum_{k=1}^{N_1-1} \sum_{p=-M}^M f\left(\frac{j_{pk} R}{j_{pN_1}}, \frac{2\pi p}{N_2}\right) E^-(ql; pk) \quad (6)$$

Similarly, the inverse transform relationship is given as

$$f\left(\frac{j_{pk} R}{j_{pN_1}}, \frac{2\pi p}{N_2}\right) \approx \frac{1}{2\pi R^2} \sum_{l=1}^{N_1-1} \sum_{q=-M}^M F\left(\frac{j_{ql}}{R}, \frac{2\pi q}{N_2}\right) E^+(ql; pk) \quad (7)$$

Consider the case of a bandlimited function, such that the function is defined over continuous  $(\rho, \psi)$  space where  $0 \leq \rho \leq W_p$  and  $0 \leq \psi \leq 2\pi$  and the function is effectively zero elsewhere (that is the function can be made as close to zero as necessary, elsewhere in the plane), the sampling points are defined as

$$r_{pk} = \frac{j_{pk}}{W_p} \quad \theta_p = \frac{p2\pi}{N_2} \quad (8)$$

and

$$\rho_{ql} = \frac{j_{ql} W_p}{j_{qN_1}} \quad \psi_q = \frac{q2\pi}{N_2} \quad (9)$$

The approximate relationship between sampled values of the continuous function and sampled values of its continuous forward 2D transform  $F(\rho, \psi)$  can be shown to be given by

$$F\left(\frac{j_{ql} W_p}{j_{qN_1}}, \frac{2\pi q}{N_2}\right) \approx \frac{2\pi}{W_p^2} \sum_{k=1}^{N_1-1} \sum_{p=-M}^M f\left(\frac{j_{pk}}{W_p}, \frac{2\pi p}{N_2}\right) E^-(ql; pk) \quad (10)$$

Similary, the inverse transform is given as

$$f\left(\frac{j_{pk}}{W_p}, \frac{2\pi p}{N_2}\right) \approx \frac{W_p^2}{2\pi} \sum_{l=1}^{N_1-1} \sum_{q=-M}^M F\left(\frac{j_{ql}W_p}{j_{qN_1}}, \frac{2\pi q}{N_2}\right) E^+(ql; pk) \quad (11)$$

### III. DISCRETE 2D FOURIER TRANSFORM TEST AND RESULTS

#### A. Method for testing the Algorithm

In this section, the ability of the 2D discrete Fourier transform is evaluated for its ability to estimate the continuous Fourier transform at the selected special sampling points in the spatial and frequency domains.

##### 1) Accuracy

In order to test the accuracy of the 2D-DFT and 2D-IDFT to calculate the continuous counterpart, the dynamic error has been used. It is defined as [11]

$$E(v) = 20 \log_{10} \left[ \frac{|C(v) - D(v)|}{\max |D(v)|} \right] \quad (12)$$

where  $C(v)$  is the continuous forward or inverse 2D-Fourier transform and  $D(v)$  is the values obtained from the discrete counterpart. The dynamic error is defined as the ratio of the absolute error to the maximum amplitude of the function, which is calculated on a log scale. Therefore, a large negative value represents an accurate discrete transform. The dynamic error is used instead of the percentage error in order to avoid division by zero.

##### 2) Precision

The precision of the algorithm is another important evaluation criterion, which is tested by sequentially performing a pair of forward and inverse transforms and comparing the result to the original function. High precision indicates that the transform does not add much error by the calculations. An average of absolute error of each sample points between the original function and the calculated counterpart was used to measure the precision. It is given by

$$\varepsilon = \frac{1}{(N_1-1) \cdot N_2} \sum_{n=1}^{(N_1-1) \cdot N_2} |f - f^*| \quad (13)$$

where  $f$  is the original function and  $f^*$  is the calculated counterpart. An ideal precision would result in the absolute error being zero.

#### B. Test Functions

##### 1) Gaussian

The first function chosen for evaluation is a circular symmetric function which is Gaussian in the radial direction. The function in the space domain is defined as

$$f(r, \theta) = e^{-a^2 r^2} \quad (14)$$

where  $a$  is some real constant. Since the function is circularly symmetric, the 2D-DFT is actually a zeroth-order Hankel Transform [12] and can be written as

$$F(\rho, \psi) = \frac{\pi}{a^2} e^{\frac{-\rho^2}{4a^2}} \quad (15)$$

The graphs for the original function and its continuous 2D-DFT (which is also a Gaussian) are shown with  $a=1$  and shown in Figure 1.

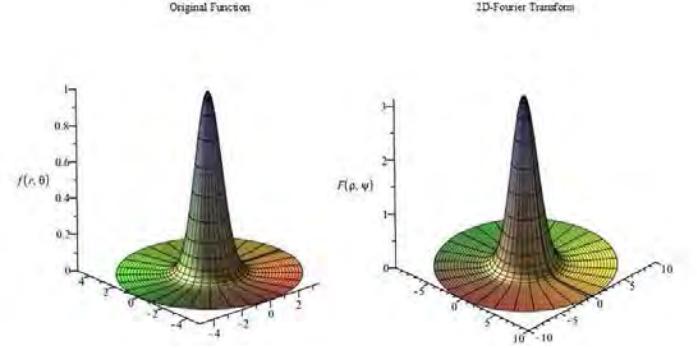

Figure 1. The original Gaussian function and its 2D-Fourier Transform

From Figure 1, the function is circularly symmetric in the angular direction and fairly smooth in the radial direction. Moreover, the function can be considered as an effectively space limited function or an effectively band limited function. For the purposes of testing it, it shall be considered as a space limited function and (6) and (7) will be used to proceed with the forward and inverse transform in sequence.

To perform the transform, the following variables need to be chosen:  $N_2$ ,  $R$  and  $N_1$ . In the angular direction, since the function in the spatial domain is circularly symmetric,  $N_2$  can be chosen to be small. Thus,  $N_2 = 15$  is chosen.

In the radial direction, the effective space limit  $R = 40$  and effective band-limit  $W_p = 30$  are chosen, which gives  $j_{0N_1} \geq R \cdot W_p = 1200$  [13]. Therefore,  $N_1 = 383$  is chosen to satisfy this constraint.

##### a) Forward Transform

Test results for the forward transform are shown in Figure 2 and Figure 3. The error gets bigger at the center as expected. However, the maximum value of the error is  $E_{\max} = -8.3842 \text{ dB}$  and this occurs at the center. The average value of the error is  $E_{avg.} = -63.8031 \text{ dB}$ .

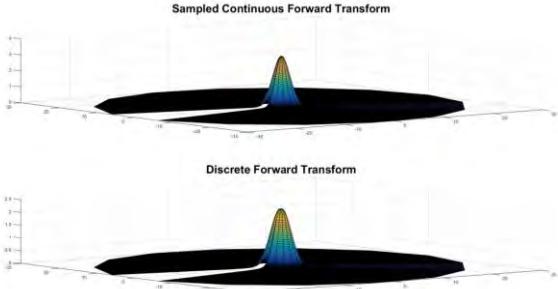

Figure 2. Sampled Continuous forward transform &. Discrete forward transform of Gaussian Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

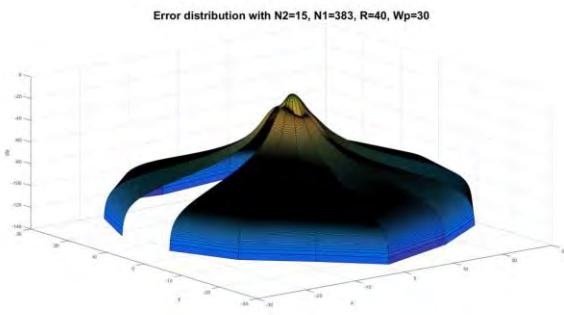

Figure 3. The error distribution of the forward transform of Gaussian Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

#### b) Inverse Transform

Figure 4 and Figure 5 show the test results for the inverse transform. The maximum value of the error is  $E_{\max} = -12.2602 \text{ dB}$  and this occurs at the center. The average of the error is  $E_{\text{avg.}} = -98.0316 \text{ dB}$ .

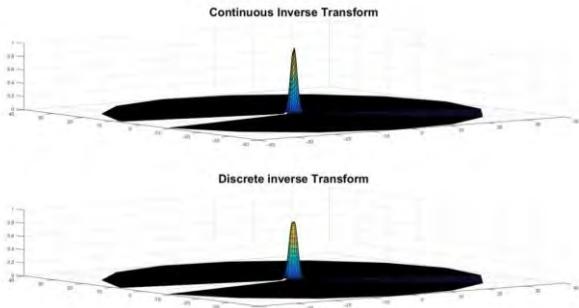

Figure 4. Sampled continuous inverse transform and discrete inverse transform of the Gaussian function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

Performing sequential 2D-DFT and 2D-IDFT results in  $\varepsilon = 4.1656 \times e^{-17}$  where  $\varepsilon$  is calculated with (13). Therefore, performing the forward and inverse transforms does not add much error.

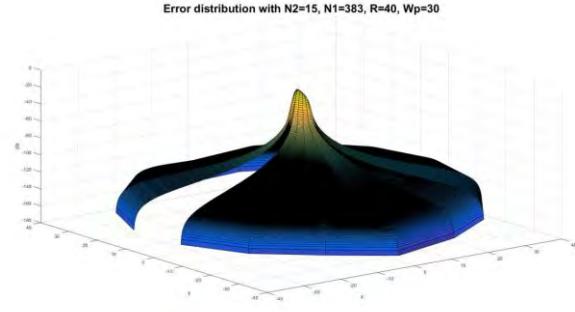

Figure 5. The error distribution of the inverse transform of Gaussian Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

#### 2) Square Donut

The second chosen function is a circularly symmetric function which is a square wave in the radial direction. The function is given by

$$f(r, \theta) = \begin{cases} 0, & r < 5 \text{ and } r > 10 \\ 1, & 5 \leq r \leq 10 \end{cases} \quad (16)$$

The continuous 2D-FT can be written as:

$$F(\rho, \psi) = \frac{2\pi}{\rho} [10J_1(10\rho) - 5J_1(5\rho)] \quad (17)$$

where  $J_n(x)$  is Bessel function of order  $n$ .

The graphs for the original function and its continuous 2D-DFT (which is also a Gaussian) are plotted and shown in Figure 6.

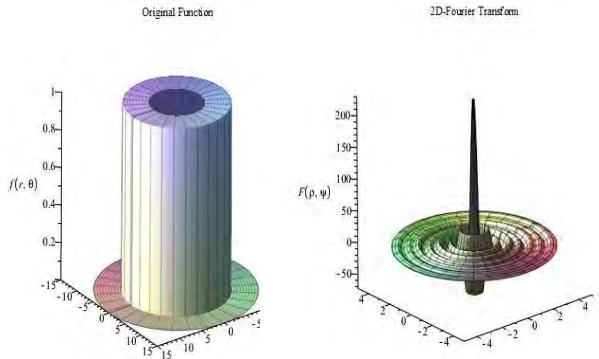

Figure 6. The original 'Square Donut' and its 2D-Fourier Transform

#### a) Forward Transform

Test results for the forward transform are shown in Figure 7 and Figure 8. Similar to the previous case, the error gets bigger at the center as expected. The maximum value of the error is  $E_{\max} = -8.1664 \text{ dB}$  and occurs at the center area. The average of the error is  $E_{\text{avg.}} = -34.5471 \text{ dB}$ .

#### b) Inverse Transform

Figure 9 and Figure 10 show the test result for the inverse transform. The maximum value of the error is

$Error_{max} = 1.5 dB$ . The average of the error is  $Error_{average} = -73 dB$ .

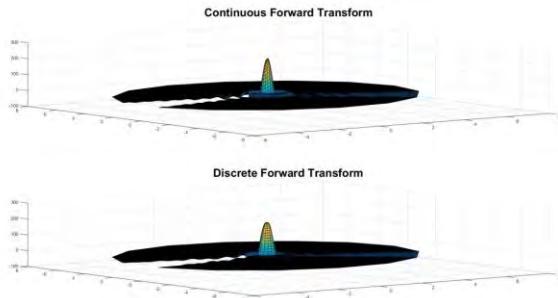

Figure 7. Sampled Continuous forward transform &. Discrete forward transform of 'Square Donut' Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

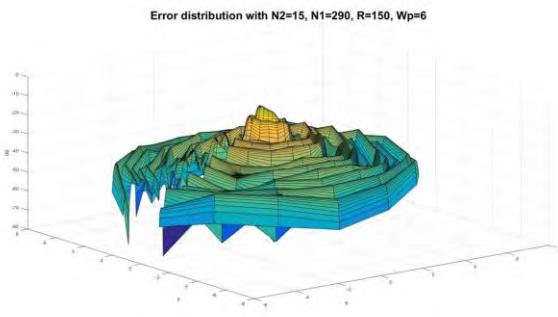

Figure 8. The error distribution of the forward transform of 'Square Donut' Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

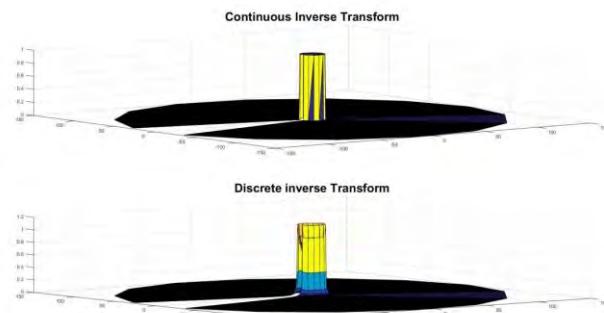

Figure 9. Sampled continuous inverse transform and discrete inverse transform of the 'Square Donut' function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

Performing sequential 2D-DFT and 2D-IDFT results in  $\varepsilon = 6.7253 \times e^{-14}$  where  $\varepsilon$  is calculated with (13). Therefore, performing forward and inverse transform does not add much error.

#### IV. SUMMARY AND CONCLUSION

From the two test cases, both the forward and inverse transform showed good accuracy to approximate the continuous Fourier transform. Moreover, the good precision results indicated that the transform itself does not add much error.

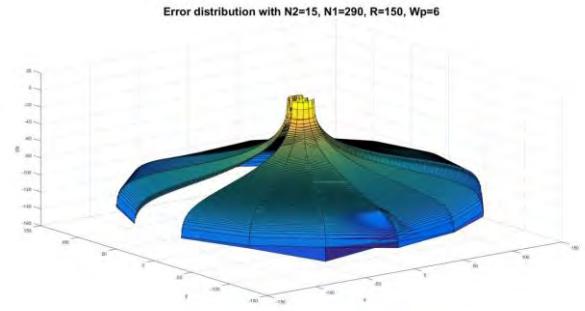

Figure 10. The error distribution of the inverse transform of 'Square Donut' Function with  $R=40$ ,  $N_2=15$ ,  $N_1=383$

**Abstract**—The development of a humanoid robot is a very prevalent area of research today. Legged robots have many advantages over wheeled robots on rough or uneven terrains, and are more suitable for an everyday household setting, however they possess many design and control challenges. The spring loaded inverted pendulum (SLIP) is frequently used as a fundamental model to analyze bipedal locomotion. In general, it consists of a stance phase and a flight phase, employing different strategies during these phases to control speed and orientation. Due to the underactuation and hybrid dynamics of bipedal robots, estimating the state of the robot and its appendages can be challenging. In this paper, various Kalman estimation techniques are used to predict the state of a simulated planar SLIP model. The state estimations utilize only simulated sensor data, as if the simulated model was a physical one.

**Keywords**—*Kalman filter; bipedal robot; legged robot; robotics; simulation; inverted pendulum; SLIP; hybrid dynamics; advanced estimation; sensor filtering.*

## I. INTRODUCTION

The simulated model consists of a planar biped robot designed and simulated in Virtual Robotic Experimentation Platform (VREP), using Open Dynamics Engine (ODE) for the physics. In flight phase, when there is no ground contact, the dynamics of the system is simply ballistic flow and has well known and analytically solved dynamics. However, due to gravity, the stance phase dynamics is much more complicated and includes coupled equations and non integratable terms. Therefore, an accurate estimation of the state based on sensor measurements becomes much more valuable than closed form analytical motion planning. The main controller design goals of the robot are:

1. To achieve dynamically stable running.
2. To be able to accelerate and decelerate to achieve a desired running speed.
3. To control its angular momentum to maintain a desired body attitude during running.

These design goals are achieved through the main control loop, however the controller relies on accurate measurements of the body attitude, leg positions and angular and linear velocity

of the robot. The Kalman filter (KF) is applied to estimate positions and velocities of these components [1]. The KF is an optimal state estimation strategy, and is widely used in the field of control and estimation theory [2, 3].

### A. SLIP Model

To study running in its simplest form, a planar running machine was built at MIT [4]. This robot only had one leg, but the principle is identical to a biped. The leg behaved as a passive spring and was telescopic. It used pneumatics to simulate a spring and could also apply thrust force. During one cycle there was a stance and flight phase. During the stance phase, the leg supports the body and remains in a fixed location on the ground. In this phase, the robot tips like an inverted pendulum and there is no chance to move the foot placement to control position. In order to change the foot position, the robot jumps to flight phase where the leg is unloaded and free to move. Marc Raibert developed a simple control strategy for simple legged robots which decomposes into the parts, the hopping height, the forward speed and the body attitude [5].

### B. Previous Research

Many methods of state estimation for planar legged locomotion exist currently [6]. Stance mapping is a commonly used approach in state estimation of linkages. It has been proven that stance dynamics are nonlinear, coupled and contain non-integrable terms [7]. Many assumptions and approximations need to be made to derive a stance map. Common assumptions include ignoring gravity, no inputs, constant speed, small spring compressions and small sweep angles [8]. Other methods use a mean value theorem derived from interactive performance testing [9]. Kalman filtering has also extensively been applied to the linkages of bipedal walking models [10], however a walking model lacks the complex hybrid dynamics of running, and again many assumptions are made to reduce the model, such as constant height CoG [6]. Applying these methods to real life models is challenging and impractical, with the introduction of system and measurement noise, uncertain impact dynamics and imperfect limb coordination and model design. An alternative to a closed form stance map is real-time adaptive state estimation from sensor data, which is implemented in this project.

### C. Kalman Filter

In order for the Raibert controller to function, the orientation, linear and angular velocity of the main body needs to be known, as well as the positions of the legs relative to the body. Two Kalman filters are applied to the entire model to determine the state relative to the robots' constituents. The first is used to determine the attitude of the body of the model. It utilizes a gyroscope and the control torque applied during stance. The second is a sensor fusion Kalman filter utilizing an accelerometer and gyroscope on the pivot points of the leg.

## II. SIMULATED MODEL

The model created in VREP originally based on Raibert planar biped [10]. The model consists a rectangular main body, with two actuated hip joints, which connect to telescopic legs (Fig. 1). The legs act as a passive spring/dampers during compression, and are capable of applying a thrust force. The robot is attached to a spherical joint at the hip by a 5m massless boom (Fig. 1). This eliminates 3DOF from the model, its yaw, roll and lateral movement. The feet consist of spheres and have perfect friction with the ground ( $\mu = 1$ ).

TABLE I. SYMBOLS AND DESCRIPTIONS

Symbol	Description
$\theta$	Leg angle relative to body vertical
$\varphi$	Body angle with respect to horizontal
$\varphi_d$	Desired body angle
$r$	Leg length at equilibrium
$z$	Body height from contact surface
$x$	Body position on track
$\dot{x}$	Body velocity
$\dot{x}_d$	Desired body velocity
$x_r$	Foot distance from body CoG
$M_B$	Mass of body
$M_L$	Mass of leg
$I_B$	Body mass moment of inertia
$g$	Gravity
$T_{st}$	Time of Stance
$K_L$	Spring constant of leg
$\tau$	Control torque of active hip

The simulation used Open Dynamics Engine as its physics engine due to its accuracy modelling spring damper systems. The main control loop is implemented directly in VREP via a child script. The running motion of the robot can be described in 5 phases: flight, touchdown, compression, thrust and takeoff. The main working principle behind the speed control is foot placement. Because the leg acts as a spring-damper, the time of the stance phase (compression and thrust) can be approximated by:

$$T_{st} = \frac{\pi}{\omega} = \pi \sqrt{\frac{M_B + M_L}{K_L}} \quad (1)$$

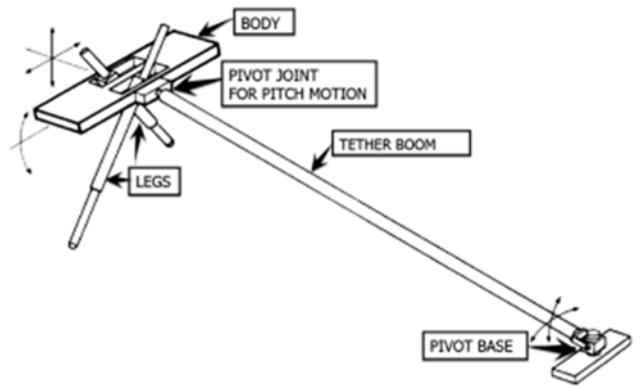

Figure 1. Biped model assembly.

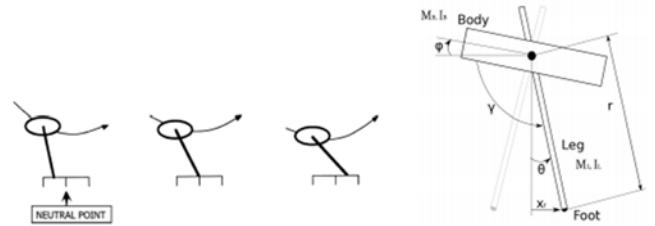

Figure 2. Foot placement effects and free body diagram.

Foot placement has a direct effect on the resultant velocity at takeoff. If the foot is placed directly at the halfway point throughout the stance (neutral point), the stance phase is symmetric and the takeoff velocity is the same as the touchdown.

$$x_{fo} = \frac{\dot{x}_{T_{st}}}{2} \quad (2)$$

Any deviation from the neutral point results in a non-zero horizontal acceleration. Placing the foot before the neutral point results in acceleration, as more of the vertical velocity is converted to horizontal, and vice versa (Fig. 2). To accelerate to a desired speed, proportional control is used.

Therefore, the algorithm for foot placement and the corresponding hip angle is:

$$x_f = \frac{\dot{x}_{T_{st}}}{2} + k_x(\dot{x} - \dot{x}_d) \quad (3)$$

$$\gamma_d = \emptyset - \sin^{-1} \left( \frac{\dot{x}_{T_{st}}}{2} + \frac{k_x(\dot{x} - \dot{x}_d)}{r} \right) \quad (4)$$

Body attitude is maintained by applying a torque about the hip during the stance phase. Since angular momentum is conserved during flight, the friction between the foot and the ground provides an opportunity to correct the angular momentum of the entire system. To servo the body to a desired attitude, this control torque is applied:

$$\tau = -k_p(\varphi - \varphi_d) - k_v(\dot{\varphi}) \quad (5)$$

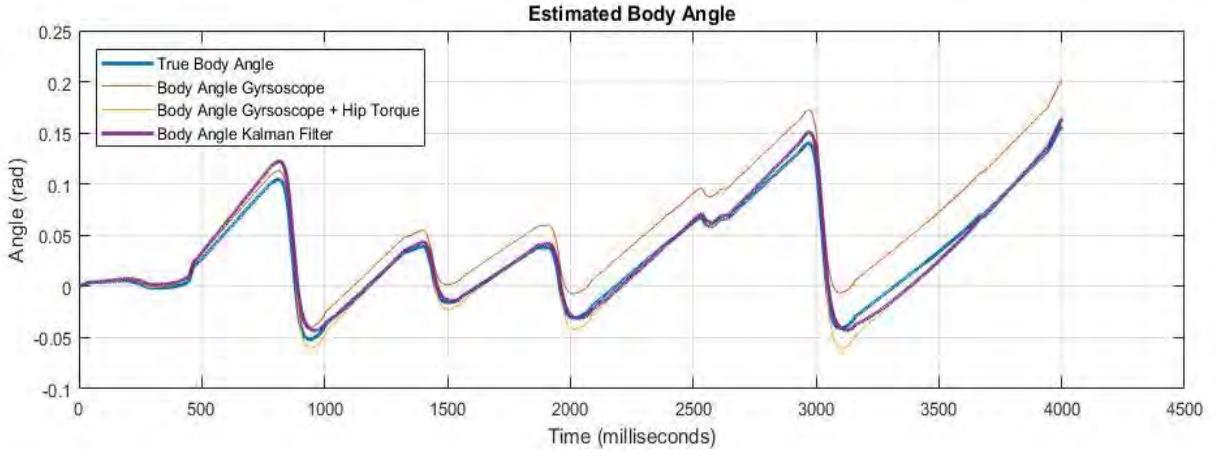

Figure 3. True and estimated body angle.

where  $k_p$  and  $k_v$  are constants, 80 and 20 respectively. During the stance and flight phases, the idle leg mirrors the active leg to cancel out any angular momentum.

### III. BODY STATE ESTIMATION

The body angle of the robot is determined through a gyroscope and the applied control torque during stance phase. The gyroscope was simulated using a reference point where the Euler angles were read, and simulation noise was added. The control torque is an input based on the current body angle and angular velocity. These values were streamed from VREP in real time to MATLAB using a remote API. They were then filtered and streamed back into VREP to calculate the control inputs for the next time step. The true angle and angular velocity of the body were also streamed to MATLAB for comparison.

TABLE II. SIMULATION PARAMETERS

Parameter	Value	Description
$t$	0.001	Simulation time step, in sec
$I$	4.708e-02	Body mass moment of inertia
$\phi_d$	0	Desired body angle, in rad
$r$	0.5575	Leg length uncompressed
$\dot{x}_d$	2	Desired body velocity, in m/s
$M_B$	9.246	Mass of body, in kg
$M_L$	0.478	Mass of leg, in kg
$T_{st}$	0.178	Time of Stance, in sec
$K_L$	2700	Spring constant of leg, in N/m

#### A. Estimation Methods

Three methods were used to estimate the angle of the body. The angle was estimated just from the gyroscope measurement of the angular velocity.

$$\varphi_i = \varphi_{i-1} + t\dot{\varphi}_i \quad (6)$$

The body angle was also calculated using the input torque applied during the stance phase to correct the body angle.

$$\varphi_i = \varphi_{i-1} + t\dot{\varphi}_i + \frac{\tau}{2I}t^2 \quad (7)$$

The body angle was also estimated using a Kalman filter.

$$\begin{bmatrix} \varphi \\ \dot{\varphi} \end{bmatrix} = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \varphi \\ \dot{\varphi} \end{bmatrix} + \begin{bmatrix} \frac{t^2}{2I} \\ t/I \end{bmatrix} \begin{bmatrix} \tau \\ \tau \end{bmatrix} \quad (8)$$

$$C = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad (9)$$

Measurement and system noise were then added to the system to simulate real world conditions. These values were assumed to be Gaussian and white. These values were approximated, and it was assumed most of the noise would stem from the sensors, so the system noise was several orders of magnitude less than the measurement noise.

#### B. Results

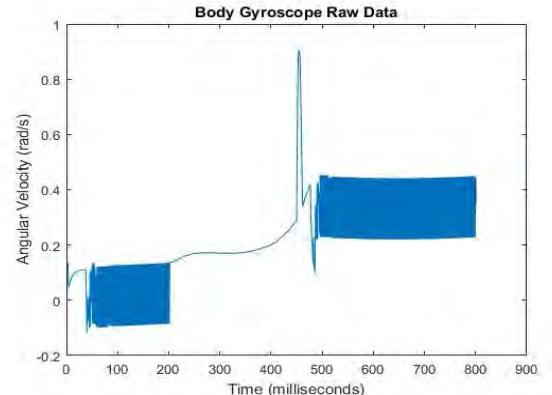

Figure 4. Body gyro data without Gaussian noise.

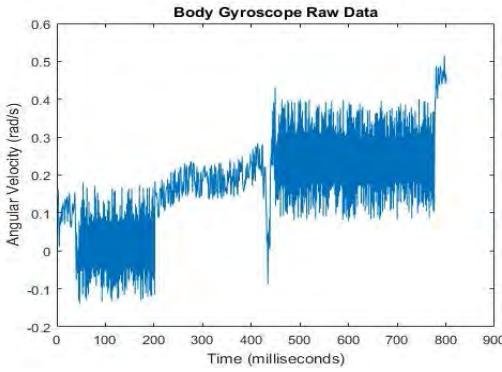

Figure 5. Body gyro data with Gaussian noise.

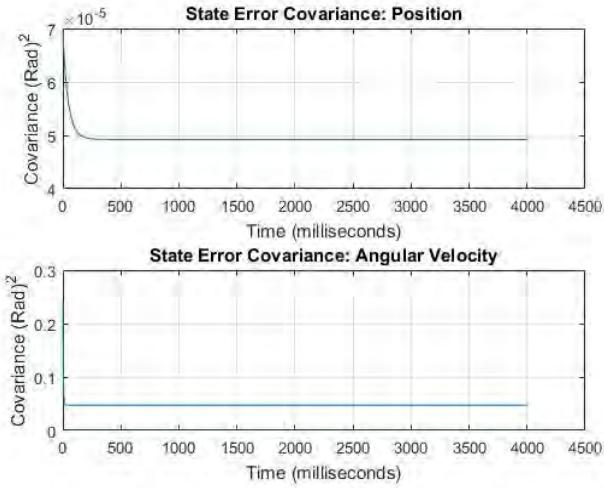

Figure 6. Position and angular velocity state error covariance.

TABLE III. ROOT MEAN SQUARE ERROR RESULTS

	Gyroscope Angle Estimation (rad <sup>2</sup> )	Gyro + Torque Angle Estimation (rad <sup>2</sup> )	Kalman Filter Angle Estimation (rad <sup>2</sup> )
RMSE	0.0393433	0.0184116	0.0071413

The KF performed the best with an RMSE approximately five times lower than that of the gyroscope estimation alone, and 2.5 times lower than that of the gyroscope and the torque estimation. As per the position estimation results, the gyroscope estimation drifts over time, while the combined estimation overshoots the extreme tilt angles. The KF accurately accounts for these deviations and best represents the true angle of the body. Although the Kalman filter is able to filter out most of the noise in the angular velocity estimation, it does seem to have a bias. This may be due to the Kalman filter counteracting the bias of the gyroscope, as the state error covariance of both the position and the velocity converge quickly over time. The estimated state of the body was streamed back into the VREP simulation to predict the next control outputs, and the robot performed just as well as if reading the true states, running at its desired speed of 2m/s with a deviation of 0.2m/s.

#### IV. LEG STATE ESTIMATION

The state estimation of the leg consists of a sensor fusion between an accelerometer and gyroscope located at the hip joint of the model. The virtual accelerometer consists of a reference mass attached to a force sensor. These values were streamed from VREP in real time to MATLAB using a remote API. They were then filtered and streamed back into VREP to calculate the control inputs for the next time step. The true angle and angular velocity of the leg were also streamed to MATLAB for comparison.

##### A. Estimation Methods

Due to the impact forces of touchdown and the rising and falling motion of the model, the calculated accelerometer angle of the leg is very noisy and very biased during the stance phase (Fig. 7). The signal is processed through two corrective algorithms before it is filtered to provide better estimations. The first one uses accelerometer data from the body rather than the leg. Because the body of the biped remains relatively level ( $\pm 5$  deg) compared to the sweep range of the leg ( $\pm 40$  deg), the calculated accelerometer angle of the body is subtracted from that of the leg to correct for the rising and falling motion of the model. The data is then corrected for the large spikes occurring during touchdown (Fig. 8). The angle of the leg was estimated using two filters, a complimentary and a Kalman. The complimentary filter combined the calculated angle from the gyroscope sensor and the accelerometer sensor.

$$\theta_{comp} = \alpha(\theta_{gyro}) + (1 - \alpha)(\theta_{accel}), \alpha = 0.9 \quad (10)$$

The state of the leg was also estimated using a Kalman filter. Measurement and system noise were then added to the system to simulate real world conditions. These values were assumed to be Gaussian and white. These values were approximated, and it was assumed most of the noise would stem from the sensors, so the system noise was several orders of magnitude less than the measurement noise.

$$\begin{bmatrix} \theta \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \varphi \\ \dot{\varphi} \end{bmatrix}, C = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad (11)$$

$$Q = \begin{bmatrix} \frac{t^3}{3} & \frac{t^2}{2} \\ \frac{t^2}{2} & t \end{bmatrix}, R = \begin{bmatrix} 10^{-4} & 0 \\ 0 & 10^{-1} \end{bmatrix} \quad (12)$$

##### B. Results

As seen in the results (Fig. 10 & 11), the KF outperformed the complimentary filter, with an RMSE less than half that of the complimentary (Table IV). The complimentary performed fairly well, however after a certain time the gyroscopic drift had too large of an effect on the estimation. The Kalman filter was able to filter out much of the noise from the accelerometer reading (Fig. 10). While the position tracking estimation was smooth, very little of the velocity estimation noise was filtered out. This is primarily due to the low measurement noise covariance applied to the gyroscope data, and a large noise covariance applied to the accelerometer. The estimated state of the active leg was streamed back into the VREP simulation to predict the next control outputs in real time. The robot performed just as well as if reading the true states, running at its desired speed of 2m/s with a deviation of 0.2m/s.

TABLE IV. ROOT MEAN SQUARE ERROR RESULTS

	Complementary Filter Angle Estimation (rad <sup>2</sup> )	Kalman Filter Angle Estimation (rad <sup>2</sup> )
RMSE	0.0562632	0.0276804

## V. CONCLUSIONS

Experimentation showed that the implementation of a Kalman filter is very effective at estimating of the states of the model. The Kalman filter worked best when the system was linear and known. The system matrix has the largest effect on the performance of the Kalman filter. Despite the challenges of predicting the overall state of the model, it has been demonstrated that it is possible to use Kalman filtering techniques to estimate the state of this model just using sensor data, allowing for a physical implementation.

## VI. FUTURE WORK

While the Kalman estimations for the states of the body and the legs were very successful, the state estimation of the entire model did not yield desirable results. Linearized state equations for the stance phase would be very useful in improving the filters, and allowing the implementation of an EKF and IMM-EKF strategy. Although the simulated model is easier to work with, a physical model would be the next step in experimentally tuning these filters. Ideally, one large filter would predict the changing center of gravity and hybrid dynamics would be state of the entire system, however the equations integrating highly complex. Finally, this system lends itself to a neural net configuration. Applying a Kalman filter to adaptively train the neural net may yield a very successful control strategy.

**Abstract**—In this paper, a new model in augmented state space allowing for faster prediction of hydrogen peroxide decay rates is proposed. This information is important for the development of new hydrogen peroxide solutions used to fight pathogens and harmful germs. The well-known Kalman filter and the unscented Kalman filter are applied on developed mathematical models and experimental measurements. The results are compared and discussed.

**Keywords**—*Hydrogen peroxide; unscented Kalman filter; interacting multiple models*

## I. INTRODUCTION

Virox Technologies Inc. (Oakville, Ontario) specializes in the development of innovative cleaning and disinfection technologies based on hydrogen peroxide as the active ingredient. Hydrogen peroxide is an optimal ingredient for use in disinfectant formulations as it has a wide spectrum of antimicrobial efficacy, has a highly preferred environmental profile, and does not leave toxic residues on surfaces upon application (i.e., it breaks down to water and oxygen). More specifically, Virox Technologies Inc. is an industry leader in innovating peroxide based antimicrobial formulations wherein very low concentrations of hydrogen peroxide (less than 1%) is synergistically made to be highly effective against pathogenic organisms. This selective acceleration of hydrogen peroxide's activity against pathogens has been possible by blending hydrogen peroxide with specific types and amounts of readily available and safe inert ingredients; such as anionic surfactants, cyclic carboxylic acids, and more. The innovative discoveries on synergistic mixtures of hydrogen peroxide at low concentrations with the select inert additives has led to development of the multi-patented accelerated hydrogen peroxide (AHP) technology platform. Today, products based on the AHP technology platform are found in over 60 countries worldwide, and in about 75% of Canadian healthcare institutions.

Experiments performed at Virox have shown that collecting statistically significant data regarding hydrogen peroxide decay requires weeks of incubation time. The need of an accelerated degradation method is required to speed up the determination of hydrogen peroxide lifetime. This paper suggests a hypothetical

setup using estimation strategies that predict two parameters: temperature variation, and hydrogen peroxide concentration.

State and parameter estimation theory is an important field in mechanical and electrical engineering. The strategies are used to predict, estimate, or smooth out important system state and parameters [1, 2]. The Kalman filter (KF) is the most popular estimation strategy, and yields a statistically optimal solution to the linear estimation problem [3]. The goal of the KF is to minimize the state error covariance, which is a measure of the estimation accuracy and is defined as the expectation of the state error squared [4]. The state error is defined as the difference between the true state value and the estimation state value. Although the KF yields a solution for linear estimation problems, it is based on a few strict assumptions: the system and measurement models must be known, the noise distribution is Gaussian, and the behavior is linear [5, 6]. If any of these assumptions are not held by the actual system, then the KF may yield inaccurate or unstable estimation results [7]. A popular nonlinear form of the Kalman filter is the unscented Kalman filter (UKF). It utilizes statistics to approximate the nonlinear probability density function (PDF) [8].

For the experiments performed in this paper, the following assumptions have been made: (1) reactions are first order only. In the event that this is not the case, one can still consider reactions as pseudo-first order but with a different reaction constant  $k_{obs}(t)$  [9]; and, (2) the loss of hydrogen peroxide is independent on the concentration when the concentration is low. This applies to the experiments in this paper due to the fact that hydrogen peroxide concentrations were relatively low, ranging between 0.5% to 2% of total solution weight. The experimental data is described in Section 2, the methods and analysis are described in Section 3, the results are found in Section 4, and the papers is then concluded.

## II. EXPERIMENTAL DATA

Experimental data was obtained within the facilities at Virox and averaged in order to determine initial reaction constant and variances that needed to be fed into matrix R, the measurement noise covariance. A summary of data is available in Tables I through III.

Based on this data, it is sufficient to determine the reaction constant  $k$ , activation energy  $E_a$  (also known as the enthalpy of decomposition), and the initial parameter  $A_0$  which come into the Arrhenius equation in (1). In (1),  $R$  is the universal gas constant and  $T$  is the temperature.

$$k[H_2O_2] = A_0 \exp(-Ea/RT) \quad (1)$$

In order to determine  $k$ , one linearly fits the natural log of peroxide loss over time via following relationship:

$$\ln[C(t)/C_0] = -k[H_2O_2]t \quad (2)$$

where  $C(t)$  and  $C_0$  are the concentrations of the current and initial time steps respectively. Analogously, one fits reciprocal temperature to natural log of  $k$  to determine  $E_a$  and  $A_0$ :

$$(-Ea/RT) + \ln(A_0) = \ln(k(T)) \quad (3)$$

Plots of the curve fitting described by (2) and (3) are shown in Fig. 1 and 2.

TABLE I. PERCENT LOSS OF H<sub>2</sub>O<sub>2</sub> AT 50°C

Time (Hr)	pH = 2		pH = 3		pH = 4		pH = 5	
	% Loss	Err or	% Loss	Err or	% Loss	Err or	% Loss	Err or

TABLE III. PERCENT LOSS OF H<sub>2</sub>O<sub>2</sub> AT 70°C

Time (Hr)	pH = 2		pH = 3		pH = 4		pH = 5	
	% Loss	Err or	% Loss	Err or	% Loss	Err or	% Loss	Err or
120	1.680	1.94	0.03	0.06	0.03	0.05	0.00	0.00
240	7.85	1.29	0.07	0.07	0.00	0.00	0.12	0.21
360	10.98	1.05	0.30	0.52	0.71	0.72	0.04	0.07

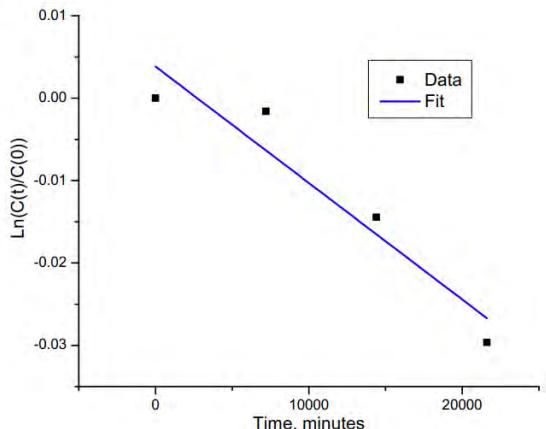

Figure 1. Linear fit of (2).

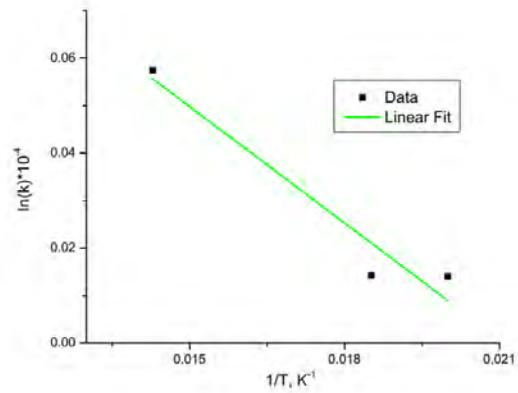

Figure 2. Linear fit of (3).

Both of these fits from Fig. 1 and 2 can provide all required ingredients for the determination of  $k$ . The constants have been determined as follows:

$$E_a = 70 \text{ kJ} \times \text{mol}^{-1}$$

$$A_0 = 0.4 \times 10^{5.8} \text{ min}^{-1}$$

$$k = 1.45 \times 10^{-6} \text{ min}^{-1} \text{ at } 50^\circ\text{C}$$

The obtained values are within reasonable agreement with results published elsewhere for aqueous solutions, keeping in mind the pH levels in this study [10]. Additionally, analysis of  $k$  constants was performed on various pH levels. Results are depicted in Fig. 3. As there are only 4 points, there is no clear relationship between  $k$  and pH. Therefore, it will be omitted in calculations.

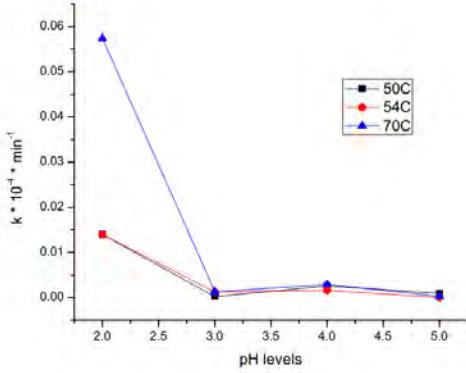

Figure 3. K at various pH Levels.

### III. METHODS AND ANALYSIS

#### A. Linear System of Equations

The augmented state space system is based on three variables,  $\mathbf{c}$  - concentration,  $\mathbf{T}$  - temperature, and  $\mathbf{k}$  - reaction rate constant. The discretized augmented state space system is written as:

$$\begin{bmatrix} c_{i+1} \\ T_{i+1} \\ k_{i+1} \end{bmatrix} = \begin{bmatrix} -k_i \Delta t + 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \times \begin{bmatrix} c_i \\ T_i \\ k_i \end{bmatrix}, \quad (4)$$

where  $\Delta t$  is sampling time (200 minutes). Initial conditions for all simulations are shown in (5).

$$\begin{bmatrix} c_0 \\ T_0 \\ k_0 \end{bmatrix} = \begin{bmatrix} 0.1615 \text{ M} \\ 323.50 \text{ K} \\ 1.45 \times 10^{-6} \text{ min}^{-1} \end{bmatrix} \quad (5)$$

#### B. Determination of Q and R matrices

In most cases, only  $\mathbf{c}$  and  $\mathbf{T}$  are measurable during experiments. Thus,  $\mathbf{H}$ , or measurement matrix, is written as:

$$H = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \quad (6)$$

Additionally, the noise covariance matrices  $Q$  (system noise) and  $R$  (measurement noise) are required to run any type of Kalman filter. The determination of  $R$  is straightforward and it is obtained through experimental setup. For this study, it is determined to be:

$$R = \begin{bmatrix} 5 \times 10^{-8} & 0 \\ 0 & 0.01 \end{bmatrix} \quad (7)$$

The determination of the  $Q$  matrix is usually the trickiest part of Kalman filtering. Matrix elements of  $Q$  are treated as tunable parameters which are determined based on the uncertainties that may arise in a system. With this experiment, these uncertainties might be temperature and humidity variations. Additionally, for the augmented state space system, matters become more complicated due to the fact that the augmented part of the system, shown below:

$$\begin{bmatrix} T_{i+1} \\ k_{i+1} \end{bmatrix} = \begin{bmatrix} T_i + w_T(i) \\ k_i + w_k(i) \end{bmatrix} \quad (8)$$

This becomes a Wiener process with unbounded variance shown in (9). One solution to this problem is to set variances  $w_T$ ,  $w_k$  to zero. However, doing so would change the controllability of the system.

$$\lim_{j \rightarrow \infty} \text{Var}(T, k) = \infty \quad (9)$$

There is another way, however, to keep variances nonzero while having bounded covariances of augmented state variables. This is described in [2], and the procedure is as follows:

- Choose matrix elements of  $Q$  to be a few percent of estimated values
- Run simulations for true and Kalman estimated systems
- Calculate variances of simulated variables
- Adjust matrix elements of  $Q$  such that (10) is satisfied

$$\text{Var}(x) = \lim_{i \rightarrow \infty} P_i(x) \quad (10)$$

The procedure from [3] was adopted and the resulting  $Q$  matrix was determined to be:

$$Q = \begin{bmatrix} 10^{-9} & 0 & 0 \\ 0 & 2 \times 10^{-8} & 0 \\ 0 & 0 & 10^{-16} \end{bmatrix} \quad (11)$$

#### C. System Setup and Kalman Estimators

The estimators used in this study were the Kalman filter (KF), unscented Kalman filter (UKF), and the interacting multiple model (IMM) setup based on the KF and the UKF. For the IMM algorithm, (12) was used as the probability transition matrix:

$$P = \begin{bmatrix} 0.95 & 0.05 \\ 0.05 & 0.95 \end{bmatrix} \quad (12)$$

Temperature profiles were treated as unknown parameters fed into the Kalman estimators. The main objective was to assess the accuracy of predicted reaction rate constants compared to their true counterparts.

## IV. RESULTS

### A. Profiles with Rising Temperatures

Rising temperature profiles were simulated through raising the temperature by a certain amount at  $pH = 2$  as demonstrated in Fig. 4, Fig. 5, and Fig. 6. The three state variables (Peroxide concentration, temperature, and k-constant) are shown in each of these figures, along with the KF, UKF, and IMM results. The probabilities ( $\text{Mu}$ ) of the IMM system being in the KF or UKF mode are also shown.

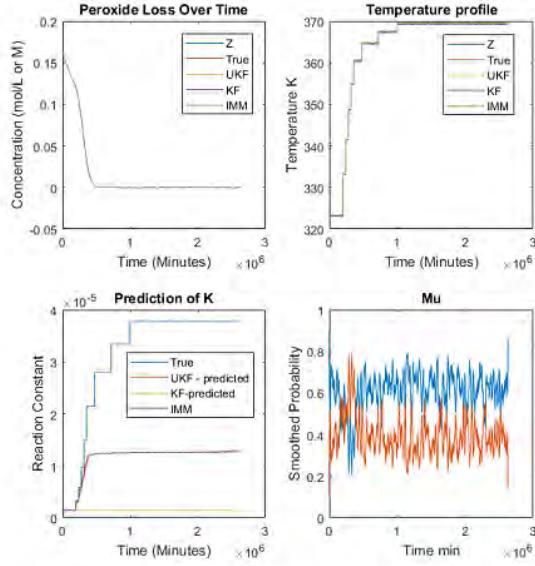

Figure 4. Temperature profile with a 50°C change.

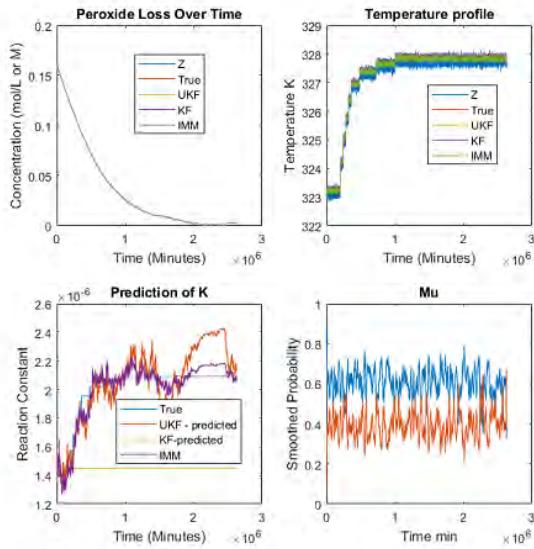

Figure 5. Temperature profile with a 5°C change, late onset.

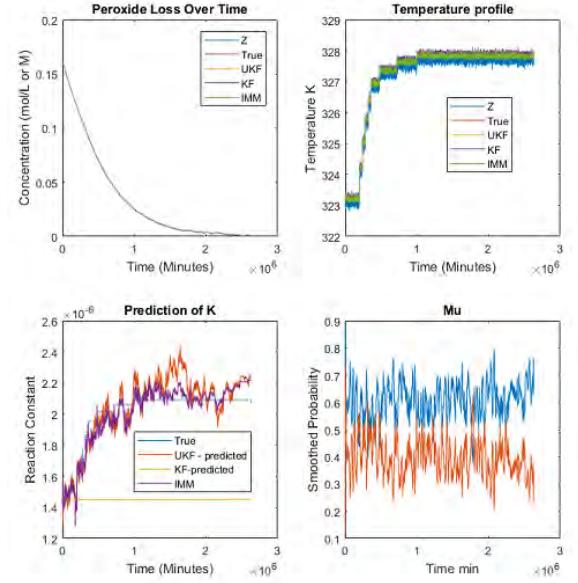

Figure 6. Temperature profile with a 5°C change, early onset.

It is interesting to note that in the case of large temperature change, neither one of the Kalman estimators provided correct values of  $k$ . At lower changes in temperature and based on the root mean square errors (RMSE) seen in Tables IV and V, one can see that the IMM and the UKF are similar in accuracy. The plain KF is unable to estimate the non-linear  $k$  constant of the system.

TABLE IV. RMSE'S FOR TEMPERATURE PROFILE WITH A 5°C CHANGE, LATE ONSET

System States	Estimator RSME		
	KF	UKF	IMM
Concentration (M)	$8.64662 \times 10^{-5}$	$8.60678 \times 10^{-5}$	$8.41062 \times 10^{-5}$
Temperature (K)	$5.25555 \times 10^{-1}$	$1.41209 \times 10^{-1}$	$7.67782 \times 10^{-2}$
K Constant (min <sup>-1</sup> )	$5.85417 \times 10^{-7}$	$1.60082 \times 10^{-7}$	$6.5447 \times 10^{-8}$

TABLE V. RMSE'S FOR TEMPERATURE PROFILE WITH A 5°C CHANGE, EARLY ONSET

System States	Estimator RSME		
	KF	UKF	IMM
Concentration (M)	$8.14059 \times 10^{-5}$	$8.15825 \times 10^{-5}$	$7.98528 \times 10^{-5}$
Temperature (K)	$5.26052 \times 10^{-1}$	$1.401 \times 10^{-1}$	$7.6568 \times 10^{-2}$
K Constant (min <sup>-1</sup> )	$5.84784 \times 10^{-7}$	$1.09314 \times 10^{-7}$	$6.8593 \times 10^{-8}$

### B. Profiles with Random Temperature Changes

Experimental setup remains the same as described in the preceding section, but here the temperature profiles have random temperature variations to simulate hydrogen peroxide products being used and stored under real world conditions.

The simulation results are shown in Fig. 7 through Fig. 9 and Tables VI through VIII.

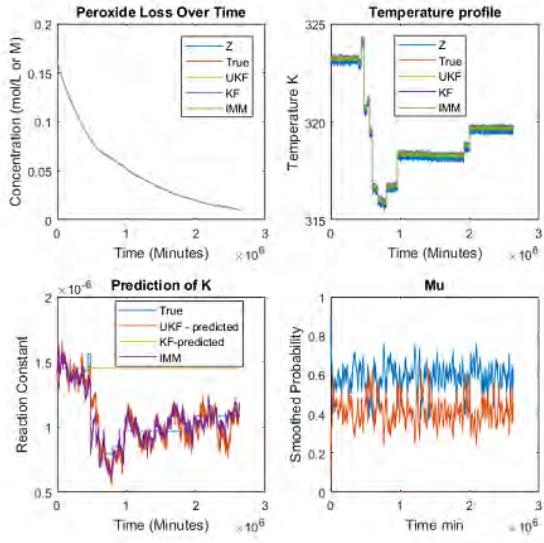

Figure 7. First profile with random temperature variation.

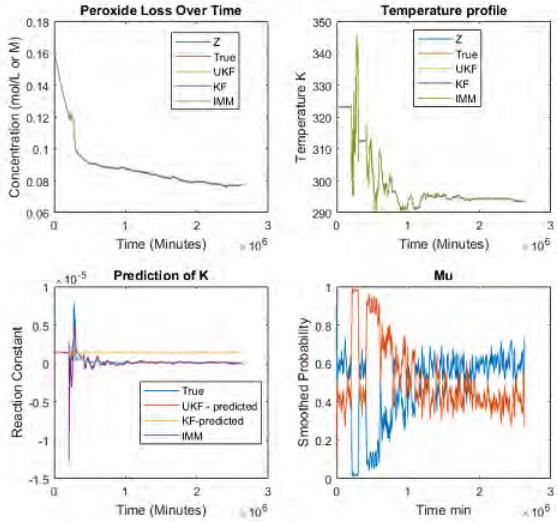

Figure 8. Second profile with random temperature variation.

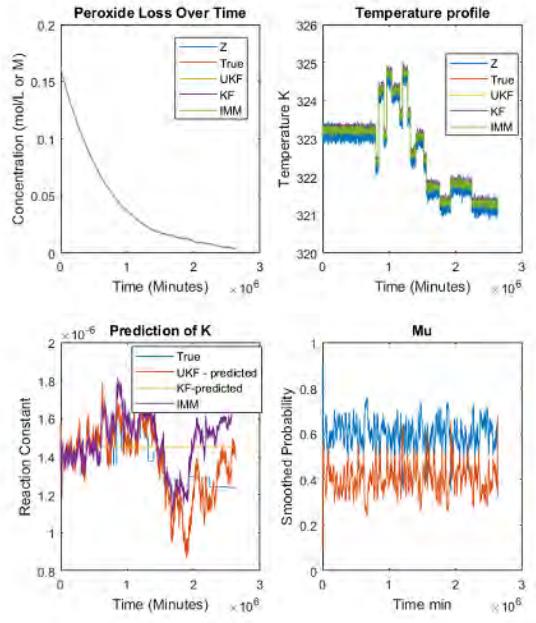

Figure 9. Third profile with random temperature variation.

TABLE VI. RMSE'S FOR FIRST PROFILE WITH RANDOM TEMPERATURE VARIATION

System States	Estimator RSME		
	KF	UKF	IMM
Concentration (M)	$8.60051 \times 10^{-5}$	$8.54607 \times 10^{-5}$	$8.3524 \times 10^{-5}$
Temperature (K)	1.02656	$1.51515 \times 10^{-1}$	$9.73733 \times 10^{-2}$
K Constant ( $\text{min}^{-1}$ )	$1.34067 \times 10^{-7}$	$1.29145 \times 10^{-7}$	$1.71801 \times 10^{-7}$

TABLE VII. RMSE'S FOR SECOND PROFILE WITH RANDOM TEMPERATURE VARIATION

System States	Estimator RSME		
	KF	UKF	IMM
Concentration (M)	$1.74623 \times 10^{-4}$	$2.27619 \times 10^{-4}$	$2.25101 \times 10^{-4}$
Temperature (K)	4.55449	$6.321 \times 10^{-1}$	$6.21528 \times 10^{-1}$
K Constant ( $\text{min}^{-1}$ )	$1.29936 \times 10^{-6}$	$2.91613 \times 10^{-7}$	$6.26771 \times 10^{-7}$

TABLE VIII. RMSE'S FOR THIRD PROFILE WITH RANDOM TEMPERATURE VARIATION

System States	Estimator RSME		
	KF	UKF	IMM
Concentration (M)	$8.13347 \times 10^{-5}$	$8.34285 \times 10^{-5}$	$8.16195 \times 10^{-5}$
Temperature (K)	$4.56238 \times 10^{-1}$	$1.47175 \times 10^{-1}$	$8.8286 \times 10^{-2}$
K Constant ( $\text{min}^{-1}$ )	$1.34067 \times 10^{-7}$	$1.29145 \times 10^{-7}$	$1.71801 \times 10^{-7}$

Based on Fig. 7 through Fig. 9 and Tables VI through VIII, one can see that the general trend is preserved. The UKF and IMM do the best job at predicting the reaction constant  $k$ , in terms of state estimation error. Additionally, the probability of switching between KF and UKF modes are more pronounced during large temperature variations. This indicates the robustness of IMM predictions with respect to random temperature spikes.

## V. CONCLUSION

This paper proposes a new augmented state space model for faster prediction of hydrogen peroxide decay under any user-defined temperature profile. It was shown that the best state estimation accuracy was achieved by the UKF and IMM methods. Additionally, it was shown that for the IMM and UKF to have the best accuracy, low temperature changes and shorter durations of particular temperature variations are required. In terms of future work, more temperature profiles will be tested, and the pH level will be incorporated into the model. As the team was unable to find equations that relate the pH level to the rate of reaction, the effects of pH level would have to be incorporated through experimental data. The team will utilize a small set of experimental data with combined estimation and deep learning algorithms to create a more comprehensive model in the future.

## ACKNOWLEDGEMENTS

The authors would like to express gratitude for the technical, financial, and in-kind support from Virox Technologies Inc. (Oakville, Ontario). The authors would also like to thank NSERC and the Ontario Centres of Excellence for their financial support.

**Abstract**—This paper presents an online tuning rule-based adaptive control algorithm to control DC motor speed. For this, a method of recursive least squares with forgetting was proposed to approximate the relation between single input (voltage) and single output (angular speed) of the DC motor system as a first order differential equation. Using this approximated first order system and Lyapunov method-based disturbance observer with the online tuning rule, a voltage input of the DC motor was generated to track a desired value of rotational speed of the motor. A performance evaluation of the proposed algorithm was conducted in the MATLAB/Simulink environment. The results show that the designed algorithm enables to track the reference speed successfully using only a single input and a single output of DC motor system.

**Keywords-** *Lyapunov direct method; recursive least squares; single input single output; disturbance observer; DC motor system*

## I. INTRODUCTION

Modeling of dynamics in many systems including the DC motor is crucial for the purpose of dynamic analysis and control. However, the actual DC system has uncertainties, which cause a modeling error and thus have a negative effect on control performance. To deal with this issues, there are several existent studies to control the DC motor system that have been mainly based on model basis control approaches.

Ali et al. presented a model-based adaptive PID controller for the DC motor. The presented controller was able to secure robust and optimized control performance despite parameter variation and uncertainties [1]. Dursun and Durdu, proposed a speed control algorithm in the DC motor using a sliding mode observer that has been widely adopted in various industry control applications with uncertainties [2]. In addition, Meena and Bhushan suggested a DC motor speed control algorithm using fuzzy logic techniques [3]. In their study, a comparative analysis of the developed controller's performance with the PID control was conducted. The above studies require a mathematical model or knowledge of the systems to predict its

dynamic behaviors and to derive an optimal input for successful control. However, it is hard to derive an accurate mathematical model (or obtain knowledge) for an optimal control in the actual system due to its nonlinearity and complexity. To address this issue, Xue et al. investigated a fractional order PID controller for a position servomechanism control system that dealt with actuator saturation and shaft torsional flexibility [4]. For an actual implementation, a modified approximation method was introduced in their study where some fixed parameters for the approximation were defined for the target system. However, the parameters need to be tuned whenever the target system is changed.

To overcome the above limitation, this study proposes a controller design method based on a model approximation that does not require parameters of the target system. In the method, an adaptive speed control algorithm with the online tuning was developed to control the DC motor speed using only single input (voltage) and single output (angular speed) of an approximated mathematical model (first order system). Also, this study introduces a disturbance observer using the Lyapunov direct method [5] that was designed to estimate disturbance.

The remainder of this paper is organized as follows. Section 2 provides a description of control concept. Section 3 describes the online tuning rule-based speed control algorithm. Section 4 provides a simulation-based performance evaluation results. Finally, Section 5 concludes the paper.

## II. CONCEPT OF CONTROL ALGORITHM

A control algorithm proposed in this study was designed based on an approximated mathematical model that was assumed to have no restoring force due to frictional force existent in the actual system and thus can be finally considered as a damped first order system (Eq. (3)).

In the typical mechanical second order system, its dynamics can be expressed by the following equation.

$$m\ddot{x} + c\dot{x} + kx + f = u \quad (1)$$

where  $m$ ,  $c$ ,  $k$  represent mass, damping coefficient, and stiffness, respectively.  $x$ ,  $u$ ,  $f$  are the state variable, input and frictional term. If the stiffness  $k$  can be assumed to have zero (no restoring force due to frictional force), the above equation can be arranged by Eq. (2) as follows.

$$\ddot{x} + \frac{c}{m}\dot{x} + \frac{f}{m} = \frac{1}{m}u \quad (2)$$

Since Eq. (2) does not include  $k$  (restoring force) and thus it can be considered to be in a neutral equilibrium state. Then Eq. (2) can be rewritten as Eq. (3) by replacing  $\dot{x}$  by  $y$ , which becomes a first order system.

$$\dot{y} + \frac{c}{m}y + \frac{f}{m} = \frac{1}{m}u \quad (3)$$

Since conditions of the first order damped system could be changed by various factors such as temperature, operating points, etc., the recursive least squares (RLS) was employed in this study to deal with an adaptive approximation of the damped system. Detailed explanation is provided in Section 3.

### III. ONLINE TUNING RULE BASED SPEED CONTROL ALGORITHM

#### A. RLS with forgetting based approximation

For the adaptive approximation of damped system based on current input and output data, the RLS with forgetting method was applied. The first order differential equation used for this approximation is expressed in Eq. (4).

$$\dot{y} + ay = u_a \quad (4)$$

where  $y$  is the system output that is controlled by the input ( $u_a$ ).  $a$  is a time-varying parameter that represents the characteristic of the first order differential equation (4). To estimate the parameter  $a$  adaptively using the system input and output,  $u_a - \dot{y}$ ,  $y$  and  $a$  are defined as the output for the RLS ( $y_r$ ), regressor ( $\Phi$ ), and estimate ( $\hat{\theta}$ ), respectively. Fig. 2 shows a model schematic for the applied RLS with forgetting.

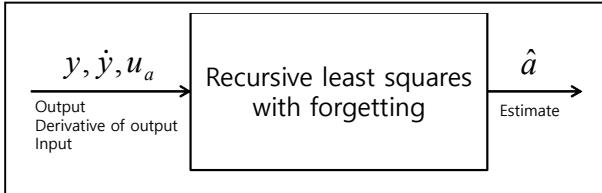

Figure 1. Model schematic for the RLS with forgetting

The following equations were used to compute the optimal gain ( $L$ ), and covariance ( $P$ ), and estimate ( $\hat{\theta}$ ) that minimize the cost function ( $J_r$ ) with forgetting factor ( $\lambda$ ) in Eq. (8).

$$\hat{\theta}_k = \hat{\theta}_{k-1} + L_k (y_{r,k} - \Phi_k \hat{\theta}_{k-1}) \quad (5)$$

$$L_k = P_{k-1} \Phi_k (\lambda + \Phi_k^T P_{k-1} \Phi_k)^{-1} \quad (6)$$

$$P_k = (I - L_k \Phi_k^T) P_{k-1} / \lambda \quad (7)$$

$$J_r(\hat{\theta}_k, k) = \frac{1}{2} \sum_{i=1}^k \lambda^{k-i} (y_r(i) - \Phi(i) \hat{\theta}_k)^2 \quad (8)$$

#### B. Disturbance observer

The role of the Lyapunov method-based disturbance observer [5] adopted in the study is to estimate the disturbance that is a main source of modeling error between the approximately modeled damped system and actual one. The disturbance ( $d$ ) in the approximated first order equation is shown in the (9).

$$\dot{y} = -\hat{a}y + u + d \quad (9)$$

The used disturbance observer requires two stages of pre-correction and estimation correction with the Lyapunov method. The following equation shows the disturbance observer's dynamics.

$$\dot{e}_y = -\hat{a}e_y - e_d + K_d (y - \hat{y}) \quad (10)$$

where  $e_y$ ,  $e_d$ , and  $K_d$  represents the output error, disturbance error, and observer gain, respectively.

#### C. Lyapunov direct method based control input

The Lyapunov candidate function ( $J$ ) defined for control input is as follows.

$$J = \frac{1}{2} e^2 \quad (11)$$

where  $e$  represents the error ( $e = y_{des} - y$ ).

Using Eq. (12) below, a proper control input is derived so that the value of derivative of  $J$  is always negative.

$$\begin{aligned} \frac{dJ}{dt} &= e \dot{e} = (y_{des} - y)(\dot{y}_{des} - \dot{y}) \\ &= -W(y_{des} - y)^2 \end{aligned} \quad (12)$$

where  $W$  is the positive weighting factor that represents a change rate in the Lyapunov candidate function. Based on Eq.

(9) and (12), The proper control input,  $u_p$  that minimizes  $J$  in Eq. (11) is derived as follows.

$$u_p = \dot{y}_{des} + W y_{des} + (\hat{a} - W) y_{des} + \hat{d} \quad (13)$$

The derived proper input can enable the output ( $y$ ) to track its desired output ( $y_{des}$ ). The derivative of the desired output ( $\dot{y}_{des}$ ) was estimated using a linear Kalman filter.

#### D. Online tuning rule

To cover the issue of degradation of control performance due to disturbance, the online tuning rule for  $W$  with the error defined in Eq. (11) was utilized as shown in Eq. (14). While  $W$  has a relatively large value in case of a large value of error,  $W$  has a relatively smaller value in the opposite case.

$$W = m_w e^2 + n_w \quad (14)$$

where  $m_w$  and  $n_w$  are coefficients with negative values.

Figure 2 shows the tuning rule in the  $W$  and  $e$  plane.

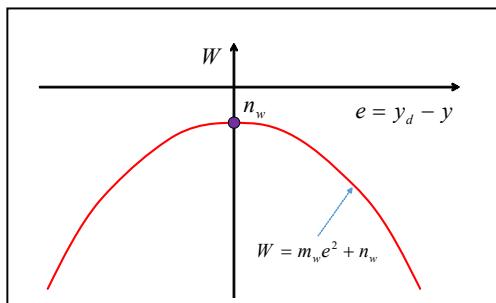

Figure 2. Model schematics for simulation model

#### IV. SIMULATION BASED PERFORMANCE EVALUATION

Simulation was conducted to evaluate the designed controller's performance with a mathematical model of DC servo motor in the MATLAB/Simulink environment. Figure 3 shows a model schematic for the control performance evaluation.

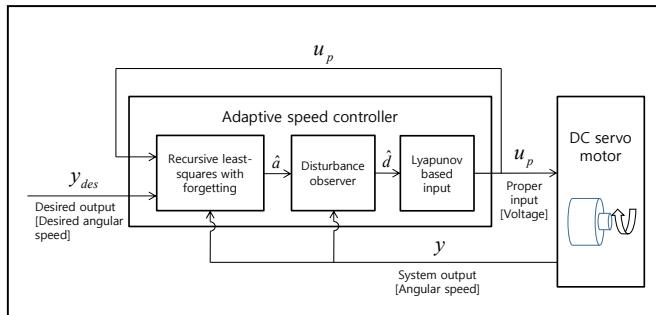

Figure 3. Model schematic for the control performance evaluation

Figure 4 shows a typical circuit diagram of DC servo motor used in this study for the performance evaluation.

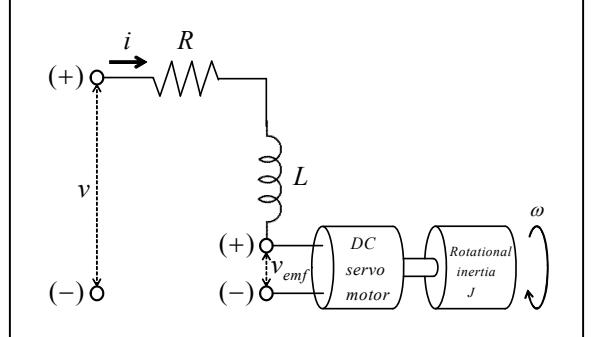

Figure 4. Circuit diagram of DC servo motor

In the figure,  $R$ ,  $L$ ,  $\omega$ ,  $i$ ,  $v$ ,  $v_{emf}$ ,  $J$  represent the resistance, inductance, angular velocity, current, input voltage, counter electromotive force, and rotational inertia, respectively. Mathematical models of DC servo motor used for the performance evaluation are given in the following equations.

$$\frac{di}{dt} = \frac{v}{L} - \frac{R}{L}i - \frac{K_\Phi}{L}\omega \quad (15)$$

$$\frac{d\omega}{dt} = \frac{K_\Phi}{J}i - \frac{b}{J}\omega \quad (16)$$

where  $K_\Phi$  represents the electromagnetic field constant. Based on the (15) and (16), the relationship between input (voltage,  $v$ ) and output (angular speed,  $\omega$ ) can be rewritten as follows.

$$\dot{\omega} + \left( \frac{K_\Phi^2}{JR} + \frac{b}{J} \right) \omega + \left( \frac{K_\Phi L}{JR} \frac{di}{dt} \right) = \left( \frac{K_\Phi}{JR} \right) v \quad (17)$$

Using the RLS-based approximation method, the DC motor system model was approximated as shown in Fig. (1) and (3). Based on the approximated model and Lyapunov direct method in Eq. (13) and (14), a proper voltage input for DC motor speed control was derived. Table I shows parameter values used for the simulation-based evaluation.

TABLE I. THE PARAMETER VALUES FOR SIMULATION-BASED EVALUATION

Division	Unit	Value
Lambda ( $\lambda$ )	-	0.99
$R$	$\Omega$	2
$L$	$H$	0.1
$b$	$Nms / rad$	0.01
$J$	$kgm^2$	0.1
$K_\Phi$	-	0.3
$m_w$	-	0.7

Division	Unit	Value
$n_W$	-	-10
$W_{\text{constant}}$	-	-10

The performance of adaptive controller with the online tuning rule was compared with one with a constant weighting factor. Figs. 5-8 describes the evaluation results.

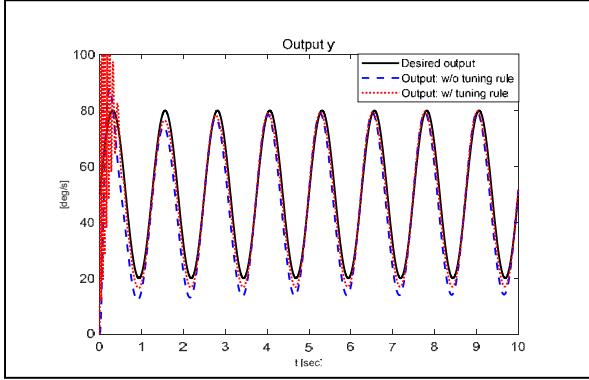

Figure 5. Evaluation results: output

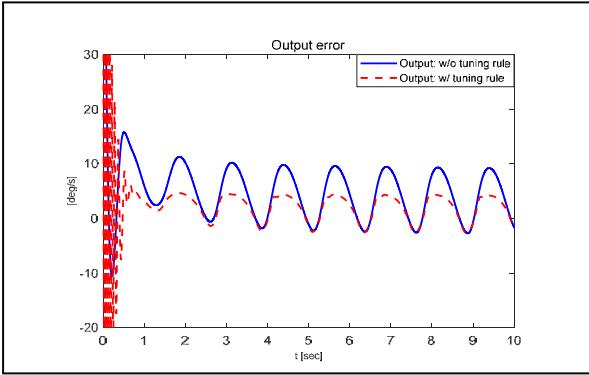

Figure 6. Evaluation results: output error

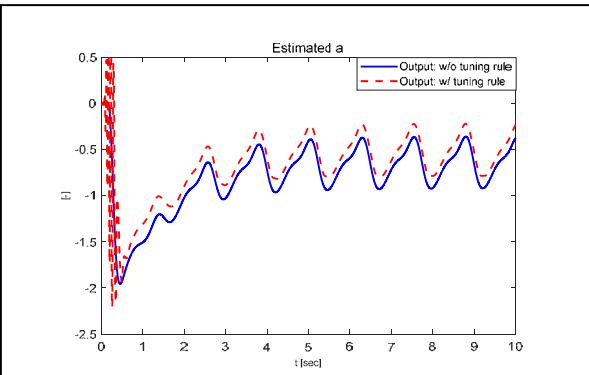

Figure 7. Evaluation results: estimated  $a$

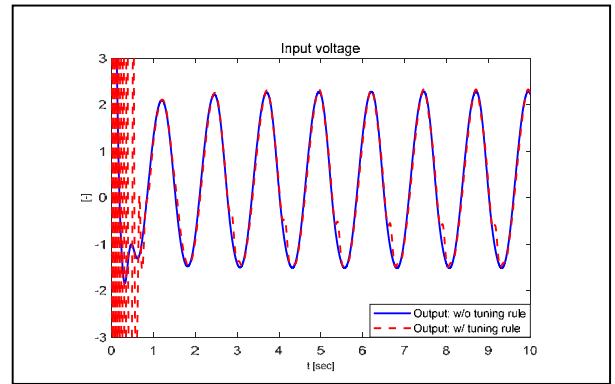

Figure 8. Evaluation results: voltage input

As seen in Figs. 5-6 and the Table 2 that shows the RMS values of output errors, the controller with the online tuning rule has smaller error than one with a constant weighting factor. However, the output  $y$  in the online tuning rule-based control algorithm shows more oscillations compared to one with a constant weighting factor in the early stage of the simulation. Also, there are steady state output errors in both cases (Fig. 6). Oscillations in the estimated  $a$  in both cases are found in Fig. 7, which are associated with oscillation of the desired output  $y_d$ . As shown in Fig. 8, there is no significant difference in the value of input voltage between both cases during the simulation time except for the beginning (i.e., transient state).

Table 2. RMS values of output errors

Division	Unit	RMS value (Output error)
Without tuning rule (With a constant weighting factor)	deg/s	7.69
With online tuning rule	deg/s	5.29

## V. CONCLUSION

In this study, the online tuning rule-based adaptive control algorithm was developed for controlling the DC motor system with single input (voltage) and single output (angular speed). For this, the approximated first order system and Lyapunov method-based disturbance observer with the online tuning rule were utilized to design the control algorithms with the MATLAB/Simulink tool. The simulation results show that the system output with the designed controller accurately tracks the desired output. In addition, the RMS value of the output errors in the designed controller is smaller than the controller without tuning rule (i.e., constant weighting factor). However, both cases show oscillations at the beginning of simulation and steady state output errors. Therefore, a further study is required to improve the control performance to cope with this issue. It is expected that the proposed adaptive controller can be used as an alternative solution for the DC motor speed control in the related industrial applications.

## Abstract—

In this paper we investigate the effects of stiffness, damping and temperature on the performance of a MEMS vibratory gyroscope. The stiffness and damping parameters are chosen because they can be appropriately designed to synchronize the drive and sense mode resonance to enhance the sensitivity and stability of MEMS gyroscope. Our results show that increasing the drive axis stiffness by 50% reduces the sense mode amplitude by ~27% and augments the resonance frequency by ~21%. The stiffness and damping are mildly sensitive to typical variations in operating temperature. The stiffness increases by 1.25%, while the damping decreases by 3.81%, when the temperature is raised from 0°C to 45°C. Doubling the damping reduces the oscillation amplitude by 80%, but ~1% change in the frequency. The predicted effects of stiffness, damping and temperature can be utilized to design a gyroscope for the desired operating condition.

## I. INTRODUCTION

Microelectromechanical systems (MEMS) based inertial sensors such as accelerometers and gyroscopes are the most commercially successful MEMS sensors to date. With the rapid advancement of semi-conductor based mass manufacturing, the cost, size and power consumption are continuously decreasing, enabling new applications in automotive, aerospace, biomedical and consumer electronics. MEMS vibratory gyroscopes are physical sensors that can detect and measure the angular motion of an object relative to an inertial frame of reference. MEMS vibratory sensors show promising vibration characteristics. Fabrication accuracies are comparable to macro-scale high performance sensors [1]-[4]. A vibratory gyroscope uses a vibrating structure (proof mass) to determine the rate of rotation [5]. The vibrating proof mass tends to vibrate along the same plane even if its support rotates. The Coriolis Effect causes the object to exert a force on its support, and the rate of rotation can be determined from the exerted force. The energy is transferred from the vibrating drive axis to the sense axis through Coriolis

force. The sense mode response detects the angular velocity. The sensing performance of the MEMS gyroscope can deteriorate because of the influence of time-varying parameters such as damping, cross stiffness, and environmental variations. They generate a frequency of oscillation mismatch between the two vibrating axes [6]. Due to fabrication imperfections and environmental effects, true values of resonant frequencies deviate from their nominal values (which is known as frequency mismatching). These lead to considerable reduction in the sensitivity of the gyroscope. Therefore, it is necessary to design proper stiffness and damping for achieving a robust gyroscope.

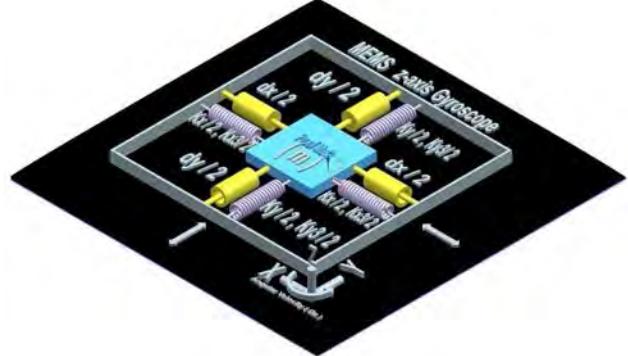

Figure 1. Schematic showing MEMS gyroscope model.

Optimization of time varying system parameters for better performance can be achieved by iterative modelling and simulation procedure. Various modeling techniques, including finite element analysis (FEA) modeling, analytical modeling and simplified lumped parameter modeling are employed [7]. FEA based modeling are robust, flexible and accurate in solving the complete multi-physics problem. Additionally, it can be coupled with controllers and electronics for selecting an appropriate controller [8].

Usually gyroscope displacement measurement varies under open loop scheme which can cause undesirable performance characteristics such as scale factor nonlinearity, limited dynamic range and narrow bandwidth [9]. In MEMS gyroscopes,

manufacturing imperfection and noises often exist which negatively influence the resolution and performance. Errors due to noise are inevitable in actual MEMS gyroscopes, and thus, the controller has to be robust and effectively designed [10]. Post-fabrication modeling of gyroscope using lumped-parameter techniques can shed light to the influence of system parameters, noise and environmental parameters on the gyro performance. This will allow iteration and design of a proper controller.

In this paper, a lumped-parameter model for predicting the gyroscope performance with the influence of various system parameters such as stiffness, damping and environmental condition (temperature) is analyzed. The results can be utilized to design a robust high performance gyroscope with efficient controller.

## II. MATHEMATICAL MODEL

In a vibratory gyroscope the main sensing element is the proof mass, which is suspended above the substrate by several flexible beams. The overall dynamic system is usually modeled as a 2 degrees-of-freedom (2-DOF) spring-mass-damper system, as shown in Figure 1. The proof mass is suspended on the substrate using four springs (Figure 1), the other end of the springs are anchored to the substrate. An electrostatic actuation is used to give an oscillatory motion to the proof mass in the drive axis. When the proof mass is subject to an angular velocity, energy is transferred from drive axis to sense axis, causing it to oscillate. The mechanism for sensing position and velocity of the proof mass along the sense axis is present. Constant velocity of the proof mass and changing angular velocity of gyroscope about the z-axis are assumed. The MEMS vibratory gyroscope model includes proof mass ( $m$ ), drive axis displacement ( $x$ ), the angular velocity input ( $\Omega_z$ ), and sense axis displacement ( $y$ ).

According to Lagrange's [11] equation, the dynamics of the gyroscope can be described by the equations of motion below [12]:

$$m\ddot{x} + d_{xx}\dot{x} + k_{xx}x + k_{xy}y + d_{xy}\dot{y} = u_x + 2m\Omega_z\dot{y} \quad (1)$$

$$m\ddot{y} + d_{yy}\dot{y} + k_{yy}y + k_{xy}x + d_{xy}\dot{x} = u_y + 2m\Omega_z\dot{x} \quad (2)$$

Manufacturing imperfections are translated mainly to the asymmetric spring and damping terms,  $k_{xy}$  and  $d_{xy}$ . The drive and sense axes spring and damping terms  $k_{xx}$ ,  $k_{yy}$ ,  $d_{xx}$  and  $d_{yy}$  are mostly known, but have small unknown variations from their nominal values. The proof mass can be determined accurately, and  $u_x$ ,  $u_y$  are the control forces in the x and y directions.

Dividing gyroscope dynamics by the reference mass, the following equation can be obtained [13]:

$$\begin{aligned} \ddot{q}^* + \frac{D^*}{m}\dot{q}^* + \frac{k_1^*}{m}q^* + \frac{k_3^*}{m} + q^{*3} \\ = \Omega_z^* q^* + S^* q^* + 2S^* \dot{q}^* + u^* \end{aligned} \quad (3)$$

where

$$q^* = \begin{bmatrix} x^* \\ y^* \end{bmatrix}, u^* = \begin{bmatrix} u_x^* \\ u_y^* \end{bmatrix}, D^* = \begin{bmatrix} d_{xx} & d_{xy}^* \\ d_{xy}^* & d_{yy}^* \end{bmatrix}, k_1^* = \begin{bmatrix} k_{xx}^* & k_{xy}^* \\ k_{xy}^* & k_{yy}^* \end{bmatrix},$$

$$k_3^* = \begin{bmatrix} k_{x^3}^* & 0 \\ 0 & k_{y^3}^* \end{bmatrix}, S^* = \begin{bmatrix} 0 & \Omega_z^* \\ -\Omega_z^* & 0 \end{bmatrix}$$

Angular rate variation may be considered to be negligible. The equations of motion of the gyroscope are normalized to generalize the model. The final non-dimensional equation is derived in terms of normalized time,  $t^* = \omega_0 t$ . With this, dividing both sides of the equation by the reference frequency and length gives [13]:

$$\begin{aligned} \ddot{q}^* + \frac{d^*}{m\omega_0}\dot{q}^* + \frac{k_1^*}{m\omega_0^2}q^* + \frac{k_3^*}{m\omega_0^2}q^{*3} \\ = \frac{\Omega_z^*}{\omega_0^2}q^* + 2\frac{S^*}{\omega_0}q^* + \frac{u^*}{m\omega_0^2} \end{aligned} \quad (4)$$

where the parameters are defined as follows:

$$\begin{aligned} q = \frac{q^*}{q_0}, d_{xy} = \frac{d_{xy}^*}{m\omega_0}, \Omega_z = \frac{\Omega_z^*}{\omega_0}, u_x = \frac{u_x^*}{m\omega_0^2} \frac{1}{q_0}, u_y = \frac{u_y^*}{m\omega_0^2} \frac{1}{q_0} \\ \omega_x = \sqrt{\frac{k_x}{m\omega_0^2}}, \omega_y = \sqrt{\frac{k_y}{m\omega_0^2}}, \omega_{xy} = \frac{k_{xy}}{m\omega_0^2}, \\ \delta_x = \frac{k_x^3}{m\omega_0^2}q_0^2, \delta_y = \frac{k_y^3}{m\omega_0^2}q_0^2 \end{aligned}$$

Consequently, the non-dimensional representation becomes

$$\ddot{q} + D\dot{q} + qk_1 + k_3q^3 = \Omega_z^2\dot{q} + 2S\dot{q} + u \quad (5)$$

where

$$\begin{aligned} q = \begin{bmatrix} x \\ y \end{bmatrix}, u = \begin{bmatrix} u_x \\ u_y \end{bmatrix}, D = \begin{bmatrix} d_x & d_{xy} \\ d_{xy} & d_y \end{bmatrix}, k_1 = \begin{bmatrix} \omega_x^2 & \omega_{xy} \\ \omega_{xy} & \omega_y^2 \end{bmatrix}, \\ k_3 = \begin{bmatrix} \delta_x & 0 \\ 0 & \delta_y \end{bmatrix}, S = \begin{bmatrix} 0 & \Omega_z \\ -\Omega_z & 0 \end{bmatrix} \end{aligned}$$

Simulation is done to observe the influence of stiffness, damping and temperature on gyroscope performance to minimize time and cost of expensive trial and error with the actual fabrication cycle.

MATLAB Simulink [14] is used for simulation and computation. Spring stiffness, damping coefficient and temperature are known to have significant influence on the output performance of gyroscope. Thus, the objective of the simulation is to quantify the effects of these parameters. The spring stiffness and damping coefficient are varied from half to double of their nominal values. The temperature is varied from  $0^\circ\text{C}$  to  $45^\circ\text{C}$  to observe the temperature effect on stiffness, damping coefficient and on sensing magnitude. For the simulation model, the nominal values for the proof mass, stiffness, and damping are extracted from the literature reported in [12]. Proof mass,  $m = 0.57\text{e}^{-8}\text{kg}$ , damping coefficient along the drive-axis,  $d_{xx} = 0.429\text{e}^{-6}\text{N s/m}$ , damping error due to manufacturing imperfection,  $d_{xy} = 0.0429\text{e}^{-6}\text{N s/m}$ , damping coefficient along the sense-axis,  $d_{yy} = 0.687\text{e}^{-36}\text{N s/m}$ , spring stiffness along the drive-axis,  $k_{xx} = 80.98\text{ N/m}$ , stiffness error

due to manufacturing imperfection,  $k_{xy} = 5$  N/m, spring stiffness along the sense-axis,  $k_{yy} = 71.62$  N/m, angular velocity,  $\Omega_z = 5$  rad/s are considered.

### III. MODEL RESULTS

#### A. Oscillation Frequency

To identify the first resonance frequency, input frequency is varied, a sinusoidal electromagnetic force is introduced at the drive-axis and output is sensed both in drive and sense directions (Fig. 2). Usually the drive mode displacement is higher compared to sense mode due to the energy transfer.

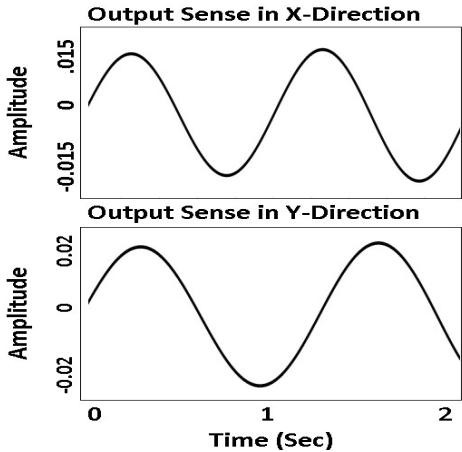

Figure 2. Displacement in drive mode (x) and sense mode (y) direction.

After sweeping the simulation with the frequency range of 1 kHz to 60 kHz (Fig. 3), the resonance frequency is found at around 9.4 kHz. So, for better focusing, the frequency range is restricted from 10 kHz - 30 kHz for other comparisons.

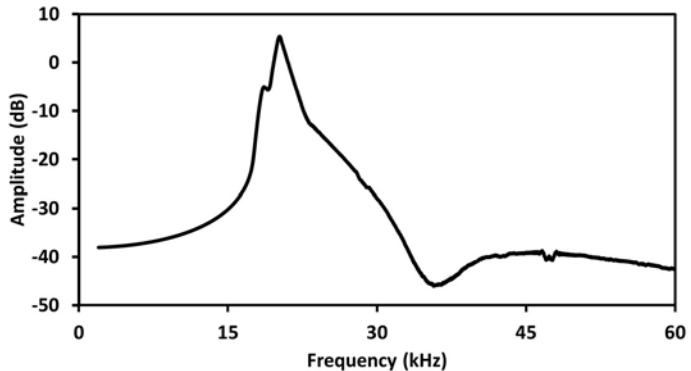

Figure 3. Frequency versus magnitude graph.

#### B. Variation in Stiffness

Suspension beam along drive and sense direction provides the stiffness necessary in each direction. Keeping the  $k_{yy}$  value constant at 71.62 N/m,  $k_{xx}$  is varied from 50% (normalized value 0.5) to 150% (normalized value 1.5). The normalized value of tuned reference stiffness (80.98 N/m) is considered as 1. It is observed that magnitudes at resonance frequencies show linear decreasing trend (Fig. 4) and amplitudes decrease (Fig. 5) as stiffness increases. However, decreasing the stiffness creates phase lag and distortion in output response.

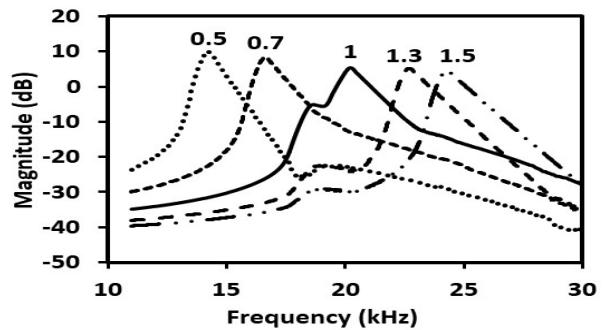

Figure 4. Effect of drive mode stiffness on resonance frequency and amplitude.

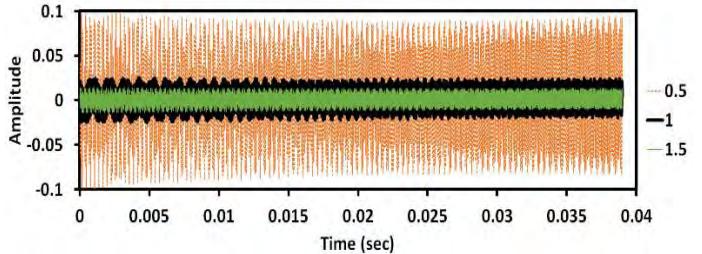

Figure 5. Effect of drive mode stiffness on output sense (sense mode stiffness is constant)

Keeping the  $k_{xx}$  value constant,  $k_{yy}$  is varied. It is observed that shift in resonance frequency is non-significant (Fig. 6).

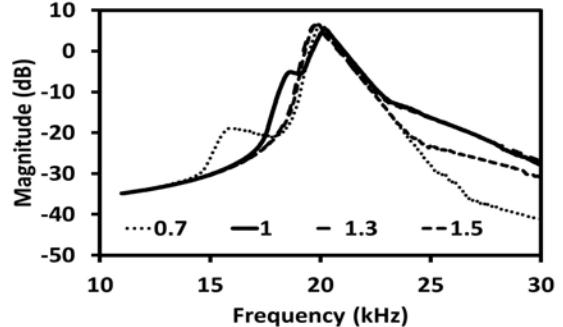

Figure 6. Effect of sense mode stiffness on magnitude (drive mode stiffness is constant).

Variation in stiffness ( $k_{xx}$  and  $k_{yy}$ ) along both axes decreases magnitudes at resonance frequencies and resonance frequencies shift towards higher frequencies (Fig. 7) and amplitudes also decreases as stiffness increases (Fig. 8).

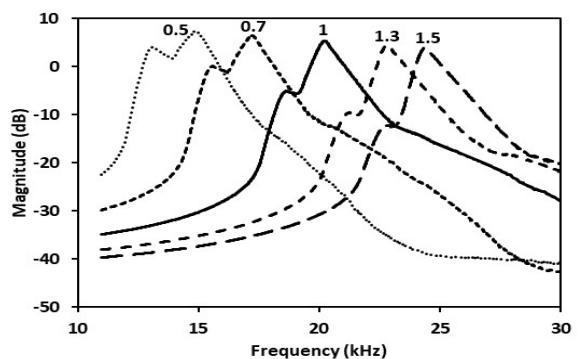

Figure 7. Combined effect of drive mode stiffness and sense mode stiffness on magnitude.

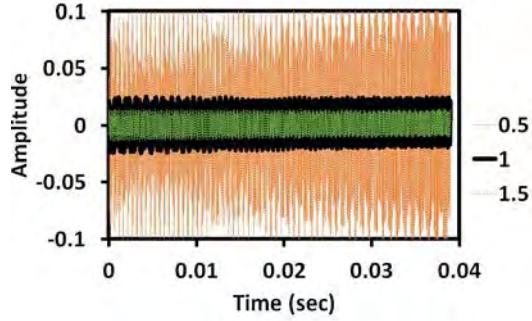

Figure 8. Effect of drive mode stiffness and sense mode stiffness on output sense.

### C. Variation in Damping

Here, damping along drive axis is varied (Fig. 9). It is obvious from the figure that the resonance frequencies do not change that much but slope steepness decreases after resonance frequencies.

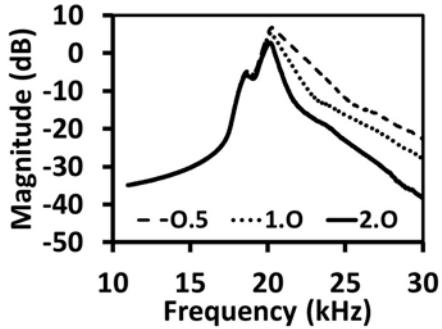

Figure 9. Effect of drive mode damping on magnitude.

### D. Temperature Variation

One key disadvantage of MEMS gyroscope is its high thermal sensitivity. The frequency of oscillation drifts with temperature. Temperature variation mainly affects the stiffness and damping of the supporting beams. Here investigation on the temperature sensitivity for stiffness and damping is done. The variation of stiffness with temperature can be modeled using simplified linear relationship of [7]  $K(T) = K_0(1 - k\Delta T)$ , where  $K_0$  is the stiffness coefficient at reference temperature 300 K and  $k=70$  ppm.

Variation of damping coefficient with temperature can be modeled as [7]  $d(T) = d_0 \cdot 1.28^{\ln(\frac{T}{300})}$ , where  $T$  is temperature in K,  $d_0$  is damping coefficient at reference temperature of 300 K. Magnitude shows positive increasing trend with the increase of temperature when stiffness and temperature relationship shows linear behaviour. The damping coefficient within industrial temperature range shows decreasing trend as temperature increases (Fig. 10, 11).

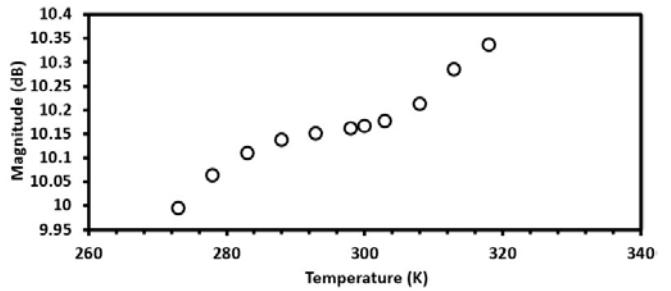

Figure 10. Effect of temperature on linear drive mode stiffness and magnitude

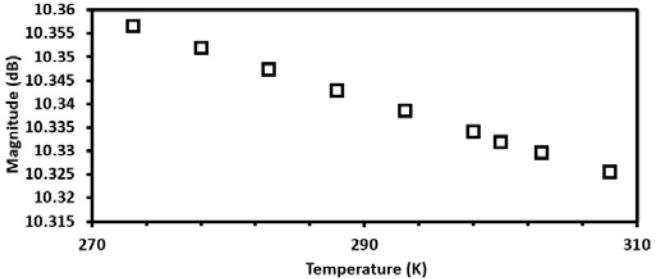

Figure 11. Effect of temperature on non-linear damping and magnitude

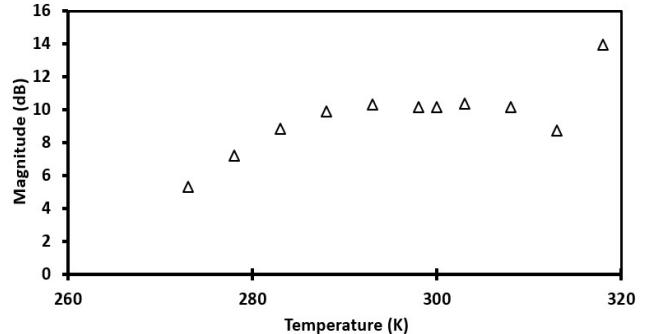

Figure 12. Effect of temperature on non-linear drive mode stiffness and magnitude.

The spring stiffness and temperature relationship shows non-linear behavior, the magnitude increases non-linearly up to a certain point before decreasing. At the end of the industrial temperature range, the magnitude increases drastically (Fig. 12).

## IV. CONCLUSION AND FUTURE WORK

This paper investigates the effect of variation of suspending stiffness coefficient, damping coefficient and temperature on the performance of MEMS gyroscope. Simulation results show how these parameters affect the error i.e. mismatch between the input and sense signals. This will help to design appropriate system parameters and controllers to increase gyroscope accuracy. Simulation results also show that stiffness is the dominant gyroscope parameter. The temperature can negatively impact resonance frequency and sense magnitude. In the future, we plan to extend this by including experimental validation of our results with MEMS gyroscopes and implementing a controller to minimize these effects and maximize the gyroscope performance.

**Abstract**—A typical and useful way to derive the dynamics equation of the tethered systems is by means of the Lagrange's equations and various dynamic models of different tethered missions are established by the Lagrangian formulation. The Hamiltonian formulation is also widely used in the mechanical systems for its well-known symplectic structure property. With this in mind, the dynamics equation of the tethered system's motion are deduced by Hamilton's equations in this research. The relation between the Lagrangian and Hamiltonian is shown by Legendre transformation. The goodness of the Hamiltonian formulation is intuitive to reveal the Energy balance property that corresponds to the passivity property. Furthermore, the Hamiltonian energy function of tethered system is employed for facilitating the controller design. In order to bring the system into operations, the energy based control is to achieve the tethered system for precise positioning. Simulations are used to demonstrate the effectiveness of the designed controller.

**Keywords**-Tethered satellite system; Passivity; Energy-based control.

## I. INTRODUCTION

Space tethered systems have been drawn great attention on its significant potential for the space missions utilization during the past decades. The tethered satellite system consists of two or more satellites which are connected by a long cable. The key challenge to bring the tethered space systems into operation is to successfully deploy the tether to the desired position in a stable and fast manner. However, the dynamics of the tethered systems are quite complex for the overall flexibility, then toward getting insight into the dynamics and control of the deployment for tethered systems, the simplified dumbbell model of the tethered systems are usually taken [1]. The mother and daughter satellites are considered as point mass connected by an inextensible massless tether. Thus, the important aspects of the dynamic behavior of the tethered system can be investigated by the simplified model without the involving the complicated mathematical equations.

In the past researches, the dynamics and control of tethered satellite system are well studied. The dynamic model of tethered system is usually derived by the Lagrangian formulation because it is easy to apply and solve the equations of motion for such two-body problem. A lot of research achievement of tethered systems are gained space applications such as the debris towed by tether, tethered satellite formation, tethered robot, etc. Among these applications, space tether deployment is the key issue, which is still a hot topic. The deployment control of the tethered system is not easy because it is prone to swing or liberating due to the coriolis force induced by deployment. Sometimes, the fast deployment speed may cause too large swing amplitude, which should be avoided to proceed space tethered operations. Many researchers are focusing on the problem how to achieve the tether deployment fast and stable with suppressing the libration [2-7]. For example, a tension control law in terms of the tether length and its velocity was firstly raised by Rupp for tether deployment [2]. Then, Fujii proposed a mission function control for the tether deployment based on the Lyapunov function [3]. A linear tension control for tether deployment was presented by Pradeep through the linearization [4]. Sun and Zhu developed a fractional order control law to eliminate the overshooting [5]. Further, Wen proposed a saturated controller by imposing a special saturation function to deal with tension constraints [6]. Kang and Zhu design a fractional order sliding mode tension control to counter the perturbations or uncertainties [7].

In this study, we proposed a natural controller design approach which is closely related to the dynamics of the tethered system. The energy-based control is used for precise positioning and effective suppressing the libration. Firstly, the dynamic equations are derived by the Lagrange's equations. The obtained dynamic equations of the tethered system are further represented in the compact form of Euler-Lagrange. The important passivity of the inherent aspect of tethered system's dynamics is revealed with specific matrix. In addition, Hamiltonian formulation is used to derive the dynamic equations of motion, which is an equivalent way of Lagrangian. Hamiltonian formulation is also widely used in the mechanical systems for its well-known symplectic structure property. Thus, energy balance property of the tethered system equivalent to passivity is given. The property is generally founded by

Hamiltonian formulation rather than specifying the expressions of the matrix. Finally, the energy-based control is developed and asymptotic stability of the closed-loop system is proved to ensure the precise positioning.

## II. MODELING FORMULATION

The widely used model of tethered space system control is the dumbbell model that is a long tether connecting two satellites at its ends, as shown in Fig.1 [8]. The system is moving in the orbit of the earth. The orbital motion coordinate is located as  $o\text{-}xyz$ . The  $y$ -axis directs toward the Earth center. The  $x$ -axis is perpendicular to the  $y$ -axis in the orbital plane and pointing at the velocity's direction of the orbit. The  $z$ -axis complies with the right-hand rule. The mass of the Main satellite and Subsatellite is  $m_1$  and  $m_2$ , respectively. To bring insight of space tether system, following assumptions are made usually.

- a) The field of the earth is central gravitational field and the Main and Sub satellites are particles.
- b) The mass ratio of the Subsatellite over Main satellite is sufficiently small such that coordinate  $o\text{-}xyz$  always remains in its nominal orbit.
- c) The tether is massless and its flexibility is ignored.
- d) The tether length  $l$  is very short compared to the distance  $R$  from coordinate  $o\text{-}xyz$  to the center of earth.
- e) External perturbation force is ignored. The orbit is circular and only motion in the orbital plane is considered.
- f) Tether tension is the only control force acts along the tether. The tether is deployed/retrieved through the tension control, i.e., the required tension is produced by the motor driving the tether reel in/out system.

Based upon the assumptions, the TSS motion can be decomposed into the orbital motion of the system's center of mass (CM) and the local libration motion  $\theta$  of tether about the CM in the orbital plane, as shown in Fig.1.

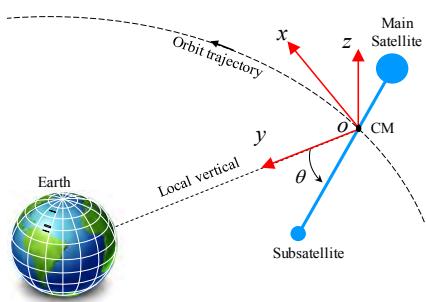

Figure 1. Sketch of the space tether system

Accordingly, the kinetic energy of the tethered system reads  $K_0 = 0.5(m_1 + m_2)R^2\Omega^2 + 0.5m_0l^2(\theta' + \Omega)^2 + 0.5m_0(l')^2$ , where the prime ( $'$ ) denotes the derivative with respect to time  $t$ , and  $\Omega$  is the orbital angular velocity.  $m_0 = m_1m_2/(m_1 + m_2)$  is the equivalent mass. Due to  $l \ll R$ , the tethered system's potential

energy can be approximated as  $U_0 = -(m_1 + m_2)R^2\Omega^2 + 0.5m_0l^2\Omega^2(1 - 3\cos^2\theta)$ .

### A. Lagrangian Formulation

Take the Lagrangian function as  $L = K - U$ , the dynamic equations of the tethered system can be straightly obtained according to the Lagrange's Equation,

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{s}} - \frac{\partial L}{\partial s} = Q \quad (1)$$

where  $s = \{l, \theta\}$  is the generalized coordinates and the nonconservative force  $Q_l = -\bar{T}$  and  $Q_\theta = 0$ .  $\bar{T}$  is the tether tension. Hence, the equations of motion are,

$$\begin{aligned} l'' - l\left[(\theta' + \Omega)^2 + \Omega^2(3\cos^2\theta - 1)\right] &= -\frac{\bar{T}}{m_e} \\ l^2\theta'' + 2ll'(\Omega + \theta') + \frac{3}{2}l^2\Omega^2 \sin 2\theta &= 0 \end{aligned} \quad (2)$$

For sake of simplicity, the dimensionless variables are introduced to normalize the equations of motion [6, 7], such as,

$$\lambda = l/l_n \quad T = \bar{T}/(m_0l_n\Omega^2) \quad \tau = \Omega t \quad \dot{s} = ds/d\tau$$

where  $l_n$  is a nominal constant of tether length.  $T$  is the dimensionless tension that is to regulate the tether deployment,  $\tau$  is the dimensionless time which equals to the true anomaly. Then, the dimensionless model of tethered system is presented as,

$$\begin{aligned} \ddot{\lambda} - \lambda[(1 + \dot{\theta})^2 - 1 + 3\cos^2\theta] &= -T \\ \lambda^2\ddot{\theta} + 2\lambda\dot{\lambda}(1 + \dot{\theta}) + 3\lambda^2 \sin\theta \cos\theta &= 0 \end{aligned} \quad (3)$$

It should be noted here,  $\lambda_{\max} \geq \lambda \geq \lambda_{\min} > 0$  to satisfy the physical real situation and avoid the singularity of second equation of the Eq.(3).

Further, to show the properties of tethered system, (3) is represented as the general form of Euler-Lagrange mechanical system,

$$M(q)\ddot{q} + C(q, \dot{q})\dot{q} + G(q) = u \quad (4)$$

where  $q = \text{col}(\lambda, \theta)$  is the general coordinates,  $M(q)$  is the mass matrix,  $C(q, \dot{q})$  is the Coriolis and centrifugal force terms,  $G(q)$  is the gravity term, and  $u = \text{col}(-T, 0)$  is the generalized force.

$$M(q) = \begin{bmatrix} 1 & 0 \\ 0 & \lambda^2 \end{bmatrix} \quad C(q, \dot{q}) = \begin{bmatrix} 0 & -\lambda(\dot{\theta} + 2) \\ \lambda(\dot{\theta} + 2) & \lambda\dot{\lambda} \end{bmatrix} \quad G(q) = \begin{bmatrix} -3\lambda\cos^2\theta \\ \frac{3}{2}\lambda^2 \sin 2\theta \end{bmatrix} \quad (5)$$

From the dimensionless equations (4), a dimensionless Lagrangian  $L(q, \dot{q})$  could be obtained as follows,

$$L(q, \dot{q}) = K(q, \dot{q}) - U(q) = \frac{1}{2}\dot{\lambda}^2 + \frac{1}{2}\lambda^2\left[\left(\dot{\theta} + 1\right)^2 - 1 + 3\cos^2\theta\right] \quad (6)$$

where  $K(q, \dot{q}) = \frac{1}{2}\dot{\lambda}^2 + \frac{1}{2}\lambda^2 \left[ (\dot{\theta} + 1)^2 - 1 \right]$  and  $U(q) = -\frac{3}{2}\lambda^2 \cos^2 \theta$  are the dimensionless kinetic energy and potential energy, respectively.

*Property 1.* The inertia matrix  $M(q)$  is positively bounded,  $\zeta_{\min} \leq \|M(q)\| \leq \zeta_{\max}$ .  $\zeta_{\min}$  and  $\zeta_{\max}$  are the minimum and maximum eigenvalue of inertia matrix, respectively.

*Property 2.* There exists a positive constant  $k_g$  satisfying  $\|\partial G(q)/\partial q\| \leq k_g$ .

*Property 3.* The time derivative of the mass matrix and the matrix of coriolis and centrifugal force terms are dependent with each other. Such that,  $0.5\dot{M}(q) - C(q, \dot{q})$  is a skew-symmetry matrix.

$$\dot{q}^T [0.5\dot{M}(q) - C(q, \dot{q})] \dot{q} = 0 \quad (7)$$

Define an energy function  $E$  satisfying the transformation

$$E = \dot{q}^T \frac{\partial L}{\partial \dot{q}} - L, \text{ then one has,}$$

$$E = \frac{1}{2}\dot{\lambda}^2 + \frac{1}{2}\lambda^2\dot{\theta}^2 - \frac{3}{2}\lambda^2 \cos^2 \theta = \frac{1}{2}\dot{q}^T M(q)\dot{q} + U(q) \quad (8)$$

The derivative of the energy function can be directly obtained, such that,

$$\begin{aligned} \dot{E} &= \dot{q}^T M \ddot{q} + \frac{1}{2} \dot{q}^T \dot{M} \dot{q} + \dot{U} \\ &= \dot{q}^T \left( \frac{1}{2} \dot{M} - C \right) \dot{q} + \dot{q}^T u + \dot{q}^T G - \dot{q}^T G \\ &= \dot{q}^T u = -\dot{\lambda} T \end{aligned} \quad (9)$$

The energy function is  $E$  bounded from below, if  $\exists P \geq -\infty$ , such that the potential energy function  $U(q) \geq P$ . Then, system satisfies passivity property as follows,

*Property 4.* Define the function  $S = E - P \geq 0$  as the storage function, then the system (4) with inputs  $u$  and outputs  $\dot{q}$  is passive in general, such that,

$$S(t) - S(0) \leq \int_0^t \dot{q}^T u \, dt \quad (10)$$

*Assumption 1.* The libration angle of the payload always remains in  $(-\pi/2, \pi/2)$ ,  $|\theta| < \pi/2$ .

## B. Hamiltonian Formulation

In Hamiltonian mechanics, the canonical coordinates  $(q, p)$  is used to describe the physical system's motion. Related to the Lagrangian formulation, the Hamiltonian is a function of  $(q, p)$  instead of  $(q, \dot{q})$  in Lagrangian. It is understood that  $\dot{q}$  is replaced by  $q$  and  $p$ , thus  $\dot{q}$  is in terms of  $(q, p)$ .  $p = \partial L / \partial \dot{q}$  is the generalized momentum.

The generalized momentum  $p = \text{col}(p_\lambda, p_\theta)$  is obtained as,

$$p_\lambda = \frac{\partial L}{\partial \dot{\lambda}} = \dot{\lambda} \quad (11-a)$$

$$p_\theta = \frac{\partial L}{\partial \dot{\theta}} = \lambda^2(\dot{\theta} + 1) \quad (11-b)$$

Invoking the Legendre transformation, the Hamiltonian function can be derived by,

$$H(q, p) = \dot{q}^T p - L(q, \dot{q}, q, p) \quad (12)$$

The Hamiltonian of the tethered satellite system is obtained, such that

$$\begin{aligned} H(q, p) &= \frac{1}{2}\dot{\lambda}^2 + \frac{1}{2}\lambda^2\dot{\theta}^2 - \frac{3}{2}\lambda^2 \cos^2 \theta \\ &= \frac{1}{2}p_\lambda^2 + \frac{\lambda^2}{2} \left( \frac{p_\theta}{\lambda^2} - 1 \right)^2 + U(q) \end{aligned} \quad (13)$$

Hamilton Equations used for mechanical system is presented as follows,

$$\begin{pmatrix} \dot{q} \\ \dot{p} \end{pmatrix} = \begin{pmatrix} I & \frac{\partial H}{\partial q} \\ -I & \frac{\partial H}{\partial p} \end{pmatrix} \begin{pmatrix} 0^{2 \times 1} \\ u \end{pmatrix} \quad (14)$$

The motivation to use Hamiltonian formulation instead of Lagrangian formulation is the symplectic structure of Hamilton equations in (14). Then the equations of motion of the tethered system can be expressed as,

$$\begin{aligned} \ddot{\lambda} &= -\lambda \dot{\theta}^2 + \lambda(\dot{\theta} + 1) + 3\lambda \cos^2 \theta - T \\ \lambda^2 \ddot{\theta} + 2\lambda \dot{\lambda}(\dot{\theta} + 1) &= -3\lambda^2 \sin \theta \cos \theta \end{aligned} \quad (15)$$

It is easy to find that (15) is equivalent to (3) which is derived by the Lagrangian formulation.

Further, the time derivative of  $H$  could be directly calculated as,

$$\begin{aligned} \dot{H}(q, p) &= \frac{\partial^T H}{\partial q} \dot{q} + \frac{\partial^T H}{\partial p} \dot{p} \\ &= \left( \frac{\partial^T H}{\partial q}, \frac{\partial^T H}{\partial p} \right) \begin{pmatrix} I \\ -I \end{pmatrix} \left( \frac{\partial^T H}{\partial q}, \frac{\partial^T H}{\partial p} \right)^T + \frac{\partial^T H}{\partial p} u \\ &= -\frac{\partial H}{\partial p_\lambda} T = -\dot{\lambda} T \end{aligned} \quad (16)$$

Equation (16) indicates the energy balance property of tethered system. The increase in energy (Hamiltonian quantity) of the system equals to the power supply. The relation shown in (16) is actually equivalent with passivity (9), Moreover, it is quite straight to observe the intrinsic property of tethered system (3) by the Hamiltonian formulation.

## III. ENERGY-BASED CONTROL

The aim of controller design is to deploy the tethered system to its desired position. As well known, the stable equilibrium position of the tethered system lies in local vertical. Thus, the desired states of tethered system is usually set at the

downward equilibrium  $(\lambda, \dot{\lambda}, \theta, \dot{\theta}) = (\lambda_d, 0, 0, 0)$ .  $\lambda_d$  is the desired tether length and tether angle is zero. By virtue of the passive property of the tethered system, the controller design for tethered system deployment is posed based on the energy modified Lyapunov function in this section.

From the Hamiltonian formulation, the quantity of Hamiltonian energy function obtained by the Legendre transformation is lower bounded when the potential energy function  $U(q) - P \geq 0$ , then one can take a function  $P = \bar{U}(q) = U(q)|_{\theta=0}$  to shift the Hamiltonian function to be positive such that,

$$V_1 = H - P = \frac{1}{2}\dot{\lambda}^2 + \frac{1}{2}\lambda^2\dot{\theta}^2 - \frac{3}{2}\lambda^2\cos^2\theta + \frac{3}{2}\lambda^2 \quad (17)$$

It is obvious that (17) is always positive. Thus, one can select the function  $V_1$  as the Lyapunov function candidate, and then controller is designed to make the closed-loop system stable.

Take the derivative of the function  $V_1$ ,

$$\dot{V}_1 = \dot{H} - \dot{P} = -T\dot{\lambda} + 3\lambda\dot{\lambda} \quad (18)$$

Thus, the closed-loop tethered system is passive if the one take output  $\dot{\lambda}$  and input  $T$  as follows,

$$T = 3\lambda + k_v\dot{\lambda}, k_v > 0 \quad (19)$$

where  $k_v$  is an strictly positive constant.

Then, substituting (19) into (18), which yields,

$$\dot{V}_1 = \dot{H} - \dot{P} = -T\dot{\lambda} + 3\lambda\dot{\lambda} = -k_v\dot{\lambda}^2 \quad (20)$$

It is straightforward to know that the closed-loop tethered system is Lyapunov stable under the controller (19). However, the final tether length is not certain since  $V_1$  is not convex at  $\lambda = \lambda_d, \theta = 0$ . It is easy to check with the Hessian Matrix of  $V_1$ , at the desired position, such that,

$$\frac{\partial^2 V_1}{\partial q^2} \Big|_{\substack{\lambda=\lambda_d \\ \theta=0}} = \begin{bmatrix} 3\sin^2\theta & 3\lambda\sin(2\theta) \\ 3\lambda\sin(2\theta) & 3\lambda^2\cos(2\theta) \end{bmatrix}_{\substack{\lambda=\lambda_d \\ \theta=0}} = \begin{bmatrix} 0 & 0 \\ 0 & 3\lambda_d^2 \end{bmatrix} \quad (21)$$

It is obvious that the Hessian Matrix  $\frac{\partial^2 V_1}{\partial q^2} \Big|_{\substack{\lambda=\lambda_d \\ \theta=0}}$  is not positive definite. Thus, even if the tether may arrive to the desired length but it will not be able to stay there.

To achieve the desired final length along the vertical, the energy Lyapunov function should be modified so that it is convex at the desired position. For the purpose of this, we construct a Lyapunov function as follows,

$$V_2 = V_1 + \frac{1}{2}k_p(\lambda - \lambda_d)^2 \quad (22)$$

where  $k_p$  is an strictly positive constant. It is obvious to find that  $V_2 \geq 0$  and compared with  $V_1$ , a positive term  $\frac{1}{2}k_p(\lambda - \lambda_d)^2$

is added, which has the unique minimum at desired tether length. Then, at the desired equilibrium we have,

$$\frac{\partial V_2}{\partial q} \Big|_{\substack{\lambda=\lambda_d \\ \theta=0}} = \begin{bmatrix} 3\lambda\sin^2\theta + k_p(\lambda - \lambda_d) \\ \frac{3}{2}\lambda^2\sin(2\theta) \end{bmatrix}_{\substack{\lambda=\lambda_d \\ \theta=0}} = 0 \quad (23)$$

$$\frac{\partial^2 V_2}{\partial q^2} \Big|_{\substack{\lambda=\lambda_d \\ \theta=0}} = \begin{bmatrix} 3\sin^2\theta + k_p & 3\lambda\sin(2\theta) \\ 3\lambda\sin(2\theta) & 3\lambda^2\cos(2\theta) \end{bmatrix}_{\substack{\lambda=\lambda_d \\ \theta=0}} = \begin{bmatrix} k_p & 0 \\ 0 & 3\lambda_d^2 \end{bmatrix} \quad (24)$$

Thus, it indicates that  $V_2$  is convex, then it is stable to stay at the desired equilibrium. Then, the controller (19) should be modified accordingly. The control law becomes,

$$T = 3\lambda + k_p(\lambda - \lambda_d) + k_v\dot{\lambda}, k_p > 0, k_v > 0 \quad (25)$$

*Theorem 1:* Under the controller (25) and Assumption 1, the deployment control of the closed-loop tethered system is asymptotically stable at desired downward equilibrium.

*Proof.* Select the Lyapunov function candidate as  $V_2$  and take the derivative of it, yields that,

$$\dot{V}_2 = -T\dot{\lambda} + 3\lambda\dot{\lambda} + k_p(\lambda - \lambda_d) \quad (26)$$

Recall (25), one has,

$$\dot{V}_2 = -k_v\dot{\lambda}^2 \leq 0 \quad (27)$$

From (27), the Lyapunov function  $V_2$  is non-increasing, then one has  $V_2 \leq V_2(0)$ . The trajectory of all the states will converge to the largest invariant set  $W = \{q \in \mathbb{R} | \dot{V}_2 = 0\}$  as the time approaches to infinity. The set  $W$  indicates  $\dot{\lambda} = 0$ , which further means the tether length keeps constant  $\lambda = \text{constant}$ . Then, recall (13) and (16), one can have,

$$\frac{1}{2}\lambda^2\dot{\theta}^2 - \frac{3}{2}\lambda^2\cos^2\theta = \text{constant} \quad (28)$$

Combine (28) with first equation of (15), we can know that there are at most two isolate solutions of  $\dot{\theta}$  for  $\dot{\theta} \in \mathbb{R}$ . Then, one can have that,

$$\ddot{\theta} = 0 \quad (29)$$

Substitute (29) into the second equation of (15), yields,

$$\sin\theta\cos\theta = 0 \quad (30)$$

Further, the solutions of tether angle can be obtained under the Assumption 1, we have  $\theta = 0$ . Combine with (25) and (15), we have,

$$k_p(\lambda - \lambda_d) = 0 \quad (31)$$

Then, one can get the unique solution for tether length  $\lambda = \lambda_d$ . Therefore, the deployment of tethered system has unique equilibrium at  $(\lambda, \dot{\lambda}, \theta, \dot{\theta}) = (\lambda_d, 0, 0, 0)$  under the controller (25) with the Assumption 1. The equilibrium

$(\lambda, \dot{\lambda}, \theta, \dot{\theta}) = (\lambda_d, 0, 0, 0)$  is concluded to be asymptotically stable, which completes the proof.  $\square$

*Remark 1:* In the proof, the LaSalle's invariance theory is used to prove the asymptotic stability of the closed-loop system. However, it should be noted that it actually can't be directly applied because of unboundedness of tether angle. But it can be circumvented by variable transform as in [6, 10], which is omitted in the proof because it has no effect on the conclusion of asymptotic stability.

*Remark 2:* The convex of the function in (24) actually implies the asymptotically stable of the closed-loop system. Because the convex of the function at desired equilibrium means that any state of motion in the small domain near desired equilibrium has the minimum at desired equilibrium. That is the reason we construct the function to make the energy Lyapunov function have minimum at the desired equilibrium.

#### IV. SIMULTION AND DISCUSSION

In this section, numerical experiments are carried on to verify the effectiveness of the proposed controller. The simulations are conducted in MATLAB R2017a using the numerical integrator ODE45. The tethered satellite system is assumed to orbit circularly with an altitude of 220 km and the orbital velocity is  $1.18 \times 10^{-3}$  rad/s. The maximum tether length is 100 km. The corresponding initial and final parameters of the tether system are selected as  $(\lambda_0, \dot{\lambda}_0, \theta_0, \dot{\theta}_0) = (0.01, 0.5, 0, 0)$  and the desired states  $(\lambda_d, \dot{\lambda}_d, \theta_d, \dot{\theta}_d) = (1, 0, 0, 0)$ , respectively.

Define two potential energy functions  $U_1 = U_0 + P$  and  $U_2 = U_1 + \frac{1}{2}k_p(\lambda - \lambda_d)^2$  according to the Lyapunov function  $V_1$  and  $V_2$ . Parameters in these functions are set as  $k_p = 4$  and  $\lambda_d = 1$ . Then, sketch the graph of the function in configuration space of  $\lambda - \theta$ , see Fig. 2. As shown in the graph of first subplot, the function  $U_1$  has the minimum if the tether angle is zero but it is not depending on tether length. It indicates that the tethered system is able to deploy to the vertical direction but the deployed tether length is not certain maybe any value. However, seen from the second subplot, the function  $U_2$  has the unique minimum at desired position. It can be observed that the function  $U_2$  is convex around the small neighborhood of the desired equilibrium.

Further, the control laws (19) and (25) are used to clarify the stability of the closed-loop tethered system. The control gains are chosen as  $k_v = 1$  in (19) and  $k_p = 2$ ,  $k_v = 4$  in (25). The profiles of the position states and tension in tether are presented in Figs.3-5. Seen in Fig. 3, the length profiles show that both two proposed controller can achieve a stable tether deployment. The controller (25) fulfill the tether deployment to desired length successfully, however the controller (19) does not. It can be found that the tether angle profiles converge to zero as we want for both two controllers, see Fig. 4. The tension in tether for two controllers are shown in Fig.5, tension is positive and finally equal to the static balance force. In conclusion, the simulation results agree with the theoretical

analysis given in Section III and the proposed controller (25) can perform the asymptotic stability for deployment control of the tethered system.

## V. CONCLUSION

In this study, we focus on the dynamics and control of space tethered system's deployment in two dimensional space. In order to get insight of the dynamic behavior of the tethered system, the dynamic model is formulated by the way of Lagrangian and Hamiltonian, respectively. In Lagrangian formulation, the dynamic equation is written into the Euler-Lagrange form and the passivity property is further presented by the specifically chosen matrix of coriolis/centrifugal force. In alternative way, the equivalent property of energy balance in the tethered system is performed by Hamiltonian formulation, which is much more intuitively due to the symplectic structure. This property is actually in general rather than depending on specified coriolis/centrifugal matrix. By virtue of the Hamilton formulation, the deployment control of the tethered system is studied based on Energy-based control methodology. Controllers are proposed for stabilizing tether deployment. The Lyapunov stability and asymptotical stability are analyzed for

each controller, respectively. Finally, the results are verified by the numerical simulations.

# Direct Switching Position Control Algorithms for Pneumatic Actuators using On/Off Solenoid Valves

Yile Zhang and Gary M. Bone\*

Department of Mechanical Engineering  
McMaster University

Hamilton, Canada

\*Corresponding author. E-mail: gary@mcmaster.ca

**Abstract**—Pneumatic actuators are advantageous in terms of cost, power to weight ratio and inherent safety. However, their dynamics makes precise closed-loop position control very difficult in practice. Two sliding-mode control algorithms for controlling the position of a pneumatic cylinder by directly switching four on/off solenoid valves are proposed in this paper. The solenoid valves are much less expensive than the commonly used servo or proportional valves. The proposed algorithms are compared to two state of the art position control algorithms. Based on experiments on a high friction cylinder with various payloads, the proposed controllers provide superior performance in terms of valve switches per second, steady state error, settling time and overshoot. The achieved number of valve switches per second is also about one tenth of the number required by the pulse-width modulation method that is commonly used with on/off valves. This should result in prolonged valve lifetimes and reduced maintenance costs.

**Keywords**—actuator; pneumatic; position control; sliding-mode control; solenoid valve.

## I. INTRODUCTION

Pneumatic actuators are widely used in automation because they provide several advantages. They are low cost, clean and provide a high power to weight ratio. They are also inherently safe due to their natural compliance. However, the closed-loop control of their position for servoing applications is very difficult and remains an active research topic (e.g. [1]-[5]). Our interest is on the closed-loop position of pneumatic cylinders. The majority of previous papers employed proportional or servo valves to control the flow of air to/from the cylinder's two chambers. In this paper, on/off solenoid valves will be used since they are much less expensive than proportional/servo valves (e.g., US\$40 vs. US\$800). This advantage is offset by the disadvantage that their flow behaviour is discontinuous, making smooth and precise position control more difficult to achieve. While pulse-width modulation (PWM) may be used with on/off valves to approximate a proportional valve in position control applications (e.g.,[6]-[8]) it also causes frequent valve switching leading to shorter valve life. In

contrast, systems employing the direct switching method only switch the valves when it is necessary for the desired closed-loop performance. This reduced switching frequency prolongs the valve life, leading to reduced repair and replacement costs. In spite of its advantages, relatively few researchers have investigated the direct switching approach.

In [9], a double acting cylinder was controlled using four two-way on/off solenoid valves (i.e. two valves per cylinder chamber) and an optical encoder for position feedback. Their sliding-mode control (SMC) algorithm used three operating modes for the valves, and was the first to consider the problem of excessive valve switching. This algorithm will be further described in section III. For a 2 kg payload and a 40 mm step input, the steady state error (SSE) was 0.1 mm and the overshoot (OS) was less than 10 mm. They did not report any robustness results. A more sophisticated SMC algorithm with seven valve operating modes was proposed in [10]. They used the same valve configuration as in [9]. The introduction of the four additional modes and two additional tuning parameters was shown to improve both the tracking errors and valve switching frequency. For a 0.9 kg payload and 40 mm step input the 7-mode controller reduced the positive OS from 7.2 mm to 0.76 mm (i.e., 89% reduction) compared with the 3-mode controller from [9]. For the same payload and a multiple sine wave reference input the switching frequency with the 7-mode controller was 48% less than with the 3-mode controller, while the tracking errors were similar. Nonlinear model predictive control algorithms were used to directly switch the valves in [11] and [12]. While these algorithms have the potential to outperform those from [9] and [10] they require a system model and greater computing power to implement.

In this paper we propose modified versions of the SMC algorithms from [9] and [10], and compare their experimental position control performance with the original algorithms. The system structure is described in section II. Next, the designs of the existing and proposed control algorithms are presented. Experimental results, including robustness tests, are presented in section IV. Finally, conclusions are drawn in section V.

## II. SYSTEM STRUCTURE

A schematic of the system structure is shown in Fig. 1. As in [9] and [10], two two-way on/off valves (also termed 2/2 valves) are connected to each chamber of the cylinder. This has the advantage of allowing the pressure of each chamber to be independently controlled. The cylinder drives a payload mass horizontally. The position and cylinder pressures are fed back to PC-based control system. The PC switches the valves via optocouplers.

## III. CONTROLLER DESIGN

### A. Three-mode Sliding Mode Control Algorithm

In this section, the three-mode sliding mode controller (abbreviated as SMC3) proposed by Nguyen et al. [9] is briefly summarized. The three operating modes are defined as follows:

Mode 1: Both chambers' valves are closed

$$(u_1 = 0, u_2 = 0, u_3 = 0 \text{ and } u_4 = 0)$$

Mode 2: Chamber A charges and chamber B discharges

$$(u_1 = 1, u_2 = 0, u_3 = 0 \text{ and } u_4 = 1)$$

Mode 3: Chamber A discharges and chamber B charges  
( $u_1 = 0, u_2 = 1, u_3 = 1 \text{ and } u_4 = 0$ )

Mode 2 is used to move the piston in the positive direction and mode 3 is used to move it in the negative direction. Mode 1 is used to reduce the chattering when the tracking error is small enough and to save energy.

They use the second-order sliding surface:

$$s = \frac{\ddot{e}}{\omega^2} + \frac{2\zeta\dot{e}}{\omega} + e \quad (1)$$

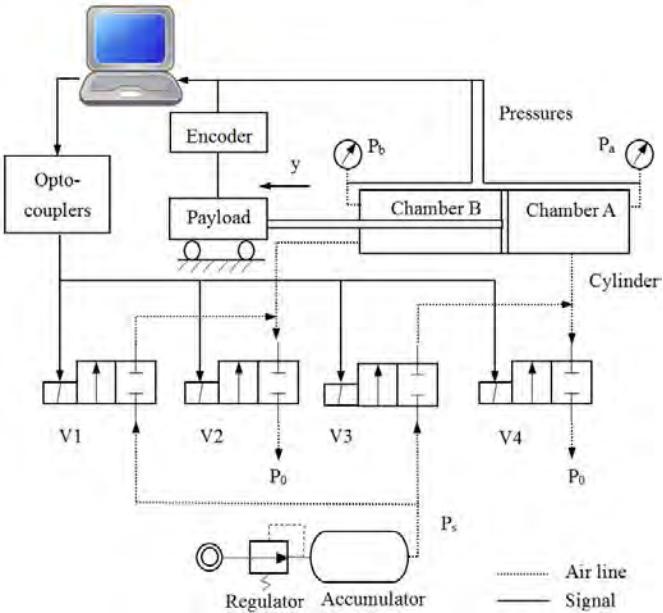

Figure 1. System schematic diagram.

where  $e = y - y_d$  is the position error,  $y$  is the actual position,  $y_d$  is the desired position, and  $\zeta$  and  $\omega$  are constant and positive numbers. The value of  $s$  determines the mode according to:

$$\begin{cases} s > \varepsilon, & \text{mode 3} \\ s < -\varepsilon, & \text{mode 2} \\ -\varepsilon \leq s \leq \varepsilon, & \text{mode 1} \end{cases} \quad (2)$$

where  $\varepsilon$  is the mode 1 boundary limit. It is used to reduce the valve switching caused by control chattering. To limit the tracking error it is desirable to choose  $\varepsilon$  as small as possible. However,  $\varepsilon$  also needs to be large enough to reduce chattering.

### B. Seven-mode Sliding Mode Control Algorithm

The seven-mode sliding mode controller (abbreviated as SMC7) proposed by Hodgson et al. [10] is briefly summarized in this section. They extended SMC3 from three to seven operating modes with the goal of reducing the number of valve switches per second. The valve states for the seven modes are defined in Table 1. Modes 1, 6 and 7 are the same as SMC3 modes 1, 2 and 3, respectively. Modes 2-5 are new.

As with SMC3 the sliding surface is defined by (1). They extended the three regions of  $s$  used with SMC3 (see (2)) to five regions. The regions, corresponding modes and qualitative forces are listed in Table 2. In addition to deadband  $\varepsilon$ , they introduce a larger boundary limit  $\beta$ . Examining Table 2, regions  $s \leq -\beta$ ,  $-\varepsilon < s \leq \varepsilon$  and  $s > \beta$  map to unique modes. Regions  $-\beta < s \leq -\varepsilon$  and  $\varepsilon < s \leq \beta$  map to two modes each, and additional logic based on the chamber pressures are required to identify the unique mode to apply. The principle behind the mode selection is the mode producing the larger acceleration should be chosen since it will reduce the tracking error faster.

For region  $-\beta < s \leq -\varepsilon$ , they deduced that the steady state payload acceleration with mode 2 is roughly proportional to  $P_s - P_b$  where  $P_s$  is the supply pressure and  $P_b$  is the pressure inside chamber B. Similarly, with mode 4 the steady state acceleration is roughly proportional to  $P_a - P_0$  where  $P_a$  is the pressure inside chamber A and  $P_0$  is atmospheric pressure. They then defined

$$E_1 = (P_s - P_b) - (P_a - P_0) \quad (3)$$

where if  $E_1$  is positive mode 2 should produce a larger acceleration than mode 4. So the following switching logic is

TABLE I. VALVE STATES FOR THE SEVEN OPERATING MODES USED BY THE SMC7 CONTROLLER

Valve	Mode						
	1	2	3	4	5	6	7
$u_1$	0	1	0	0	0	1	0
$u_2$	0	0	1	0	0	0	1
$u_3$	0	0	0	0	1	0	1
$u_4$	0	0	0	1	0	1	0

applied in the region  $-\beta < s \leq -\varepsilon$ :

$$\begin{cases} E_1 > 0, & \text{mode 2} \\ E_1 \leq 0, & \text{mode 4} \end{cases} \quad (4)$$

For region  $\varepsilon < s \leq \beta$ , a similar approach is employed. Note that the steady state acceleration will be negative. They defined

$$E_2 = (P_s - P_a) - (P_b - P_0) \quad (5)$$

where if  $E_2$  is positive mode 5 should produce a larger acceleration than mode 3. So the following switching logic is applied in the region  $-\beta < s \leq -\varepsilon$ :

$$\begin{cases} E_2 > 0, & \text{mode 5} \\ E_2 \leq 0, & \text{mode 3} \end{cases} \quad (6)$$

In order to reduce the number of switches between modes when (5) and (6) are applied, they introduced a timeout parameter  $\tau$ . Mode 2, 3, 4 or 5 is maintained for a period of  $\tau$  or longer. A larger  $\tau$  therefore reduces the switching but may also lead to larger tracking errors.

### C. Proposed Sliding Mode Control Algorithms

We propose two SMC algorithms in this section. Both are modifications of the existing algorithms, and are based on the idea that adding integral action can reduce settling time and SSE if it is properly applied.

In order to add integral action, the sliding surface is based on  $\int_0^t e dt$  rather than  $e$ . Thus, we define the new sliding surface as:

$$s = \frac{\ddot{e}}{\omega^3} + \frac{3\zeta\dot{e}}{\omega^2} + \frac{3\zeta^2e}{\omega} + \int_0^t e dt \quad (7)$$

where  $\int_0^t e dt$  provides the integral action. Integral windup may occur when there is a large change in the desired position or a large disturbance, and the integral term accumulates a significant error during the transient. The time required to reduce this large integral term can lead to overshoot and a longer settling time. Anti-windup is implemented by bounding the integral action as follows:

$$\left| \int_0^t e dt \right| \leq e_{\text{limit}} \quad (8)$$

The first proposed algorithm, termed integral SMC3

TABLE II. FIVE REGIONS OF  $S$  USED BY THE SMC7 CONTROLLER

Region	Corresponding Modes	Qualitative Pneumatic Force
$s \leq -\beta$	6	Large positive
$-\beta < s \leq -\varepsilon$	2 or 4	Small positive
$-\varepsilon < s \leq \varepsilon$	1	Zero
$\varepsilon < s \leq \beta$	3 or 5	Small negative
$s > \beta$	7	Large negative

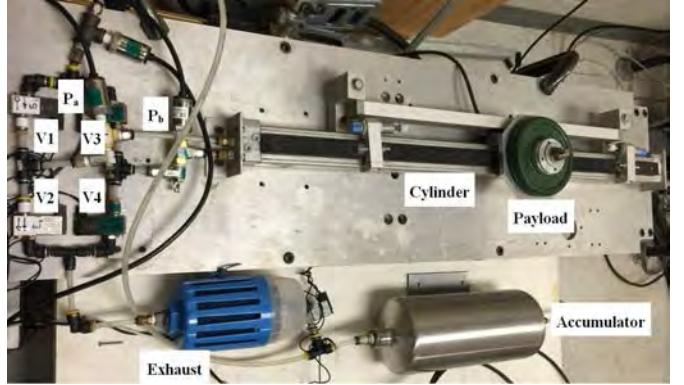

Figure 2. System hardware (PC and optocouplers are not shown).

(ISMC3), is derived from SMC3 by replacing (1) with (7) and (8). The second proposed algorithm, termed integral SMC7 (ISMC7), is similarly derived from SMC7 by replacing (1) with (7) and (8).

## IV. EXPERIMENTS

### A. Hardware

The hardware implementation of the system structure presented in section II is shown in Fig. 2. The cylinder (Festo, model number GPL-25-600) is rodless; and has a 600 mm stroke and 25 mm bore. The four on/off valves are made by MAC, model number 34B-AAA-GDFB-1BA. The linear encoder has a resolution of 0.01 mm. The pressure sensors are SSI Technologies, model number P51-100-A-B-I36-5V-000-000. The supply pressure is regulated at 0.6 MPa. All of the sensor signals and control signals are interfaced with the PC using a National Instruments PCIe-6365 card. The PC runs 64-bit Windows 7 with a 3.10 GHz Intel i5-2400 processor and 8.00 GB RAM. This data acquisition and control system is programmed in C and operates at a 1 kHz sampling frequency.

### B. Experimental Results and Discussion

To test both the transient and steady state performance, the desired position trajectory consists of a series of step changes. The step heights are 200 mm, -200 mm, 100 mm and 10 mm. The total duration is 4 s. The controller parameters were tuned for a nominal payload of 2.14 kg.

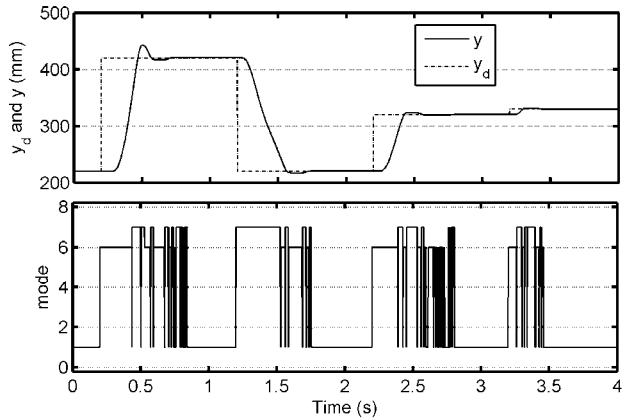

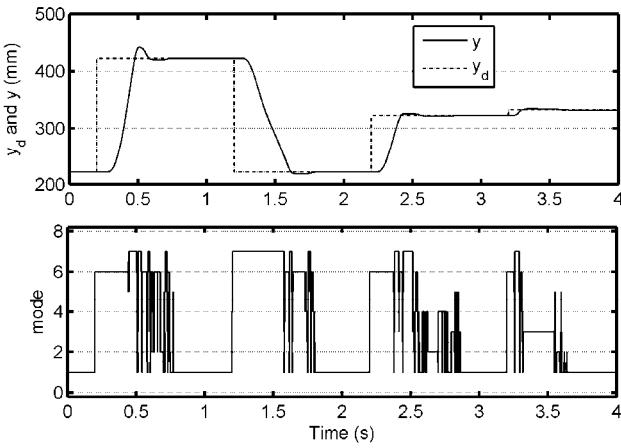

Figure 3. Experimental result for SMC3 with the nominal payload.

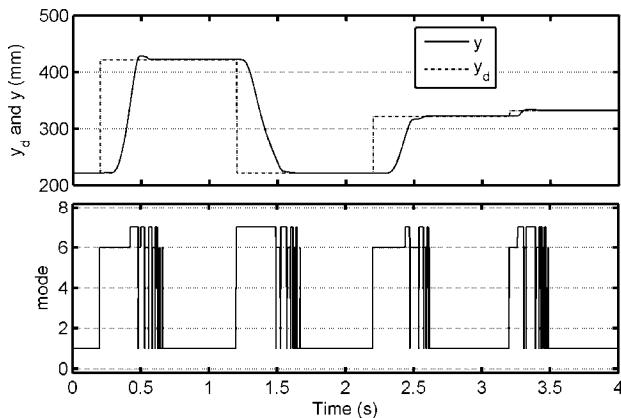

**Figure 4.** Experimental result for SMC7 with the nominal payload.

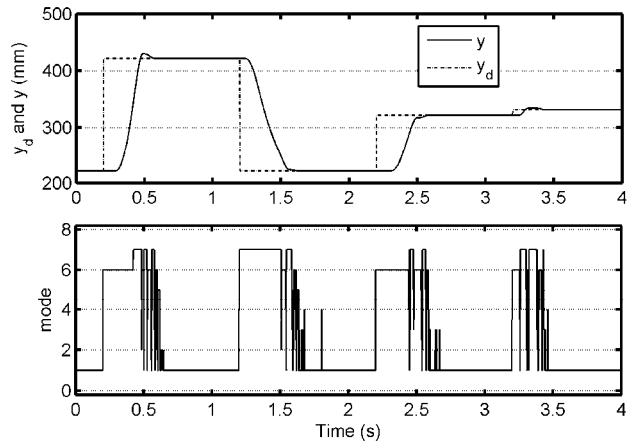

Sample responses for the four controllers with the nominal payload are plotted in Figs. 3-6. In these figures SMC3 and ISMC3 modes 2 and 3 are plotted as 6 and 7 (which are equivalent in terms of the valve states) to allow the 3-mode and 7-mode plots to be more easily compared.

Comparing Figs. 3 and 4 the responses obtained with SMC3 and SMC7 appear to be quite similar in terms of their position tracking and number of mode switches. In contrast, the performance of ISMC3 (Fig. 5) is clearly better than SMC3 (Fig. 3). ISMC3 exhibits lower OS and longer periods were no mode switches occur. ISMC7 (Fig. 6) demonstrates similar improvements over SMC7 (Fig. 4). As with SMC3 and SMC7, the benefits of ISMC7 relative to ISMC3 are not obvious from these plots. A quantitative comparison based on numerous experiments will be discussed next.

In addition to tests with the nominal payload, tests were performed with a decreased payload (0.95 kg) and an increased payload (3.24 kg) to quantify each controller's robustness to payload mismatch. The performance metrics include the SSE, OS, and the settling time  $t_s$ , which is defined here as the time for the response to settle within 1 mm of the desired steady state position. These were averaged over the four step changes. The final metric is the average number of times each valve is switched per second (SPS). Five tests were

**Figure 5.** Experimental result for ISMC3 with the nominal payload.

**Figure 6.** Experimental result for ISMC7 with the nominal payload.

performed with each controller and payload combination. The averaged results of these tests are reported in Table III.

Examining the Table III results for the nominal payload, the SPS of SMC7 is 18% smaller than that of SMC3. For SSE,  $t_s$  and OS the differences are -6%, +10% and -22%, respectively. While SMC7 demonstrates improved performance vs. SMC3, the improvement is modest compared to the results reported in [10]. It is hypothesized that the much larger static friction due to the seals of the Festo DGPL cylinder used in our experiments (~80 N vs. ~0.3 N for the Airpel M16 cylinder used in [10]) is the reason for the modest improvements observed here for SMC7.

The tabulated results for both ISMC3 and ISMC7 are consistently superior to the SMC3 and SMC7 results. For example, with the nominal payload the reductions in SPS, SSE,  $t_s$  and OS for ISMC3 vs. SMC3 were 37%, 57%, 15% and 65%, respectively. The improvements with the altered payloads were smaller. For example, with the increased payload, ISMC3 reduced SPS, SSE,  $t_s$  and OS by 43%, 19%, 16% and 47% respectively, compared with SMC3. The improvements in SSE and  $t_s$  were expected due to the integral

TABLE III. AVERAGED EXPERIMENTAL RESULTS

Controller	Payload	SPS	SSE (mm)	$t_s$ (s)	OS (mm)
SMC3	Nominal	17.85	0.35	0.40	7.99
SMC3	Decreased	19.50	0.21	0.34	2.87
SMC3	Increased	20.35	0.26	0.45	12.53
SMC7	Nominal	14.60	0.33	0.44	6.20
SMC7	Decreased	16.03	0.28	0.42	2.43
SMC7	Increased	18.60	0.40	0.47	12.77
SMCI3	Nominal	11.20	0.15	0.34	2.78
SMCI3	Decreased	14.05	0.17	0.35	0.78
SMCI3	Increased	11.65	0.21	0.38	6.61
SMCI7	Nominal	9.65	0.19	0.34	3.28
SMCI7	Decreased	11.88	0.20	0.35	1.14
SMCI7	Increased	8.55	0.17	0.38	6.60

action included in ISMC3, but the improvements in the other two metrics were not. The results also show that the performances of ISMC7 and ISMC3 are similar, except that ISMC7 lowered the SPS. For example, with the increased payload the SPS was 27% smaller with ISMC7. Lastly, the results with the altered payloads demonstrate the SPS, SSE and  $t_s$  metrics were robust to changing the payload, but the OS was not.

## V. CONCLUSION

We have proposed two control algorithms, ISMC3 and ISMC7, for controlling the position of a pneumatic cylinder by directly switching the on/off solenoid valves. The proposed algorithms experimentally outperform the existing algorithms in terms of the SPS, SSE,  $t_s$  and OS performance metrics. The proposed algorithms also switch the valves much less than if PWM was used. For example, the PWM period used in [7] produces an SPS of 100 (assuming the duty cycle is not equal to 0 or 100%). This is 10 times larger than the SPS achieved by ISMC7 in our experiments. This reduced switching should prolong the life of the valves, and lower maintenance costs. Since the performances of ISMC3 and ISMC7 are similar, it is recommended that ISMC3 be used since it does not require any pressure sensing.

**Abstract**—This paper presents the mechanical design and mathematical modeling for the first joint of a five degrees of freedom collaborative manipulator. The robot is actuated using Magneto-Rheological (MR) clutches in order to ensure full back-drivability and intrinsic torque control for safe human-friendly operation. One of the unique features of this design is the usage of a single motor for powering all five joints of the robot simultaneously and independently. After a brief description of the MR clutch principles, the details of the mechanical design and a state-space representation of the first joint are discussed. The paper will conclude with some preliminary simulation results.

## I. INTRODUCTION

In recent years, the need for a human-friendly robot that can safely operate in close proximity to humans is driving progress in robotic technologies. Many research groups [4] [5] [6] [9] [10] achieved remarkable results in the development of automated systems that can interact with the person without posing a significant threat of injury.

Among all sources of danger, the risk of injury caused by a collision between a human and a robot is one of the biggest. Direct interactions make collisions unavoidable, and mitigating impacts from such collisions is one of the top priorities for research and development.

A number of approaches address the safety of robotic systems through development of compliant actuators. Possible solutions include variable stiffness transmission approach, elastic actuation, MR brakes and MR clutches, joint torque control, Distributed MacroMini Actuation, etc.

In this paper the Distributed Active Semi Active (DASA) approach [7] is briefly discussed, and the first steps in the development of an innovative five degrees of freedom (5-DOF) manipulator are presented.

DASA approach is intended to address the safety at the level of transmission, while the majority of commercially available

\*This work was supported in part by Canadian Foundation for Innovation (CFI) and Natural Sciences and Engineering Research Council (NSERC) of Canada under grant No.25031 and RGPIN-346166.

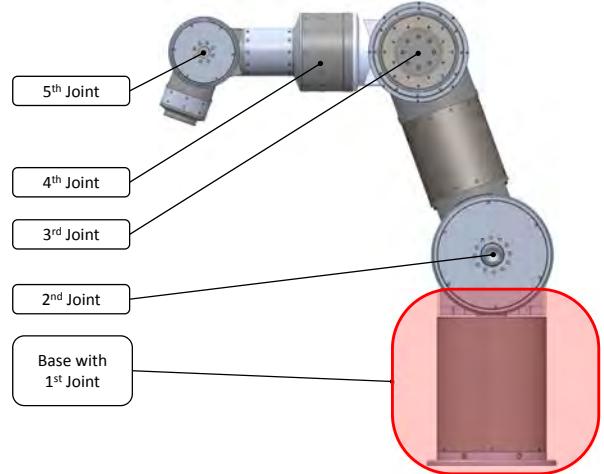

Fig. 1. Visualisation of the prospective 5-DOF robot.

robotics platforms (KUKA LBR iiwa, Kinova JACO, Franka Emika) utilize the joint torque control methodology, that could be subject to software errors or control system malfunction.

Rigorous studies regarding the safety of MR clutch for direct interactions with humans were presented previously [7]. This paper does not discuss and validate the safe characteristics of MR clutches for human-robot interactions.

The contributions of this work are as follows:

- An innovative mechanical design of the base of the intended 5-DOF manipulator is introduced. The base comprises a single motor that actuates all joints of the robot, a Harmonic Drive (HD) gearbox, and a pair of MR clutches for the first joint.
- The derivation of a state-space model of the first joint transmission is presented.
- The simulation results for a simple control algorithm and the developed mathematical model are discussed.

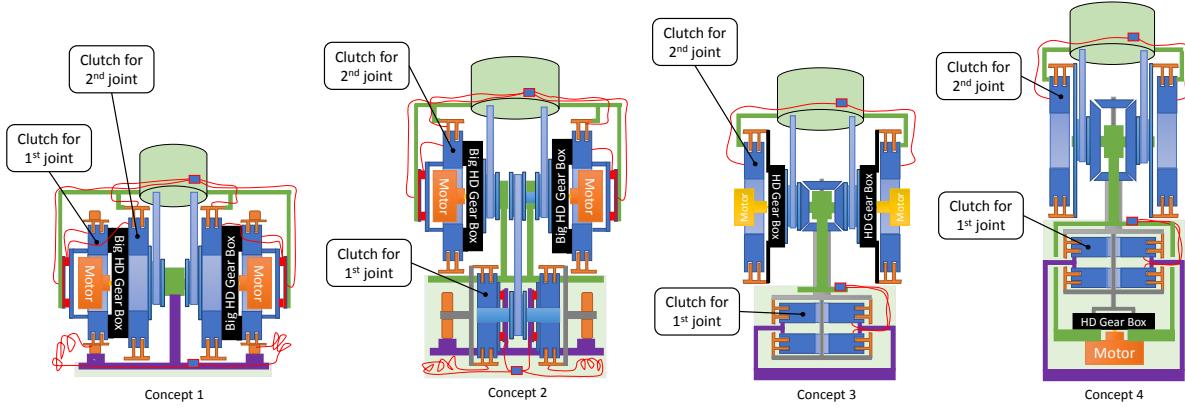

Fig. 2. Robot base design concepts

## II. OVERVIEW

### A. Design Objective

The main objective of the project is to develop a robotic manipulator using Magneto-Rheological actuators that address both safety and performance requirements of a collaborative robot. The manipulator includes five degrees of freedom that when combined with the degrees of freedom of the end-effector provide full kinematic redundancy. All joints of the intended manipulator are powered with the single motor located at the base of the robot. The targeted payload for the manipulator is 10 kg at full extension of the robotic arm.

Each joint of the manipulator is actuated using a pair of MR clutches coupled in an antagonistic configuration. The manipulator in total includes 10 MR clutches and the torque is directly delivered by the clutches to the corresponding joint without gear reduction mechanism.

### B. Working Principles of MR clutches

The utilization of a pair of MR clutches at each joint of the manipulator is a key feature of the proposed design. The main function of the MR clutch is the continual transmission of the actuation torque from the motor side to the load side. By changing the viscosity of the MR fluid in the clutch the exact amount of transmission torque between moving parts is regulated. The viscosity of MR fluid can be precisely controlled by applying a magnetic field in accordance with the requirement of the load transfer. The details of MR clutch construction and its features can be found in [2] [3] [8].

A pair of MR clutches can be configured to provide antagonistic actuation of a robot joint. In this case, the rotors of the MR clutches are rotated in opposite directions and the stators of both MR clutches are attached to a common shaft. Depending on the electromagnetic activation of each clutch, the torque can be applied by one or both MR clutches in either direction.

A complete comparison of various MR clutch configurations can be found in [1][2].

## III. DESIGN OF THE MANIPULATOR BASE

### A. Early design concepts

At the early stage of this work, multiple design concepts for the base of the manipulator were considered and analyzed. In order to reduce the mass of the robot base, a lightweight high-speed motor with a harmonic drive gear box was decided to be used. Low weight along with a high gear ratio became the main reasons for choosing an expensive HD transmission for gear reduction.

Four concepts that were studied in details are shown in Fig. 2.

- The first concept comprises two motors and two pairs of clutches mounted co-axially on the wide moving frame. The two MR clutches of the 1st joint run on a circular rail. The motors are located inside the 1st joint clutches, two harmonic drive gear boxes mounted between the 1st and 2nd joint clutches.
- The second concept is similar to the one discussed previously with the exception that the 2<sup>nd</sup> joint clutches and the two motors and two harmonic drives are positioned above the 1<sup>st</sup> joint clutches in order to reduce the diameter of the base.
- The third concept has a set of miter gears to change the orientation of the axis of rotation in order to mount 1<sup>st</sup> joint clutches coaxial in the base. A pair of 2<sup>nd</sup> joint clutches with a pair of motors and harmonic drives are positioned above the base.
- The fourth concept utilizes only one motor and one harmonic drive gear box. The pair of 1<sup>st</sup> joint clutches is mounted coaxially to the vertical axis of rotation. The pair of 2<sup>nd</sup> joint clutches is positioned above the base. A set of bevel gears distribute the motion between the clutches of the first and second joints.

The main disadvantage of the first concept is the unacceptable large size of the base and the need to use slip rings to actuate the magnetic coil and receive measurements from Hall sensors inside the MR clutches. Slip rings add additional

resistance to the electrical circuit, bring more friction to the moving joint and may corrupt the signals of the sensors.

The second concept improves the base's footprint, but still requires slip rings to energize MR clutches and connect to Hall sensors.

The third and fourth concepts both have a small footprint in the base and do not require slip rings for MR clutches. But the third design requires two motors and two harmonic drives to ensure antagonistic actuation of the joints, while the last concept can use a single motor with a single HD gear box.

Taking into account the features described above, concept 4 was selected for further development.

#### B. Transmission and control

In selected configuration the single motor at the bottom of the robot base provides motion to the upper joints through a serial transmission that consists of several shafts and belts. As seen in Fig. 3, rotation speed of the motor shaft is reduced by the harmonic drive gear box.

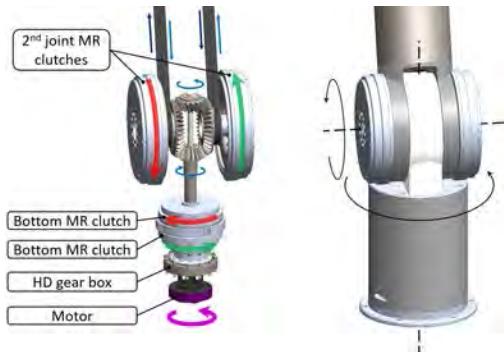

Fig. 3. Transmission of the 1-st and 2-nd joints of the manipulator.

The set of bevel gears located at the 2nd joint produce rotation in two opposite directions. Both clockwise and counterclockwise rotation is delivered to the pair of clutches at each joint through the belt transmission. Two belts moving in opposite directions provide antagonistic motion for the rotors in each pair of MR clutches.

#### C. Design of the robot base (1-st joint)

Manipulator base is designed to be properly mounted on the horizontal surface. The base comprises a pair of MR clutches that actuate the first joint responsible for the rotation of the second link around the vertical axis, as shown in Fig. 4. The single motor that drives all 5 upper joints is located at the very bottom in the base; it is fixed on the movable motor frame that rotates together with the upper links around the vertical axis of the base.

The wave generator of the harmonic drive gear box is directly connected to the motor shaft. The circular spline of the harmonic drive is mounted on the movable motor frame, while the flexspline is connected to the inner shaft and to the rotor of the bottom MR clutch via cylindrical adapters. The harmonic drive has high reduction ratio that allows utilization of the light but powerful high-speed electric motor.

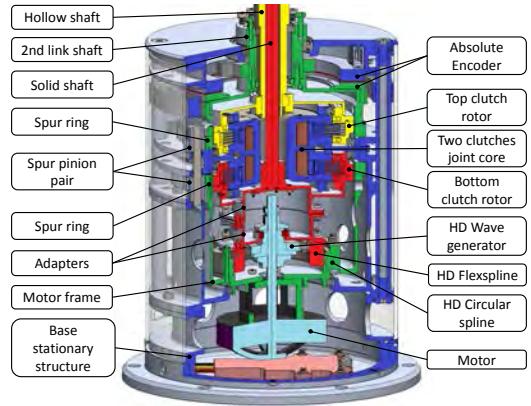

Fig. 4. Robot base zonal section view.

In order to compensate for the reaction moment, the torque from the motor and harmonic drive is transmitted from the motor frame to the upper links spur gears arrangement. The large spur gear - in the shape of a ring (spur gear ring) - is located on the top of the motor frame. It is in mesh with six pinion pairs mounted on the stationary fixed cylindrical support. Through these pinion pairs, the rotation of the motor frame spur gear ring is mechanically transmitted to the similar spur gear ring that is mounted on the cylindrical frame of the second link. This construction allows to mechanically connect the motor frame with the second link frame, and at the same time provide fixation of the MR clutches to the stationary part of the base.

In the center of the manipulator base, there is a pair of MR clutches responsible for the rotation of the second robot link along the vertical axis (first joint). In order to save weight and space, both MR clutches share a joint magnetic core with two separate windings. Each clutch designed to generate torque up to 15 N·m.

While the rotor of the bottom MR clutch is actuated directly by the circular spline of the harmonic drive, the rotor of the top clutch is rotated in opposite direction by the hollow shaft coming from the set of bevel gears located in the second link on top of the robot base.

In order to measure the angular position of the second joint, there is an absolute encoder mounted at the top plate of the manipulator base.

#### D. Design of the 2nd joint

The frame of the second link is mounted on the hollow shaft that spins around the vertical axis of the robot base. The link comprises a set of bevel gears to produce rotation in two opposite directions for all the upper joints of the robot. The transmission of the motion to the upper joints realized through the two belts as shown in Fig. 3.

From the harmonic drive located in the base, the rotation of the solid inner shaft is coming to the small bevel gear on the top of the link. Two big bevel gears in mesh with the small gear spin in opposite directions to each other with reduced speed 1:2. The bottom small bevel gear in mesh with big

bevels rotates in an opposite direction relative to the top one. The hollow shaft coming from the bottom gear transmits the rotation to the rotor of the top MR clutch in the base.

Spinning in clockwise (CW) and counter-clockwise (CCW) directions big bevel gears rotate the rotors of two MR clutches of the second joint. The clutches should be able to produce up to 200 N·m torque each in order to actuate the third link of the robot.

#### IV. MODELLING IN MATLAB/SIMULINK

##### A. State-Space Model of the Joint

In order to develop a state-space model, the simplified scheme of the manipulator first joint was considered, as shown in Fig. 5.

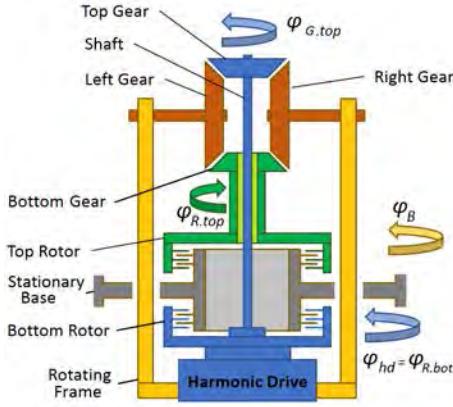

Fig. 5. Manipulator First Joint Scheme

In this figure, four separate groups of parts with common motions are identified with different colors, namely, HD Drive, bottom rotor, shaft, and top gear shown in blue; bottom gear, hollow shaft, and top rotor in green; rotating frame in yellow; and finally, left and right gears in red.

Assuming that the resulting angles, angular velocities, and angular accelerations of all parts of the assembly in the first group (blue color) are in the counterclockwise direction (looking from the top), then it can be shown that,

$$T_{hd} - T_{R.btm.inert} - T_{R.btm.fr} - T_{R.btm.mr} - T_{Sh.elast} = 0$$

where  $T_{hd}$  is the torque on Harmonic Drive,  $T_{R.btm.inert}$  is the torque due to the inertia of the bottom rotor,  $T_{R.btm.fr}$  is the torque on clutch bottom rotor due to friction,  $T_{R.btm.mr}$  is the torque on bottom rotor due to MR effect, and  $T_{Sh.elast}$  is the torque due to the elasticity of the shaft.

Harmonic drive output torque is a function of time,

$$T_{hd} = T_{hd}(t)$$

$$T_{R.btm.inert} = I_{R.btm} \ddot{\phi}_{R.btm}$$

where  $I_{R.btm}$  and  $\phi_{R.btm}$  are the moment of inertia and the angle of the rotor of the bottom clutch respectively.

$$T_{R.btm.fr} = T_{R.btm.visc} + T_{R.const.fr}$$

where  $T_{R.btm.visc}$  is the torque on bottom rotor due to viscosity,  $T_{R.const.fr}$  is the torque due to constant friction.

$$T_{R.btm.visc} = b_{R.visc} \dot{\phi}_{R.btm}$$

where  $b_{R.visc}$  is the coefficient of viscous friction.

$$\phi_{R.btm} = \phi_{hd}$$

where  $\phi_{hd}$  is the angle of Harmonic Drive.

The torque due to the elasticity of the shaft can be calculated,

$$T_{Sh.elast} = k_{sh} \Delta \phi = k_{sh} (\phi_{hd} - \phi_{G.top})$$

where  $k_{sh}$  is the stiffness of the shaft,  $\phi_{G.top}$  is the angle of the top bevel gear (top of the shaft).

For the second group of parts (green color), it is assumed that resulting angles, angular velocities, and angular accelerations of all parts of the assembly have clockwise direction (looking from the top), then it can be shown that,

$$T_{G.btm} - T_{R.top.inert} - T_{R.top.fr} - T_{R.top.mr} - \frac{1}{2} T_{b.g.result} = 0$$

where  $T_{G.btm}$  is the torque acting on the bottom bevel gear,  $T_{R.top.inert}$  is the torque due to the inertia of the clutch top rotor,  $T_{R.top.fr}$  is the torque on clutch top rotor due to friction,  $T_{R.top.mr}$  is the torque on clutch top rotor due to MR effect,  $T_{b.g.result}$  is the resulting torque from bevel gears.

Due to mechanical differential properties, the torque acting on bottom gear is always equal to the top gear torque  $T_{G.top}$ ,

$$T_{G.btm} = T_{G.top} = T_{Sh.elast}$$

$$T_{R.top.inert} = I_{R.top} \ddot{\phi}_{R.top}$$

where  $I_{R.top}$  and  $\phi_{R.top}$  are the moment of inertia and the angle of the rotor of the top clutch respectively.

$$T_{R.top.fr} = T_{R.top.visc} + T_{R.const.fr}$$

where  $T_{R.top.visc}$  is the torque on bottom rotor due to viscosity. The top rotor rotates in opposite direction relative to the rotation of the stationary base.

$$T_{R.top.visc} = b_{R.visc} \dot{\phi}_{R.top}$$

where  $\phi_{G.btm}$  is the angle of the bottom bevel gear.

$$\phi_{R.top} = \phi_{G.btm}$$

$$T_{R.top.visc} = b_{R.visc} \dot{\phi}_{G.btm}$$

In the third group (yellow color) the HD drive with the Motor is fixed on the rotating frame, so the reaction from the generated torque  $T_{hd}$  is directly transmitted to the frame. Assuming that resulting angles, angular velocities, and angular accelerations of all parts of the frame assembly have counterclockwise direction (looking from the top),

$$T_{Sh.elast} - T_{hd} + T_{G.btm} - T_{F.inert} + T_F - T_{b.g.result} = 0$$

where  $T_{F.inert}$  is the torque due to the inertia of the rotating frame,  $T_F$  is the torque acting on rotating frame from upper

links (external). In this case torques  $T_{Sh.elast}$ ,  $T_{G.btm}$ , and  $T_F$  have the same (counterclockwise) direction, while torques  $T_{hd}$  and  $T_{F.inert}$  have opposite direction.

$$T_{G.btm} = T_{G.top} = T_{Sh.elast}$$

$$T_{F.inert} = I_F \ddot{\phi}_F$$

where  $I_F$  and  $\phi_F$  are the moment of inertia and the angle of the rotating frame respectively.

In the fourth group (red color) the left and right bevel gears comprise the mechanical differential as well as transmit the torque from the top and bottom gears to the rotating frame.

According to design, both bevel gears have the same gear ratio  $R_{b.g}$  in mesh with the top and with the bottom bevel gears. It is assumed that external torques applied to the left and right bevel gears have counterclockwise direction when looking from left and from right side respectively, so their resulting torque is:

$$T_{b.g.result} = R_{b.g}T_{G.L} + R_{b.g}T_{G.R}$$

where  $T_{G.L}$  and  $T_{G.R}$  are the external torques acting on the left and right bevel gear respectively.

Angles of the mechanical differential in the rotating frame are governed by the following relation:

$$\dot{\phi}_{G.top} + (-\dot{\phi}_{G.btm}) - 2\dot{\phi}_F = 0$$

$$\dot{\phi}_{G.btm} = \dot{\phi}_{G.top} - 2\dot{\phi}_F$$

In case of the motionless frame assembly, the angle  $\dot{\phi}_{G.btm}$  has opposite direction relative to  $\dot{\phi}_{G.top}$  due to the property of mechanical differential.

For angular velocities and accelerations,

$$\dot{\phi}_{G.btm} = \dot{\phi}_{G.top} - 2\dot{\phi}_F$$

$$\ddot{\phi}_{G.btm} = \ddot{\phi}_{G.top} - 2\ddot{\phi}_F$$

Using relations described above, the following system with state equations was derived:

$$\begin{aligned} \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \\ \dot{x}_5 \\ \dot{x}_6 \end{bmatrix} &= \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ -\frac{k}{I_1} & -\frac{b}{I_1} & \frac{k}{I_1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ \frac{k(4I_2+I_3)}{I_2I_3} & 0 & -\frac{k(4I_2+I_3)}{I_2I_3} & -\frac{b}{I_2} & 0 & \frac{2b}{I_2} \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \frac{2k}{I_3} & 0 & -\frac{2k}{I_3} & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{bmatrix} \\ &+ \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{1}{I_1} & -\frac{1}{I_1} & 0 & 0 & 0 & 0 & -\frac{1}{I_1} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -\frac{2}{I_3} & 0 & -\frac{1}{I_2} & -\frac{3R}{I_3} & -\frac{3R}{I_3} & \frac{2}{I_3} & -\frac{1}{I_2} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -\frac{1}{I_3} & 0 & 0 & -\frac{R}{I_3} & -\frac{R}{I_3} & \frac{1}{I_3} & 0 \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \\ T_7 \end{bmatrix} \end{aligned}$$

where variables are:

$$\begin{aligned} x_1 &= \phi_{hd}(t), & T_5 &= T_{G.R}(t), \\ x_2 &= \dot{\phi}_{hd}(t), & T_6 &= T_F(t), \\ x_3 &= \phi_{G.top}(t), & T_7 &= T_{R.const.fr}, \\ x_4 &= \dot{\phi}_{G.top}(t), & I_1 &= I_{R.btm}, \\ x_5 &= \phi_F(t), & I_2 &= I_{R.top}, \\ x_6 &= \dot{\phi}_F(t), & I_3 &= I_F, \\ T_1 &= T_{hd}(t), & b &= b_{R.visc}, \\ T_2 &= T_{R.btm.mr}(t), & k &= k_{sh}, \\ T_3 &= T_{R.top.mr}(t), & R &= R_{b.g}, \\ T_4 &= T_{G.L}(t), & \end{aligned}$$

## B. Verification of the model in MATLAB/Simulink software

Based on the state-space system above, the MATLAB/Simulink model was developed and analyzed. Based on the preliminary SolidWorks model analysis, the following values of variables were used in simulation:

$$\begin{aligned} k &= 550 \text{ [N·m/rad]} - \text{Elastic coefficient of the shaft}, \\ b &= 0.5 \text{ [N·m·sec/rad]} - \text{Viscous friction coefficient}, \\ I_1 &= 0.012[\text{kg} \cdot \text{m}^2] - \text{Inertia moment of bottom rotor}, \\ I_2 &= 0.010[\text{kg} \cdot \text{m}^2] - \text{Inertia moment of top rotor}, \\ I_3 &= 0.064[\text{kg} \cdot \text{m}^2] - \text{Inertia moment of rotating frame}. \end{aligned}$$

To build a discrete time model, a minimum required sampling rate was estimated (Nyquist criterion) and the sampling period  $T_s = 0.01 \text{ sec}$  was selected.

In order to verify the developed model, the HD drive torque, continuous friction torque, and top clutch MR torque were applied in a form of a step-function:

- At the time  $t = 5 \text{ sec}$  the HD drive started to generate torque  $T_{hd} = 1 \text{ N} \cdot \text{m}$ , the constant friction torque  $T_{R.btm.fr} = 0.1 \text{ N} \cdot \text{m}$  appeared in the bottom clutch, and the constant friction torque  $T_{R.top.fr} = 0.1 \text{ N} \cdot \text{m}$  appeared in the top clutch;
- At the time  $t = 150 \text{ sec}$  the top MR clutch started to generate torque  $T_{R.top.mr} = 0.1 \text{ N} \cdot \text{m}$ .

Resulting states representing angle and angular velocity of the bottom rotor, top bevel gear, rotating base, and derived parameters for top rotor are shown in Fig. 6 and Fig. 7.

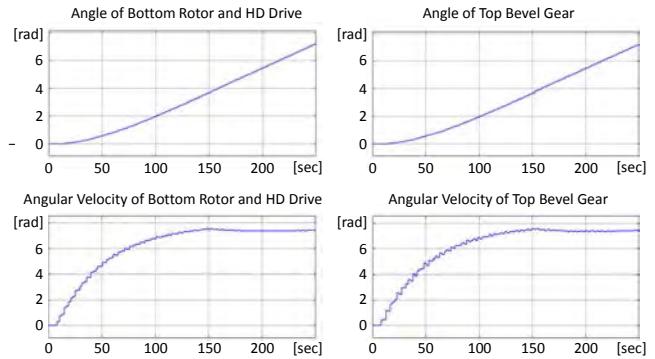

Fig. 6. Graphs of output angles and angular velocities for bottom rotor and top bevel gear

It can be observed on the graphs that at the time  $t = 5 \text{ sec}$  when the harmonic drive started to generate torque  $T_{hd} = 1 \text{ N} \cdot \text{m}$ , angular velocities of the bottom rotor, top bevel gear,

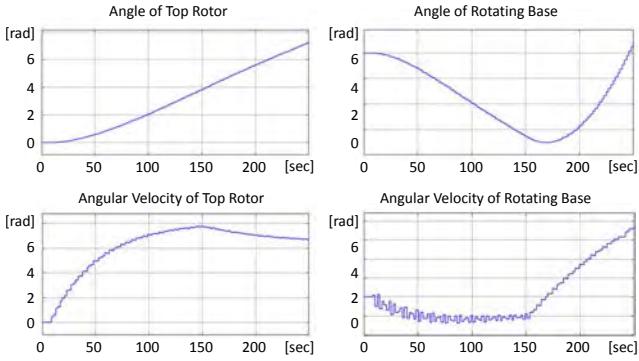

Fig. 7. Graphs of output angles and angular velocities for top rotor and rotating base gear

top rotor, and rotating base started to rise towards the certain values where the viscous friction of the parts equalizes generated torque. The rotating base started to turn in a clockwise direction and reached about  $-0.07 \text{ rad}$  angle at the time = 150 sec. On the angular velocity graphs for the top bevel gear and rotating base, one can clearly see the oscillations due to the flexibility of the shaft. Oscillations of the top and bottom rotor are not so visible but still can be noted.

When the top MR clutch was activated at  $t = 150 \text{ sec}$  and started to generate torque, the angular velocity of the top rotor started to decline, both bottom rotor and top bevel gear speeds showed a minor reduction, the angular velocity of the base changed its direction to counter-clockwise and the angle started to rise.

Shown on the graphs, the behavior of the parts corresponded very well with the expected motions of the actual hardware. Additional analogous simulations were performed to ensure the correct behavior of the developed system.

#### C. Simple control design in MATLAB/Simulink software

For further analysis, the simple input transducer is designed to process the desired reference trajectory of the rotating base into the controlling signals for clutches and HD drive. The required torques are calculated proportional to the derivative of the desired angle with respect to the time. The desired reference trajectory designed in MS Excel is shown with red color in Fig. 9.

The graphs of the torques applied to the system to follow desired trajectory of the rotating base are shown in Fig.8.

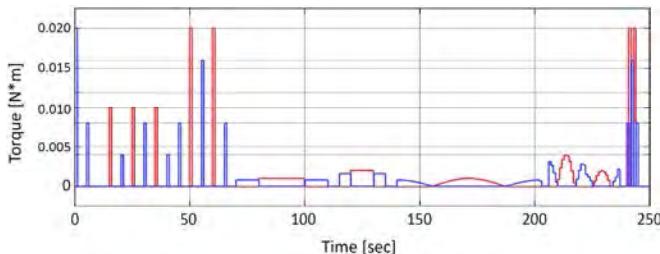

Fig. 8. Graph of the torque applied to the top (blue) and bottom (red) clutch in order the rotating base to follow the desired trajectory

It can be seen on the presented graphs, that in order to ensure the base is following the desired trajectory, the bottom MR clutch torque  $T_2$  fluctuates from 0 up to  $0.020 \text{ N}\cdot\text{m}$ . The top MR clutch torque  $T_3$  reaches  $0.025 \text{ N}\cdot\text{m}$ . Both clutches cannot produce negative torque due to physical limitations, so the minimum torque is  $0 \text{ N}\cdot\text{m}$  as shown on the graphs.

The rotation base follows the desired trajectory close enough. The graph of the simulated angle is shown in Fig.9.

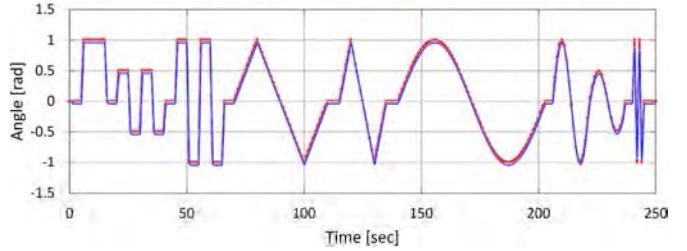

Fig. 9. Graph of the desired (red) and resulting (blue) trajectory of the rotating base.

The profile on the graph (blue) is almost identical to the profile of the desired trajectory (red) shown in Fig. 9. The error between the guiding profile and the actual angle of the base stays within  $\pm 0.04 \text{ rad}$ .

## V. CONCLUSIONS

Design and simulation results for the first joint of the prospective 5-DOF manipulator, presented in this paper, demonstrate the possibility of building the complex robot that can be actuated by a single motor at the base. The use of MR clutches in the joints of the manipulator brings power and safety to the system.

Further work is planned to model and simulate the rest of the joints in the robot. Future steps include parts manufacturing, control system development, assembling and testing the manipulator.

**Abstract**— A comparative analysis of four different OptiTrack motion capture systems is provided in this paper. Tracking accuracy, workspace volume, marker size and camera range are the main criteria used for comparison. The tracking accuracy is tested using Quanser's linear motion platform by comparing the measured position of the cart with the position obtained using the encoder. The workspace volume limits are obtained by flying a LiteHawk Neon drone in circles of increasing radius at different heights until tracking fails. The relationship between marker size and camera range is obtained through theoretical calculations. Experimental as well as theoretical results are presented, illustrating the performance of these four systems. These will serve as a baseline to select the right motion capture system for any particular application.

**Keywords-** Motion capture; OptiTrack; Optical-Passive

## I. INTRODUCTION

Motion capture (mocap) is the process of recording the movement of objects or people. It involves measuring the position as well as orientation of the objects or people in physical space [1]. The technology was originally developed for gait analysis in the life science market but is now used in a wide variety of other fields. Some of these include computer graphics animation, robotics and military use.

Over the past few decades, a lot of advancements have been made in motion capture technology resulting in many different approaches such as:

- Optical-passive: Retroreflective markers are tracked by a set of infrared cameras. It is the most practical and commonly used method in the industry [2]. The motion capture systems selected for comparative analysis in this paper are all optical-passive.
- Optical-active: Infrared LED markers are tracked by a set of infrared cameras. Note that a suitable power supply source is required to power active markers.
- Video: Software is used to track the object motion in each frame. Depending on the object detection and tracking algorithm used, the accuracy of the results

may vary. This technique is less accurate than the marker-based solutions.

- Inertial: Independent of cameras, this technique uses inertial measurement sensors on the subject. Short term accuracy is a major drawback.

Optical-passive motion capture systems are widely used for validation and control of computer vision and robotics in an indoor laboratory setting. They have great practical value in indoor mobile robotics applications. Hence, choosing the right motion capture system for a particular application is extremely important. In this paper, a series of systematic tests are performed using four different OptiTrack motion capture systems to characterize their performance. The results obtained from these tests will provide a baseline for users to choose the right motion capture system for any computer vision or robotics application based on tracking accuracy, size of workspace, marker size and camera range.

This paper is organized as follows. In Section II, the four different OptiTrack motion capture systems selected for evaluation are presented. In Section III, the experimental setup used to test the performance of these motion capture systems is described and the test procedure is explained in detail. The results obtained by performing the test using the four different systems are showcased in Section IV. Finally, the conclusions drawn from this work are presented in Section V.

## II. MOTION CAPTURE SYSTEMS

OptiTrack makes high-performance motion capture systems at an affordable price. A single OptiTrack motion capture system may track the 6 degrees of freedom (DOF) pose of one or more objects in the workspace. Objects tracked in space need to be defined as rigid bodies. Each rigid body is a cluster of reflective markers arranged in a unique configuration. Fig. 1 shows two quadrotors (a LiteHawk Neon and LiteHawk Highroller) defined as rigid bodies, one using 1/2-inch by 1/2-inch square markers and the other using 5/8-inch diameter spherical markers. OptiTrack manufactures spherical markers with diameters ranging from 1/4-inch to 3/4-inch. Additionally, OptiTrack also does fabricate reflective 1/3-inch diameter dots and 1/2-inch by 1/2-inch squares. Depending on the size and limitations of the rigid body, appropriate size markers may be

Figure 1. LiteHawk Neon and Highroller quadrotors tagged with retroreflective markers

chosen. For example, we use squares on the LiteHawk Neon due its payload capacity and spherical markers on the LiteHawk Highroller because of its fuselage design.

In this paper, four different OptiTrack systems are chosen for comparative analysis, comprising: Flex 3 (x12), Flex 13 (x6), Prime 13 (x6) and Prime 17W (x6). Table 1 provides detailed specifications for the cameras used in each of these systems. The specifications provided are obtained directly from the manufacturer's website [3]. The number of cameras for each of the systems are chosen to cover roughly the same workspace area and to be able to track rigid bodies using square markers. Note that the dot and square markers expose less retroreflective surface area compared to the spherical markers. The Flex 3 cameras have a much lower resolution compared to the rest. The ethernet connectivity of the Prime series allows for a faster frame rate and lower latency compared to the Flex series. All cameras use wide angle lenses. The system cost is the number of cameras times the cost per camera. However, this does not include the costs of the hubs, proprietary software and the ground control station as they are much smaller compared to the cost of the cameras.

TABLE I. MOTION CAPTURE SYSTEMS CHOSEN FOR COMPARATIVE ANALYSIS

	OptiTrack Flex 3 (x12)	OptiTrack Flex 13 (x6)	OptiTrack Prime 13 (x6)	OptiTrack Prime 17W (x6)
Resolution	640 × 480 (0.3 MP)	1280 × 1024 (1.3 MP)	1280 × 1024 (1.3 MP)	1664 × 1088 (1.7 MP)
Frame rate	100 FPS	120 FPS	240 FPS	360 FPS
Lens	4.5 mm	5.5 mm	5.5 mm	6 mm
Horizontal FOV	46.2°	56°	56°	70°
Vertical FOV	34.7°	46°	46°	49°
Connectivity	USB 2.0	USB 2.0	Ethernet	Ethernet
Latency	10 ms	8.3 ms	4.2 ms	2.8 ms
Cost per camera	599 USD	999 USD	1999 USD	3499 USD
System cost	7188 USD	5994 USD	11994 USD	20994 USD

### III. EXPERIMENTAL SETUP AND TEST PROCEDURE

The four different motion capture systems are compared using tracking accuracy, workspace volume, marker size and camera range. The tracking accuracy and workspace volume are obtained experimentally while the relationship between

marker size and camera range is derived geometrically based on the pinhole camera model.

#### A. Tracking Accuracy

Fig. 2 shows the experimental setup used to test for rigid body tracking accuracy. Quanser's linear motion platform is used where the cart and the two ends of the track are defined as rigid bodies, tracked by the motion capture system. The positions of the rigid bodies are attained using the motion capture system. The cart is driven on the track by a DC motor via a rack and pinion mechanism that ensures consistent and continuous traction [4]. It has an encoder with a resolution of 4096 counts/rev to measure its position. To start, the cart is placed at one of the ends and using the encoder feedback, a PID position controller is used to move the cart with a fixed amplitude at increasing frequency. The position of the cart on the track is obtained using its initial position, the track unit vector (defined using the positions of the two ends of the track) and the encoder count. The calculated position is then compared with the cart position obtained from the motion capture system (to test the accuracy of the four different motion capture systems). For each camera system, three sets of tests are done in three different table orientations and for each orientation, data for five experimental runs are logged.

Figure 2. Experimental setup to test tracking accuracy

Let  $P_{CC}$  and  $P_{CE}$  denote the positions of the cart measured using the motion capture system and calculated based on the encoder count respectively. Let  $P_{E1}$  and  $P_{E2}$  denote the positions of the two ends of the cart obtained using the motion capture system.

$$\hat{t} = \frac{P_{E1} - P_{E2}}{\|P_{E1} - P_{E2}\|_2} \quad (1)$$

where  $\hat{t}$  is the track unit vector. The displacement of the cart from its initial position,  $d$  can be calculated using the encoder count,  $c$ . The effective linear tracking resolution,  $k = 2.2749 \times 10^{-5}$  m is based on the gear ratio, pitch and encoder resolution.

$$d = kc \quad (2)$$

The position of the cart at any time,  $t$  can then be calculated as follows:

$$P_{CE}(t) = P_{CC}(t_0) + fd. \quad (3)$$

The tracking error,  $e$  at every time instant,  $t$  is then given by

$$e(t) = P_{CE}(t) - P_{CC}(t). \quad (4)$$

Fig. 3 shows the experimental data for a single run using the OptiTrack Prime 13 motion capture system. The position controller moves the cart back and forth with a fixed amplitude of 0.15m at increasing frequency. The x, y and z positions of the cart measured using the motion capture system (shown in blue) are compared with those obtained using the encoder count (shown in orange). Fig. 4 shows the errors in position along the x, y and z direction for the same run.

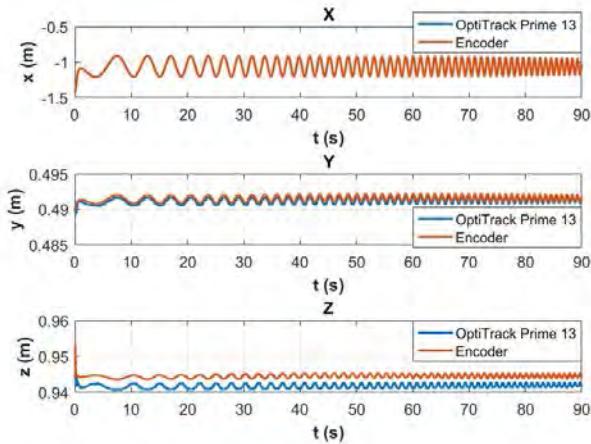

Figure 3. Measured (OptiTrack Prime 13) vs. encoder position of cart

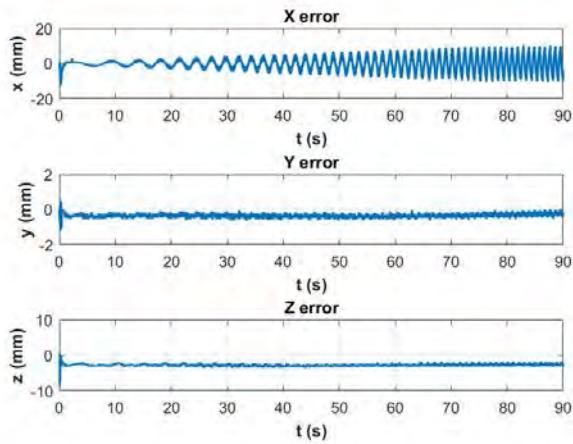

Figure 4. Tracking error (OptiTrack Prime 13)

It is important to note the tracking accuracy of the motion capture system for different cart velocities, accelerations and jerks. The velocity of the cart,  $V_{CC}$  is obtained using a fourth order forward finite difference approximation [5] of the cart position given by

$$V_{CC}(t) = \frac{(-25P_{CC}(t) + 48P_{CC}(t+h) - 36P_{CC}(t+2h) + 16P_{CC}(t+3h) - 3P_{CC}(t+4h))}{12h} \quad (5)$$

where  $h$  is the sample time. A sample time of 0.001s is used in all experimental runs. Similarly, acceleration and jerk are obtained by differentiating the approximated velocity and acceleration respectively.

### B. Workspace Volume

The workspace of each motion capture system is the volume in which a rigid body can be successfully tracked. To estimate the workspace volumes of the four different motion capture systems, a LiteHawk Neon drone is flown around in the workspace to test its limits. A PID controller is used to control the position of the drone in the workspace using measurements from the motion capture system as feedback. The drone is flown around in circular trajectories of increasing radius starting at an altitude of  $z = 0.25$ m until tracking is lost. This is then continued for altitudes all the way up to  $z = 3$ m with increments of  $\Delta z = 0.25$ m. By logging the position of the drone continuously during the experiment, the workspace volume can be estimated.

### C. Marker Size and Camera Range

OptiTrack manufactures spherical markers of sizes ranging from 1/4-inch to 3/4-inch in diameter. Limited by camera resolution and Field Of View (FOV), there is a maximum range to see markers of a particular size. Based on camera imaging geometry, the number of pixels seen in a marker of known size at a distance can be calculated. Knowing the marker diameter,  $d$ , the maximum cross-sectional area for each marker can be calculated using

$$A_{CS} = \frac{\pi}{4} d^2. \quad (6)$$

If  $r = a \times b$  pixels is the camera resolution, the aspect ratio is

$$AR = \frac{a}{b}. \quad (7)$$

Given the horizontal  $FOV(h_{FOV})$ , vertical  $FOV(v_{FOV})$  and focal length of the camera ( $f$ ), the diagonal  $FOV$  can be calculated as follows

$$FOV = 2 \operatorname{atan2} \left( \frac{f \sqrt{\tan^2 \left( \frac{v_{FOV}}{2} \right) + \tan^2 \left( \frac{h_{FOV}}{2} \right)}}{2}, f \right). \quad (8)$$

The area seen by the camera at a distance,  $h$  is

$$S = \frac{\left( 2h \tan \left( \frac{FOV}{2} \right) \right)^2}{AR + \frac{1}{AR}}. \quad (9)$$

The number of pixels seen in a marker at a distance,  $h$  is

$$N = \frac{abA_{CS}}{S}. \quad (10)$$

#### IV. RESULTS

The experimental and theoretical results for the four different motion capture systems are presented in this section. Average error for different frequencies, velocities, accelerations and jerks of the cart are provided in the tracking accuracy subsection. Top and sectional views of the workspace volumes are shown in the workspace volume subsection. In the last subsection, the number of pixels seen in a marker by a single camera is related to its range based on the calculations in the previous section. Fig. 5 shows a scatter plot of the average error plotted against system cost. Note that the Flex 3 motion capture system is comprised of twelve cameras (twice as many as the number of cameras in the other motion capture systems). The Flex 3 cameras are mounted at a lower height to be able to track the 1/2-inch by 1/2-inch squares given their lower resolution compared to the rest of the cameras. The area seen by the cameras is thus much lower. Hence, twelve cameras are used to cover roughly the same workspace volume. The system costs reflect important characteristics of the cameras such as resolution, frame rate and latency based on the average tracking error of the four systems.

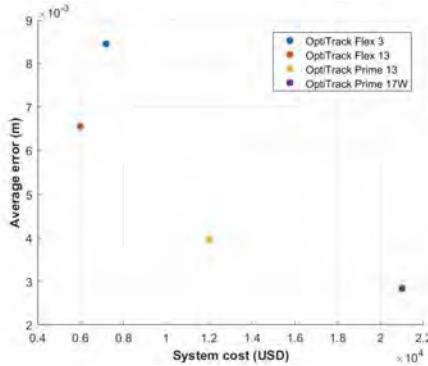

Figure 5. Average error vs. system cost

##### A. Tracking Accuracy

Fig. 6 shows the average error plotted against the frequency at which the cart moves back and forth along the track with an amplitude of 0.15m. The rise in average error with an increase in frequency follows a linear trend. The rate at which error increases with increase in motion frequency is a function of the frame rate and latency of the camera system. Figs. 7, 8 and 9 show plots of the average error vs. cart velocity, acceleration and jerk respectively. Note that the cart velocity, acceleration and jerk are derived using fourth order forward finite difference approximation of the cart position measured using the motion capture system. This is only an approximation and is subject to error. Straight lines were used to fit the data best from scatter plots of the average error vs. cart velocity, acceleration and jerk. The average error increases linearly with increase in cart velocity, acceleration and jerk. Once again, it can be noted that

Prime series have a lower tracking error compared to the Flex series because of higher frame rate and lower latency.

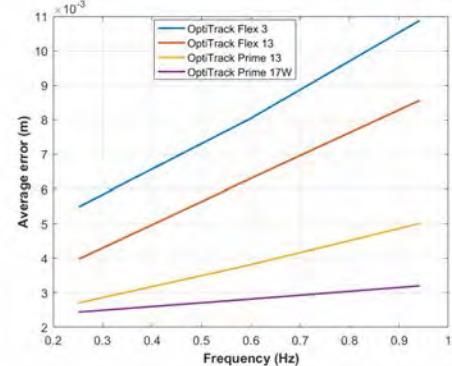

Figure 6. Average error vs. frequency

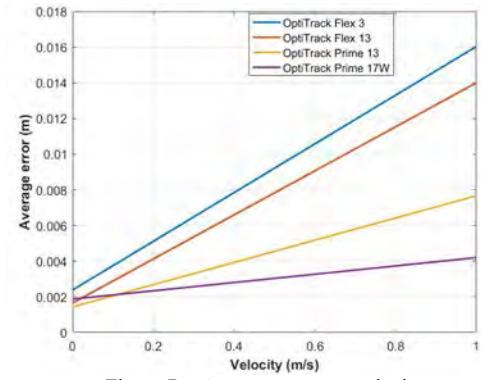

Figure 7. Average error vs. velocity

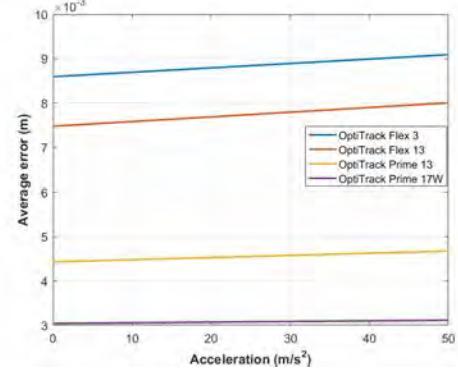

Figure 8. Average error vs. acceleration

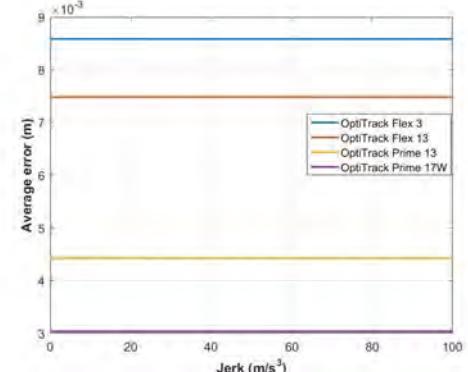

Figure 9. Average error vs. jerk

## B. Workspace Volume

The limits of the workspace volume for each of the four motion capture systems were tested by flying the LiteHawk Neon drone in circular trajectories of increasing radius at different heights. Fig. 10 shows the top and sectional views for each of the four different motion capture systems. The shape of the workspaces roughly resembles that of a dome. The top views show the circles at different heights within which the drone can fly while being tracked successfully. It can be noted that the flying radius in each transverse plane decreases with increase in height. The workspace volume depends on many factors such as the positioning of the cameras, resolution, focal length and FOV.

## C. Marker Size and Camera Range

Fig. 11 shows the relationship between marker sizes and range for the different camera systems. In the first plot, the number of pixels as a function of distance is seen for different marker sizes using a Flex 13 camera. The larger the marker, the more pixels are seen by the camera and hence can be seen from a longer range. The number of marker pixels seen by a camera decreases exponentially with increase in range. In the second plot, comparing the four different cameras using the same size marker at a fixed distance, the Flex 13 and Prime 13 capture the most number of pixels closely followed by the Prime 17W leaving the Flex 3 with the least. For a marker to be detected, at least 4 pixels are needed to be seen by a camera. The black line in the plots indicates this threshold.

## V. CONCLUSIONS AND RECOMMENDATIONS

The Prime series cameras have a lower tracking error for aggressive rigid body manoeuvres due to higher frame rate and lower latency. High frame rate and low latency are useful in estimating rigid body velocity, acceleration and jerk more accurately. The OptiTrack Prime 17W cameras offer maximum workspace volume due to wider angle lens with bigger FOV. Using a camera with a larger FOV will result in a bigger workspace volume. The OptiTrack Flex 13, Prime13 and Prime 17W cameras offer longer marker range due to higher resolution and longer focal length. The camera resolution is important based on the type of markers used to identify rigid bodies in space. It will determine the minimum separation distance between the markers to be identified uniquely, and the minimum size of marker needed at a particular distance from the camera.

# Impact Force Reduction Strategies to Achieve Safer Human-robot Collisions

Behrad Rouzbeh and Gary M. Bone\*

Department of Mechanical Engineering  
McMaster University  
Hamilton, Canada

\*Corresponding author. E-mail: gary@mcmaster.ca

**Abstract**—The increasing use of robots operating close to people has made human-robot collisions more likely. In this paper, strategies intended to reduce the impact force to a safe level, without sacrificing the robot's performance, are investigated. The strategies can be applied to a robot arm without modifying its internal hardware. They include the existing strategies: lowering the actuator controller's stiffness; actuator switched off upon impact detection; withdrawing the arm upon impact detection; and adding a compliant cover. We also propose the novel strategy of limiting the controller's feedback term. The collision scenario studied is a robot arm colliding with a person's constrained head. An improved lumped parameter model of the constrained impact is proposed. Simulation results are included for a UR5 collaborative robot. Sixteen combinations of the impact force reduction strategies are compared. The results show that using a high stiffness controller with a feedback limit and compliant cover reduces the impact force to a safe level, and achieves precise trajectory tracking.

**Keywords**—collaborative robot; compliant covering; human-robot collision; impact force; robot control; robot safety

## I. INTRODUCTION

In emerging applications, such as collaborative robots and service robots, robot arms (also termed “manipulators”) may operate in close proximity with people. This proximity makes human-robot collisions much more likely so the ability to reduce the human-robot impact force to a safe level is a critical requirement for these robots. Research on the design and control of safe collaborative robots (also termed “human-friendly robots” in the literature) aims to address this safety requirement without sacrificing the robot's performance and functionality.

Previous researchers have proposed a wide variety of approaches for reducing the human-robot impact force. In [1]

the impact force is reduced by applying a time-varying limit to the actuator torques based on a dynamic model of the robot. While this can work in certain situations, an undesirable reduction in the precision of the robot's trajectory tracking may also occur when the actuator torques are limited. Reducing the inertia of the robot is very effective at reducing the impact force. The robot developed by DLR [2] is a prime example of this approach whose special design and use of lightweight materials, such as carbon fiber, produced a very low inertia arm. However, this is a costly solution and obviously cannot be used to improve the safety of conventional robots. Reducing the stiffness of the transmission between the actuators and links is another approach for improving the collision safety, e.g. [3][4]. With conventional robots the transmission between each actuator and link is very stiff so both of their inertias contribute to the severity of the collision. The objective of variable-stiffness actuation (VSA) is to dynamically decouple the actuator's rotor inertia from the link's inertia. Since the contact occurs between the human and the link, and the link's inertia is lower than the combined inertia, the impact force will be reduced by the VSA's decoupling effect. The lower the stiffness the lower the force, however low transmission stiffness also tends to lower the precision of the robot's position control. Similarly, a lower arm velocity also reduces the impact force, but clearly sacrifices the robot's performance. The VSA mitigates these two problems by lowering the stiffness when the velocity is high, and increasing the stiffness when the velocity is low. This addresses the safety aspect, but will also cause the tracking precision to deteriorate during the higher velocity sections of its motion trajectories. Furthermore, using VSAs for the robot's six joints will increase the complexity, cost and inertia of the arm. Adding an electromechanical clutch between the link and actuator is an alternate approach to decouple the actuator's and link's inertias [5][6]. This behaves like a VSA with two stiffnesses and is termed a “series clutch actuator” (SCA). When clutch is engaged the transmission's stiffness is very high, and when it is disengaged the stiffness drops to zero. Unlike a VSA, the SCA should not affect the robot's performance during normal conditions since the clutch should only disengage when a collision happens. The clutch's torque threshold can also be

---

Research sponsored by the Natural Sciences and Engineering Research Council of Canada (NSERC) through a Discovery Grant.

varied to satisfy both the safety and performance requirements [5]. Unfortunately, using SCAs will increase the complexity, cost and inertia of the robot arm.

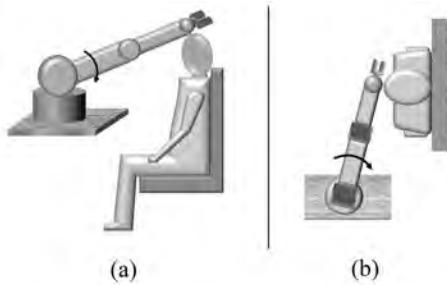

While the approaches in [2]-[6] all have merit, we are interested in methods for reducing the impact force that can be applied to existing robot arms with little or no modifications to the arm's hardware. The actuator torque limiting method in [1] is such an approach, but has serious side effects as previously discussed. A better approach is to add a collision detection and reaction strategy to the robot's control software, e.g. [7]-[9]. The detection can use either the robot's existing sensors [7][8] or externally mounted sensors [9]. The former approach requires a dynamic model of the robot while the latter does not. Using either approach detection times of a few ms can be achieved [7]-[9]. Various reaction strategies may be executed after contact detection to reduce the impact force, such as: braking to a stop [7][9], switching the actuator off [8], or having the arm reflexively withdrawn from the location of the impact [8]. Another method for increasing the safety of an existing robot is to add a compliant cover over its surface, e.g. [7][10][11]. The cover's stiffness can be chosen to satisfy a safety constraint without being excessively thick [11]. The compliant cover cannot be used with the end effector if it interferes with its function. If this is the case, quick release mechanisms, such as the QuickSTOP collision device (Applied Robotics Inc.), can be used to increase the safety of collisions with the end effector.

In this paper we will investigate strategies intended to reduce the impact force when a robot collides with a human's head, while maintaining the robot's performance during normal conditions. These can be applied to an existing robot without modifying its internal hardware. They include the previously applied strategies: lowering the actuator controller's stiffness, actuator switched off by controller upon impact detection, withdrawing the arm as fast as possible upon impact detection, and adding a compliant cover. We also propose the novel strategy of limiting the magnitude of the feedback term used with the controller.

The collision scenario is described in section II. In section III the impact model for this scenario is derived. Section IV covers the controller design. Simulation results are presented and discussed in section V and conclusions are drawn in section VI.

## II. COLLISION SCENARIO

Although the human-robot impact could occur almost anywhere on the human's body we will investigate impact with the human head since it is the most likely to result in serious injuries. The collision scenarios being studied are illustrated in Fig. 1. We assume that the impact takes place at the tip of the forearm link when the robot arm is fully extended as shown. This contact location and elbow angle maximizes the moment of inertia of the arm which will produce the maximum impact force, all other parameters being equal. We also assume the impact direction and human's surroundings do not allow the head to move – this is termed a “constrained impact” and produces much larger forces than the unconstrained case where the head is allowed to move [11].

**Figure 1.** Illustration of the collision scenarios being studied. a) Head impact caused by robot's shoulder joint movement. b) Head impact caused by robot's waist joint movement.

The robot is assumed to be a standard articulated arm with six or seven motorized rotary joints. The impact may be caused by either the rotation of the robot's shoulder joint (Fig. 1a) or its waste joint (Fig. 1b). The elbow joint is assumed to be infinitely stiff which is a conservative assumption.

## III. HUMAN-ROBOT IMPACT MODELING

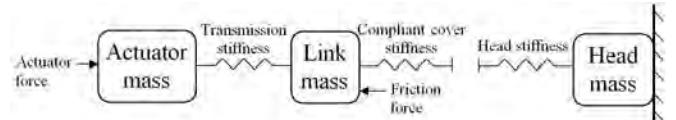

As is common practice in the literature [3][4][10][11][12], the human-robot impact dynamics in the normal direction are modelled by a linear one dimensional lumped parameter model consisting mainly of masses and springs. Fig. 2 shows the schematic for the linear robot-head impact model. The actuator force (commanded by the controller), equivalent masses of the actuator and link are included. The mass of the head is shown but not included in our equations since it is constrained. Knowing the elastic modulus and contact area of the compliant material, the compliant cover can be modeled as a spring acting between the link and head. The human head's stiffness is also modelled as a spring. Its value for robot-head contact is included in the international technical specification for collaborative robots [12]. Including this spring makes the model more realistic than previous models that assumed the skull is perfectly rigid. Displacement due to transmission deflection adds one degree of freedom to the model which is shown as spring acting between the actuator position and the robotic arm position. Most existing robots use a low-backlash high-precision transmission at each joint which has a high stiffness compared to the controller's stiffness (due to feedback). Thus the transmission spring can be reasonably neglected, making the actuator and links act as a single mass. Fig. 3 shows the simplified model that is employed in the remainder of this paper.

The conventional position controller equation for the joint is:

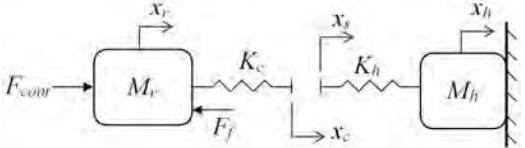

$$\tau_{cont} = K_p (\theta_d - \theta_r) + K_d (\dot{\theta}_d - \dot{\theta}_r) + I_r \ddot{\theta}_d \quad (1)$$

subject to:

$$|\tau_{cont}| \leq \tau_{max} \quad (2)$$

**Figure 2.** Linear robot link-head blunt constrained impact model.

**Figure 3.** Simplified model for robot link-head blunt constrained impact.

where  $\tau_{cont}$  is the joint torque to be applied by the actuator;  $\tau_{max}$  is the maximum actuator torque;  $\theta_r$  is the joint angle;  $\theta_d$  is the desired angle;  $K_p$  and  $K_d$  are the proportional and derivative feedback gains respectively;  $I_r$  is the combined inertias of the actuator and links; and  $I_r \ddot{\theta}_d$  is the feedforward term used to compensate the inertial torque. Assuming the post-impact deflections are small, the equivalent controller force in the normal direction at the point of contact is:

$$F_{cont} = K_{cont} (x_d - x_r) + C_{cont} (\dot{x}_d - \dot{x}_r) + M_r \ddot{x}_d \quad (3)$$

where  $K_{cont} = K_p/L^2$ ,  $C_{cont} = K_d/L^2$ ,  $M_r = I_r/L^2$ ,  $x_d = \theta_d L$ ,  $x_r = \theta_r L$  and  $L$  is the distance from the impact point to the joint. If all displacements are relative to  $x_h$ , the robot's equation of motion is:

$$M_r \ddot{x}_r = F_{cont} - F_f - F_i \quad (4)$$

where  $F_f$  is the friction force and  $F_i$  is the impact force. The impact force is given by:

$$F_i = \begin{cases} K_{hc} x_r & x_r > 0 \\ 0 & x_r \leq 0 \end{cases} \quad (5)$$

where:

$$K_{hc} = K_h K_c / (K_h + K_c) \quad (6)$$

Substituting (3) and (5) into (4) and rearranging gives:

$$M_r \ddot{x}_r + C_r \dot{x}_r + K_r x_r = M_r \ddot{x}_d + C_{cont} \dot{x}_d + K_{cont} x_d - F_f \quad (7)$$

where:

$$C_r = C_{cont} \quad (8)$$

$$K_r = \begin{cases} K_{hc} + K_{cont} & x_r > 0 \\ K_{cont} & x_r \leq 0 \end{cases} \text{ and} \quad (9)$$

The friction force is modelled as the sum of dry and viscous components as follows:

$$F_f = \begin{cases} f_k \text{sign}(\dot{x}_r) + k_v \dot{x}_r & \dot{x}_r \neq 0 \\ F_{cont} - F_i & \dot{x}_r = 0 \wedge |F_{cont} - F_i| < f_s \\ f_s \text{sign}(F_{cont} - F_i) & \text{otherwise.} \end{cases} \quad (10)$$

where  $f_k$  is the kinetic friction force,  $f_s$  is the static friction force and  $k_v$  is the coefficient of viscous friction.

Lastly, the deflections of the compliant cover and head may be calculated using (11) and (12), respectively.

$$\Delta x_c = x_c - x_r = F_i/K_c \text{ and} \quad (11)$$

$$x_s = F_i/K_h \quad (12)$$

#### IV. CONTROLLER DESIGN

The position controller can be designed for trajectory tracking by specifying the desired closed-loop bandwidth,  $f_{bw}$ , and damping ratio,  $\zeta$ . The corresponding controller gains are given by:

$$K_p = I_r \omega_n^2 \quad (13)$$

$$K_d = 2\zeta \sqrt{K_p I_r} \quad (14)$$

where:

$$\omega_n = 2\pi f_{bw} / \left( \zeta + \sqrt{1 + \zeta^2} \right) \quad (15)$$

The proposed feedback limited (FBL) controller is obtained by replacing (1) with:

$$\tau_{cont} = \tau_{fb} + \tau_{ff} \quad (16)$$

$$\tau_{fb} = K_p (\theta_d - \theta_r) + K_d (\dot{\theta}_d - \dot{\theta}_r) \text{ and} \quad (17)$$

$$\tau_{ff} = I_r \ddot{\theta}_d \quad (18)$$

subject to (2) and:

$$|\tau_{fb}| \leq \tau_{lim} \quad (19)$$

where  $\tau_{lim}$  is the feedback torque limit.

#### V. SIMULATIONS

Simulations were created to compare the position control performance and impact forces produced under a variety of conditions. The simulated robot is a Universal Robot model UR5 which is one of the most common collaborative robots in use today. The robot's commanded trajectory is defined such that it collides with the head at a velocity of 0.25 m/s which is the highest speed permitted by the Canadian [13] and international safety standards [14] when a human is within reach of a robot arm. Two different sets of controller gains  $K_p$  and  $K_d$  were used, one for a high bandwidth, high stiffness controller (HSC) and the other for a lower stiffness, lower bandwidth controller (LSC). The two bandwidths for the HSC and LSC are 50 Hz and 5 Hz, respectively. The corresponding stiffnesses are 355 kN/m and 3.55 kN/m, respectively. The other simulation parameters are listed in Table I.

Several impact conditions have been simulated and comparisons made. The HSC and LSC were simulated with and without compliant cover (CC). The other impact force reduction strategies simulated are: limiting the controller feedback force applied to the link (FBL); switching off the actuator when the impact is detected (SOA); and implementing an arm withdrawal reflex (AWR) by applying the maximum actuator torque in the opposite direction. The impact detection

TABLE I. SIMULATION PARAMETERS

Parameter	Value	Description
$dt$	0.01 ms	Integration timestep
$f_k$	19.4 N	Kinetic friction force <sup>a</sup>
$f_s$	19.4 N	Static friction force <sup>a</sup>
$K_c$	25 kN/m	Compliant cover stiffness [11]
$K_h$	150 kN/m	Head stiffness [12]
$k_v$	0.554 Ns/m	Coefficient of viscous friction <sup>b</sup>
$L$	0.85 m	Distance from joint to impact location on the robot [16]
$M_r$	9.57 kg	Equivalent robot mass <sup>c</sup>
$T_d$	5 ms	Impact detection delay
$T_s$	1 ms	Controller sampling period
$\zeta$	0.7	Controller damping ratio
$\tau_{lim}$	20 Nm	Controller feedback limit
$\tau_{max}$	150 Nm	Maximum joint torque [15]

a. Friction torque from [15] divided by  $L$ .

b. Coefficient of rotary viscous friction from [15] divided by  $L^2$ .

c. Obtained by dividing the sum of the actuator's and arm's moments of inertia about the joint (assuming the robot uses inertia matching) from [16] by  $L^2$ .

delay for the AWR was assumed to be 5 ms. The robot was simulated tracking a trapezoidal velocity trajectory before collision and the tracking root-mean-squared-error (RMSE) values were computed. To make the tracking more realistic the friction coefficients were subjected to a 5% random variation from the nominal. Table II lists the results for the cases simulated.

The International Organization for Standardization (ISO) specifies 130 N as the maximum permissible force for the skull and forehead. Studying the results in the table, it can be observed that the robot with HSC and no CC, FBL or AWR exerted an impact force of 410 N (case 1), well beyond the ISO safety limit. This 410 N value is used as the benchmark for comparison. Using the LSC reduced the impact force 24% to 313 N (case 9), while adding a carefully selected limit with the

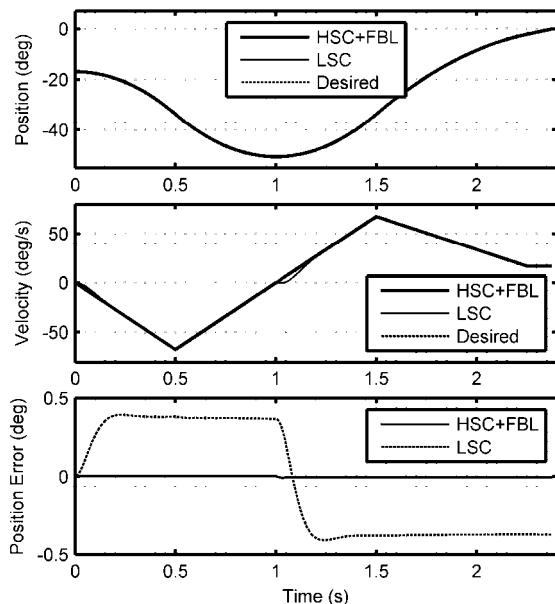

Figure 4. Comparison of the joint's motion tracking performances before impact for higher stiffness controller with feedback limit (HSC+FBL) and the lower stiffness controller (LSC).

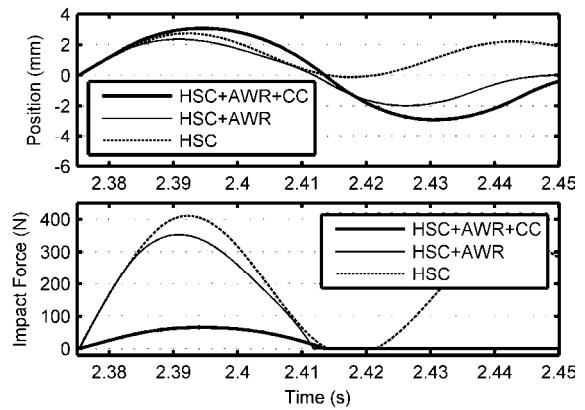

Figure 5. Post-impact link tip position and impact force for the high stiffness controller with different features: with no impact reduction feature (HSC), with arm withdrawal reflex (HSC+AWR), and with arm withdrawal reflex and compliant cover (HSC+AWR+CC).

FBL strategy reduced the force 26% to 303 N (case 2). Although these two strategies have a similar effect on the impact force, the RMSE before the impact is 99% smaller when FBL is used (case 2 vs. case 9). Fig. 4 compares the tracking performance for these two cases. The larger position and velocity errors with LSC are obvious in this figure. Adding CC to the robot with HSC reduced the impact force 36% (case 5) and when combined with FBL, the impact force reduction is 72% (case 6) and the force of 117 N is less than the ISO limit.

For the uncovered robot with HSC, SOA (case 3) and AWR (case 4) produced similar forces to FBL (case 2) since the impact force rises so fast that it is near its peak before the impact is detected by the SOA and AWR strategies. However when CC is used with HSC the force rises more slowly, allowing SOA (case 7) and AWR (case 8) to reduce the impact force by 75% and 84%, respectively, to values well within the ISO safety limit. Fig. 5 compares the effectiveness of AWR strategy with and without CC to the benchmark case (without any force reduction method) for the HSC. With the benchmark case, in addition to large forces it can be observed that repeated impacts occur.

Regarding the LSC, cases 9-16 show a similar pattern to the corresponding HSC cases 1-8. Fig. 6 shows the results for the

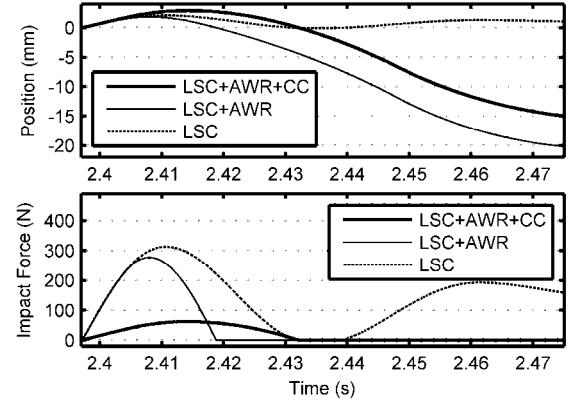

Figure 6. Post-impact link tip position and impact force for the low stiffness controller with different features: with no impact reduction feature (LSC), with arm withdrawal reflex (LSC+AWR), and with arm withdrawal reflex and compliant cover (LSC+AWR+CC).

LSC and the same combinations of AWR and CC as in Fig. 5. Compared with Fig. 5, the same improvement can be observed when CC is added, with the main difference being the arm is withdrawn much further back after the impact when using the LSC. From these figures and the tabulated results it can be observed that the LSC provides no significant safety advantage when CC and AWR are used together.

## VI. CONCLUSION

Several strategies for reducing the impact force caused by the collision of a robot arm with a constrained human head were investigated. The effect of the strategies on the robot's trajectory tracking precision during normal operation was also studied. An improved lumped parameter model for the constrained impact was proposed for simulating the collisions. Sixteen combinations of impact reduction strategies were simulated and compared for a UR5 collaborative robot. Compared to the uncovered robot with the HSC, the LSC (with 1% of the HSC's stiffness) only made the impact force slightly smaller, and made the tracking errors much larger. The SOA and AWR strategies were effective when CC was used, but have the disadvantage of requiring rapid impact detection. Combining the proposed FBL strategy with HSC and CC reduced the impact force to less than the ISO safety limit and achieved precise trajectory tracking. This combination also does not require any impact detection.

# Estimation and Control of a Double-Inverted Pendulum

Bowen Xu\*, You Lyu, and S. A. Gadsden  
College of Engineering and Physical Sciences,  
University of Guelph, Ontario, Canada  
\*bxu04@uoguelph.ca

**Abstract**—This paper studies estimation and control methods applied on a double-inverted pendulum. The most popular estimation strategy, referred to as the Kalman filter (KF), was programmed and implemented on a double-inverted pendulum built by Quanser (Markham, Ontario). A linear quadratic regulator (LQR) was used to control the actuator joints of the double-inverted pendulum to keep it vertically balanced under different conditions. The application of the KF improved the tracking performance. The results of the paper are discussed, and future work is considered.

**Keywords**—double inverted pendulum; control system; Kalman filter; estimation.

## I. INTRODUCTION

The double-inverted pendulum is one of the most popular mechatronic research systems used to study control and estimation strategies. The system itself is relatively easy to build, and is naturally unstable which makes it quite popular to study. The complex dynamics of a double-inverted pendulum offers a system suitable for the development and examination of new control and estimation methodologies. The findings can be applied to problems in current research, such as holding the balance of a robot or rotor-based aircraft [1]. In order to improve the control performance of the system, estimation strategies can be used to provide better knowledge of the states [1].

State and parameter estimation theory is an important field in mechanical and electrical engineering. The strategies are used to predict, estimate, or smooth out important system state and parameters [2, 3]. The Kalman filter (KF) is the most popular estimation strategy, and yields a statistically optimal solution to the linear estimation problem [4]. The goal of the KF is to minimize the state error covariance, which is a measure of the estimation accuracy and is defined as the expectation of the state error squared [5]. A popular nonlinear form of the Kalman filter is the unscented Kalman filter (UKF). It utilizes statistics to approximate the nonlinear probability density function (PDF) [6]. These filters can be applied on mechanical or electrical systems to improve the overall control tracking performance [4].

The brief paper is organized as follows. In Section II, the linear-quadratic regulator (LQR) controller, the standard KF, and the MATLAB simulation is summarized. The application results are provided and discussed in Section III. Conclusions and future work are considered in the final section of the paper.

## II. METHODOLOGY

### A. Model and Linear-quadratic regulator (LQR) control

The double-inverted pendulum has a complex dynamic system [7]. In order to improve the control performance (e.g., balancing the system dynamics), a linear-quadratic regulator control strategy is applied in this paper. Quanser (Markham, Ontario) built the double-inverted pendulum system used in this paper [7]. The results of this paper were built upon this platform and the provided software. The first step of applying the LQR control strategy is to obtain the state-space model of the system. The motion equations may be obtained by using the following Euler-Lagrange equation, as follows [7]:

$$Q_i = \frac{\partial L}{\partial t \partial \dot{q}_i} - \frac{\partial L}{\partial q_i} \quad (1)$$

The generalized coordinate  $q_i$  may be found as follows [7]:

$$q(t)^T = [x_c(t) \quad \alpha(t) \quad \theta(t)] \quad (2)$$

$$\dot{q}(t)^T = \left[ \frac{\partial x_c(t)}{\partial t} \quad \frac{\partial \alpha(t)}{\partial t} \quad \frac{\partial \theta(t)}{\partial t} \right] \quad (3)$$

where the above parameters are defined as follows [7]:

$$Q_1 = \frac{\partial^2 L}{\partial t \partial x_c} - \frac{\partial L}{\partial x_c} \quad (4)$$

$$Q_2 = \frac{\partial^2 L}{\partial t \partial \alpha} - \frac{\partial L}{\partial \alpha} \quad (5)$$

$$Q_3 = \frac{\partial^2 L}{\partial t \partial \theta} - \frac{\partial L}{\partial \theta} \quad (6)$$

The Lagrange (or energy) equation for the double-inverted pendulum system is defined by:

$$L = T - V \quad (7)$$

In equation (7),  $T$  refers to the kinetic energy of the double-inverted pendulum system,  $V$  is the total potential energy of the double-inverted pendulum system. According to equations (4) through (7), the generalized forces of the system may be found as follows [7]:

$$Q_1 = F_c - B_{eq} \dot{x}_c \quad (8)$$

$$Q_2 = -B_{p1} \dot{\alpha} \quad (9)$$

$$Q_3 = -B_{p2} \dot{\theta} \quad (10)$$

After obtaining the nonlinear motion equations, a Jacobian matrix is calculated and the linear state-space model may be found as follow:

$$\dot{x} = Ax + Bu \quad (11)$$

$$y = Cx + Du \quad (12)$$

where  $x$  refers to states,  $u$  is the input from the motor,  $A$  is the system matrix,  $B$  is the input matrix,  $C$  is the measurement matrix, and  $D$  is the feedforward matrix. The state and output equations are respectively as follows:

$$x^T = [x_c \ \alpha \ \beta \ \dot{x}_c \ \dot{\alpha} \ \dot{\beta}] \quad (13)$$

$$y^T = [x_1 \quad x_2 \quad x_3] \quad (14)$$

After obtaining the linear state-space matrices, the LQR controller can be implemented. The LQR control strategy can provide full feedback control of the system [4]. The LQR equation is defined by [7]:

$$J = \int_0^\infty x(t)' Q x(t) + u(t)' R u(t) dt \quad (15)$$

In equation (15),  $Q$  and  $R$  are system and measurement noise covariances, respectively:

$$Q = \begin{bmatrix} 10 & 0 & 0 & 0 & 0 & 0 \\ 0 & 50 & 0 & 0 & 0 & 0 \\ 0 & 0 & 50 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.9 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.9 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (16)$$

$$R = 0.02 \quad (17)$$

In order to reduce regulation error of the linear cart, an integral term is added:

$$\eta = \begin{bmatrix} A & 0 \\ 1 & 0 \end{bmatrix} \eta + \begin{bmatrix} B \\ 0 \end{bmatrix} u \quad (18)$$

$$[x_c - x_{c,d} \ \alpha \ \theta \ \dot{x}_c \ \dot{\alpha} \ \dot{\theta} \ \int(x_c - x_{c,d})dt] \quad (19)$$

According to the control law, the equation of control feedback of this double-inverted pendulum may be found as follows:

$$u = -K(\eta) \quad (20)$$

There are three important model characterizations for control of the double-inverted pendulum: observability, controllability, and stability. Observability of a system states can be observed from the system output [8]. In this paper, the system is observable but not completely observable because the measurement matrix is a non-square matrix. The dynamic system is said to be controllable which means for any desired final state, the system can be driven by the input [8]. In this paper, by calculating the rank of the controllability matrix, the controllability can be proven. The system is stable if every bounded input produces a bounded output (principle of BIBO stability). In this paper, the stability was calculated using Maple, because some poles are positive, the system is considered to be unstable [9].

### B. Kalman Filter and Matlab Simulink

For the control of the double-inverted pendulum, the cart position, and both pendulum angles are measured. According to the measurements, a voltage is determined that is used by the control system to actuate the cart's motor. As a result, the cart balances the double inverted pendulum and keeps the upright, vertical position.

For the software, the programs Matlab and Simulink were used. For this system, the controller could only be implemented in Simulink, whereas the programming environment of Matlab offers more possibilities. The workstation provides specialized Simulink blocks to communicate with the pendulum control. In real-time, the measurements of the position and angles are processed to control the motor by setting the voltage (as per the Figure 1). Simulink was used as the interface with the workstation, and Matlab as the data processor and background algorithms. The goal of this setup was to go beyond the setup provided commercially by Quanser in [7], and create a setting that enables real-time signal processing and the capability to add features over the time without losing the overview.

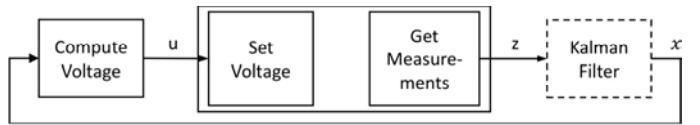

Figure 1. Control loop of the double-inverted pendulum.

### C. Implementation of the Kalman Filter

For the Kalman filter, a linear, discrete-time, and time-invariant system model is used [10]:

$$x_{k+1} = Ax_k + Bu_k + w_k \quad (21)$$

$$z_{k+1} = Cx_{k+1} + v_{k+1} \quad (22)$$

The Kalman filter is based on two stages: prediction and update. In each stage, the state vector and its covariance matrix are calculated. To simplify the notation, we write for the expected value of the a-priori density of the prediction as follows:

$$E\{x_{k+1}|z_k\} = \hat{x}_{k+1} \quad (23)$$

For the expected value of the a-posteriori density of the update as follows:

$$E\{x_{k+1}|z_k\} = \hat{x}_{k+1} \quad (24)$$

The estimation criterion is the minimization of the square norm if the estimation error:

$$E\{|\hat{x}(n) - x(n)|^2|z(n)\} \rightarrow \min \quad (25)$$

With the linearized matrices of the dynamic coefficient matrix  $A$ , the coupling matrix  $B$ , and the measurement matrix  $C$ , we can use the extended Kalman filter (EKF) to decrease our measurement deviation. For the computation, the equations are shown below [11]:

Prediction stage:

$$\hat{x}_{k+1|k} = A\hat{x}_{k|k} + Bu_k \quad (26)$$

$$P_{k+1|k} = AP_{k|k}A^T + Q_k \quad (27)$$

Update stage:

$$K_{k+1} = P_{k+1|k} C^T (C P_{k+1|k} C^T + R_{k+1})^{-1} \quad (28)$$

$$\hat{x}_{k+1|k+1} = \hat{x}_{k+1|k} + K_{k+1} [z_{k+1|k} - C \hat{x}_{k+1|k}] \quad (29)$$

$$P_{k+1|k+1} = (I - K_{k+1} C) P_{k+1|k} \quad (30)$$

The unscented Kalman filter (UKF) belongs to the group of sigma point Kalman filter, which uses a weighted statistical linear regression strategy that approximates the nonlinear model statistically [6].

#### D. Implementation of the Developed Interface

The Kalman filters are implemented in a Matlab block in Simulink. The advantage is its simplicity. The block has to be created, the function to be written and the connection of inputs and outputs to be made. The drawbacks are the computation time that might be slower in comparison with the usage of Simulink-only state space blocks. Nevertheless, the Matlab function block can be used. The value of the gain ‘FilterChoice’ can be modified using the user interface. With the if-operation and the modification of the choice input, different code sections can be executed, performing different KF options. The voltage input for the KF is provided by a ‘Data Store Read’ block. If we would connect the input  $u$  with the output of the voltage determination step, we would create an algebraic loop. Due to the discrete state space model, the computation has to be executed in a finite time step. By calling itself, an infinite circle is created making a discrete state space computation impossible. Due to this, instead of initiating the execution of the KF function by the arrival of the voltage input, we write the input  $u$  in a ‘Data Store Write’ block and the value can be read out if the measurements initiate the execution of the block.

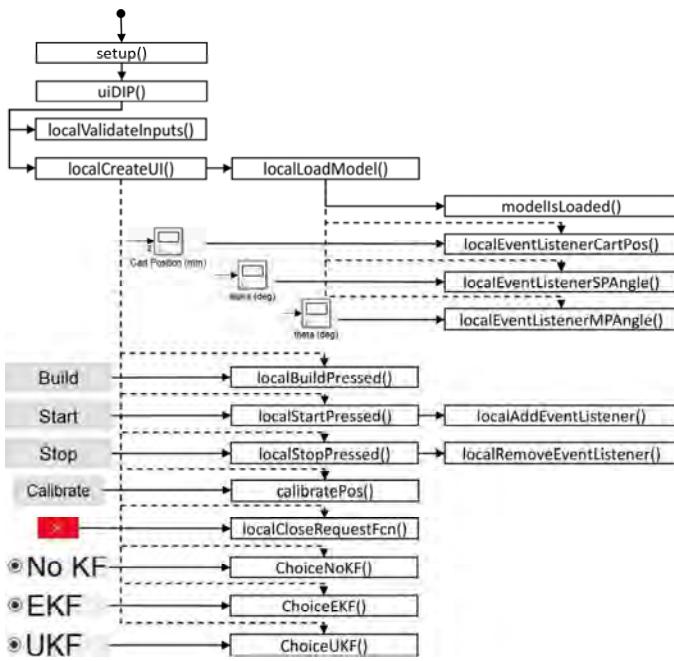

Figure 2. Structure of the workstation software.

Matlab can modify the Simulink model and the user interface during the simulation by changing the parameters in Matlab’s data structure. In the opposite way, Matlab obtains the data from

Simulink over event-listeners and from the user interface over callbacks. In order to accomplish this, the event listeners and callback functions have to be implemented first. The function ‘localCreateUI’ creates the figure of the user interface with all components and adds callback functions that are executed, each time the buttons are pressed. Additionally, this function also executes the function ‘localLoadModel’, which implements the event-listeners for the measurements of the cart position and the angles of the short and medium pendulum. Each time, a value arrives at one of the event-listener blocks, the event-listener function in Matlab is executed. By this approach, a bidirectional connection between the Simulink model and the user interface over the model is possible.

### III. SIMULATION RESULTS

#### A. Software Simulation

The software only simulation is based on Matlab and Simulink. It provides software-based system running simulation for this double inverted pendulum system. All of the important parameters of the system such as output voltage, cart position, and pendulum angles are visible by real time graphs. Software only simulations can be roughly divided into ideal and non-ideal cases. Ideal types do not have system and measurement noises included in the simulation. While the non-ideal cases take all these factors in count and the results are closer to real system. In this paper, we test system performance for all these situations.

The system is built in Simulink and all components are represented by functional blocks. There are two key parts in the system design, namely LQR balance controller and the pendulum system. The pendulum system itself can be simulated in several ways. Regardless, using any method to simulate the pendulum system, there is only one input (motor voltage) for this system. The three output states are cart position and angles of the two pendulums.

##### 1) Ideal Case

This specific simulation employs an ideal system model, which contains no noise interference. The results should be ideal inputs and output which will be considerably different from the hardware-connected case. However, this insight-view provides a convenient way to become familiar with the system and can benefit the configuration and optimization of the physical system. Simulink is the platform to perform this work. All of the parameters will be monitored in Simulink scopes. The Matlab file provides all the matrices and parameters of the system. The operation of the Simulink model is based on content loaded into Matlab’s workspace. The pendulum system itself is represented by the state space model. Data flow for this target mainly contains the input, which is the voltage applied to the cart motor. The output are the three states of the system, cart position, angle of the first pendulum and the angle of the second pendulum, respectively. LQR balance control is the selected controller in this paper; however, the popular PID controller could also be used. The LQR part sends the calculated voltage values to control the motor motions. The simulation performed is set to contain two position values: the cart is supposed to stay at one place for ten seconds, then move to the second position and stay there for the next ten seconds, before returning to the original position. The simulation results are shown next.

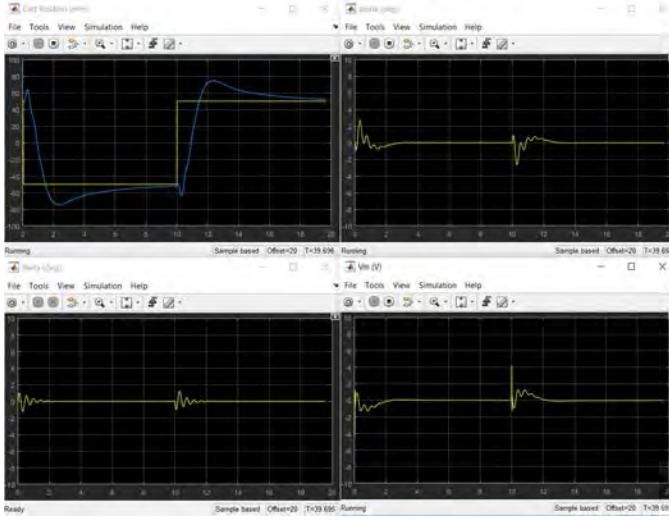

Figure 3. Simulation output without noise (Case 1).

In Figure 3(top-left), the yellow curve is the position setting and the blue curve is the cart output. The simulated cart moves in a rather smooth manner to reach the settling points. Compared with the yellow curve, the blue curve shows reasonable overshoot and low steady state error. The joint angles and voltage show small fluctuations, only occurs when the cart moves from one location to another.

## 2) Noisy Measurement Case

In this case, noisy measurements are considered and added to the simulation. In order to improve the control results, the Kalman filter was added to estimate the states. The noisy signal with filtered results are shown in Figure 4.

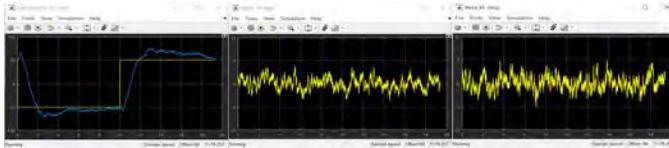

Figure 4. Simulation output with the KF (Case 2).

The results contain small fluctuations during the stabilization process of the cart (after quick position movements). The simulation shows that the steady-state error stays approximately at the same level compared with the ideal case. In contrast, the angles were more unstable. However, unlike the ideal case, the fluctuations never settle.

## 3) System with Process and Measurement Noise

In this case, the simulation contains both system and measurement noise. The cart position results without the addition of the KF shows significantly more fluctuations compared to the ideal case. The angles reveal the same trend as the cart position. In contrast, the addition of the KF shows more fluctuations which means the cart requires additional movements to keep the system balanced.

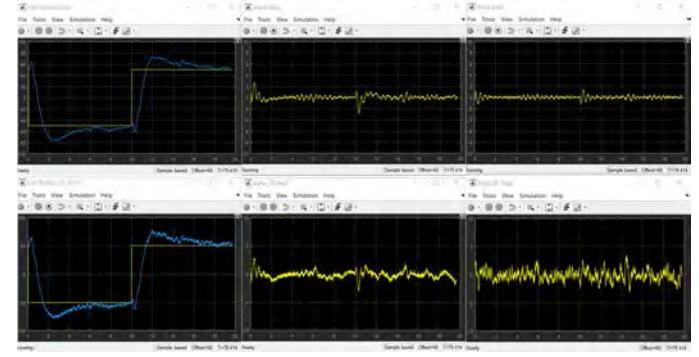

Figure 5. Simulation output with the KF (Case 3).

## B. Experimental System and Software Simulation

This section focuses on the simulation with the pendulum. The motion and status of the real system is considerably different from the simulated type. The goal is to achieve and demonstrate the successful control of the double-inverted pendulum system.

### 1) Normal Case

In case, consider the system noise covariance matrix as per equation (16) and the measurement uncertainty covariance matrix as per equation (17). The normal case results are shown in the following figure.

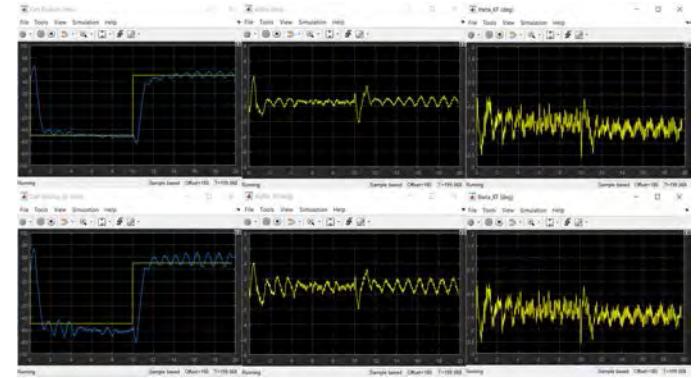

Figure 6. Normal case results.

The movement of the cart is fast and steady. The cart moves forward and backward in small scales to keep the balance of both pendulums. The angle values fluctuate as the cart moves to keep the whole system balanced. The addition of the KF improved the overall steady-state error of the system. Note also that the two angle states were quite similar in these two cases.

### 2) Noisy Case

The noisy system cases were simulated by increasing the noise covariance. The results are shown as per Figure 7. The system noise covariance matrix was changed as follows:

$$Q = \begin{bmatrix} 30 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 350 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 100 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (31)$$

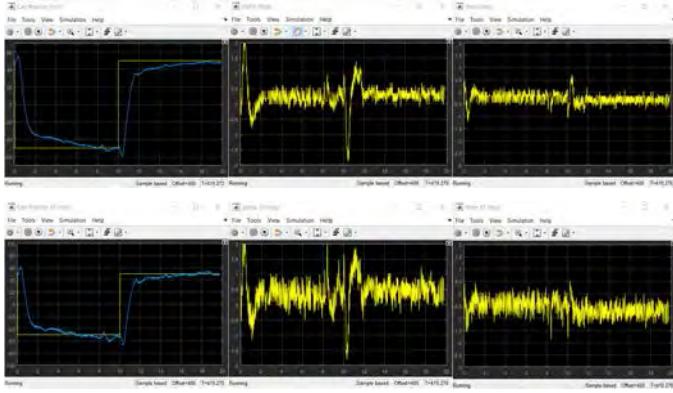

Figure 7. Noisy case results.

The cart moves quickly but in small movements in this case. The addition of the KF to the system improves the system performance, and the required settling time was decreased. It is important to note that both the LQR and the LQR with the KF methods were able to balance the double-inverted pendulum system. However, the LQR with KF method had improved response and faster settling time.

#### IV. CONCLUSIONS AND FUTURE WORK

In this brief paper, the results of applying a controller and estimation strategy on a double-inverted pendulum were summarized and discussed. With well-defined parameters and a well-tuned KF, the system is able to overcome instabilities and external forces. The results demonstrate that the KF results are closer to the true values, which means that the LQR control strategy with the KF provides a better performance for the double-inverted pendulum system. Future work will look at implementing other control strategies, such as an adaptive PID, and comparing the results.

**Abstract**— The current paper investigates two control methods for stabilizing a two-wheel inverted pendulum (TWIP) robot. It is well-known that the controller in the mobile robot plays a critical role in self-balancing and stabilizing. The TWIP robot has two DC gear motors with a high-resolution encoder and zero backlash, but with friction. It is a highly nonlinear and unstable system, which poses challenges for controller design. In this paper, a mathematical dynamic model is built using Lagrangian function method. Furthermore, a sliding mode controller (SMC) is proposed for auto-balancing and yaw rotation. A comparison of the proposed SMC controller and linear quadratic regulator (LQR) has been conducted. The experimental test results demonstrate the SMC controller outperforms (LQR) in terms of transient performance and disturbance rejection ability.

**Keywords-** *Linear Quadratic Regulator (LQR), Sensor data fusion, Sliding mode control, Two-wheel inverted pendulum (TWIP) robot*

## I. INTRODUCTION

In recent years, self-balancing robots have attracted increasing attention in both industry and academia, since designing and testing control algorithms become more achievable with the rapid development of microcontrollers. Two-wheeled inverted pendulum (TWIP) robots have become more and more popular due to its light weight, small footprint, rapid rotation and high maneuverability. One of the applications of using these robots can be a service robot platform like Segway. However, the inherent instability and nonlinearity of the TWIP requires a sophisticated control scheme.

PID is a commonly used non-model based control method for self-balance robot, as there is no need to build the mathematics model. The three parameters can be tuned by trial and error or by experience. Although PID owns some robustness to disturbance and uncertainties to a certain extent, it cannot handle the sudden, large disturbance and modeling error [1]. Moreover, the control input cannot perfectly be optimized by using PID control. It could be targeted by having

state feedback control (SFC) with optimized linear quadratic regulator (LQR) [2]. However, the optimized SFC can only work in the certain operating range and cannot react to system uncertainty. When the operating point is changed, the control gains have to be re-tuned in order to stabilize the robot, which is not very practical in the operation. Recently, the soft computing techniques such as fuzzy logic and neural networks have been used to control TWIP robot [3]. Two fuzzy controllers based on Mamdani and Takagi-Sugeno are designed for an inverted pendulum subjected to disturbance. Moreover, artificial neural network-based real-time switching dynamic controller is designed to solve balancing problem on various loose surfaces such as sand, pebble and soil [4]. A visual robot control interface is developed in C++ software development environment so that robot controller parameters can be changed as desired.

Recently, the model-based control of TWIP has been proposed to deal with the nonlinearity and disturbance. In [6], a linear SFC has been designed based on the linearized model, which needs very accurate dynamic models of the robots. One of the typical model-based control is SMC method. SMC is known to have a good robustness to the model uncertainties and disturbance. It can deal with the nonlinear unstable system with easy implementation, insensitivity to parameters variation and quick response independence of external disturbances. SMC has been successfully used for controlling the TWIP robot. In [5], a back-stepping slide model control has been proposed for balancing and trajectory tracking of a two-wheeled robot. The balancing and angular velocity controllers are implemented in a cascade way.

In this paper, a dynamic model of a customer built TWIP robot is derived by using Lagrangian function method. The robot is composed of two gear DC motors driving two wheels, a structure, battery, sensors and controller. It is a highly nonlinear and unstable system. Two controllers, i.e. LQR and SMC have been designed for balancing and stabilizing the robot. Both controllers have been implemented on the robot and experimental tests have been carried out to compare performances of two controllers. The results demonstrate the

superiority of SMC controller in terms of transient performance and disturbance rejection capability.

The paper is organized as follows. The paper begins with an introduction and the next section provides a dynamic of the model of the TWIP robot built in our lab. In Section III, the LQR and SMC are designed and the simulation results of both controllers are presented. Section IV presents the experiment results of both controllers. The conclusion is drawn in Section V.

## II. DYNAMIC MODELLING

The TWIP robot is built in our lab to serve as test platform for various controllers. In order to control this type of unstable robot effectively, the first step is to model the robots dynamic behavior in the yaw and pitch motions. The schematic diagram of the TWIP robot is shown in Figure 1 and the parameters' description has been provided in TABLE 1.

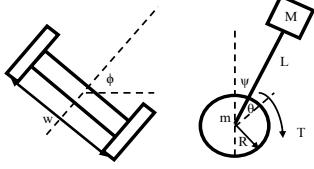

Figure 1 Schematic diagram of the TWIP robot.

The dynamic model of the robot is built based on the Lagrangian function method [6]. Equation (1) presents Lagrangian where  $L_1$ ,  $L_2$  and  $B$  are translation kinematic energy, rotational kinematic energy and potential energy, respectively.

$$L_a = L_1 + L_2 + B \quad (1)$$

It is assumed that the robot has 3 degree of freedoms (DOFs). The generalized variables of the robot are angle of the wheel ( $\theta$ ), pitch angle ( $\phi$ ) and yaw angle ( $\psi$ ) [7]. According to the robot dynamics, the translational and rotational kinetic energies are described as follows:

$$L_1 = \frac{1}{2}m(\dot{x}_l^2 + \dot{y}_l^2) + \frac{1}{2}m(\dot{x}_r^2 + \dot{y}_r^2) + \frac{1}{2}M(\dot{x}_b^2 + \dot{y}_b^2 + \dot{z}_b^2) \quad (2)$$

$$L_2 = \frac{1}{2}J_w\dot{\theta}^2 + \frac{1}{2}J_w\dot{\theta}^2_r + \frac{1}{2}J_\psi\dot{\psi}^2 + \frac{1}{2}J_\phi\dot{\phi}^2 + \frac{1}{2}n^2J_m(\dot{\theta}_l - \dot{\psi})^2 + \frac{1}{2}n^2J_m(\dot{\theta}_r - \dot{\psi})^2 \quad (3)$$

$$B = Mgz_b \quad (4)$$

The Lagrangian equations are:

$$\begin{aligned} \frac{d}{dl}\left(\frac{\partial L_a}{\partial \dot{\theta}}\right) - \frac{\partial a}{\partial \theta} &= F_l + F_r \\ \frac{d}{dl}\left(\frac{\partial L_a}{\partial \dot{\psi}}\right) - \frac{\partial a}{\partial \psi} &= -F_l - F_r \\ \frac{d}{dl}\left(\frac{\partial L_a}{\partial \dot{\phi}}\right) - \frac{\partial a}{\partial \phi} &= \frac{W}{2R}(F_r - F_l) \end{aligned} \quad (5)$$

where,  $F_l$  and  $F_r$  are the torques on the left and right wheels, respectively. Moreover, they could be defined as follows:

$$\begin{aligned} F_l &= nK_l i_l + T_s + \sigma_m(\dot{\psi} - \dot{\theta}) \\ F_r &= nK_r i_r + T_s + \sigma_m(\dot{\psi} - \dot{\theta}) \end{aligned} \quad (6)$$

TABLE 1. Parameters of Two Wheeled Inverted Pendulum

Parameters	Unit	Description
W=0.242	m	Body Width
M=1.047	kg	Body Mass
m=0.118	kg	Wheels mass
R=0.060	m	Diameter of wheel
g=9.810	m/s <sup>2</sup>	Gravity acceleration
L=0.030	m	Distance of the center of the mass from the Wheel axle
D=0.050	m	Body Depth
n=64:1		Gear ratio
J <sub>w</sub> = mR <sup>2</sup> /2	kgm <sup>2</sup>	Wheel inertia moment
J <sub>y</sub> = ML <sup>2</sup> /2	kgm <sup>2</sup>	Body pitch inertia moment
J <sub>φ</sub> = M(W <sup>2</sup> + D <sup>2</sup> )/12	kgm <sup>2</sup>	Body yaw inertia moment
R <sub>m</sub> =1.900	Ω	DC motor resistance
K <sub>t</sub> =13.400	mNm/A	DC motor torque constant
K <sub>b</sub> =1.400	mv/rpm	DC motor back E.M.F constant
f <sub>m</sub> = 0.0022		Friction coefficient between body and DC motor
θ,ψ,φ		Rotary angle of the wheel, pitch angle and yaw angle of the robot
l,r,b		Subscripts indicating left or right wheels and the robot body, respectively

By substituting the kinetic and potential energies in the Lagrangian equations:

$$\begin{aligned} ((2m+M)R^2 + 2J_w + 2n^2J_m)\ddot{\theta} + \\ (MRLcos\psi - 2n^2J_m)\ddot{\psi} - MLR\psi^2sin\psi = F_\theta \end{aligned} \quad (7)$$

$$\begin{aligned} (MRLcos\psi - 2n^2J_m)\ddot{\theta} + (ML2 + J_\psi + 2n^2J_m)\ddot{\psi} \\ - MgLsin\psi - ML^2\dot{\phi}^2sin\psi cos\psi = F_\psi \end{aligned} \quad (8)$$

$$\begin{aligned} (0.5mW^2 + JJ_\phi + \frac{W^2}{2R^2}(J_w + n^2J_m) + ML^2sin^2\psi)\ddot{\phi} \\ + 2ML^2\dot{\psi}\dot{\phi}sin\psi cos\psi = F_\phi \end{aligned} \quad (9)$$

The aforementioned equations can be transformed to nonlinear state space, by defining:

$$\theta, \dot{\theta}, \psi, \dot{\psi}, \phi, \dot{\phi}$$

as the state variables:

$$X = [x_1, x_2, x_3, x_4, x_5, x_6] = [\theta, \dot{\theta}, \psi, \dot{\psi}, \phi, \dot{\phi}]$$

Hence, the general form of the state space is given as following equations:

$$M(x)\dot{x} = f(x) + u \quad (10)$$

where:

$$M(x) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ M_{21} & M_{22} & -M_{24} & M_{24} & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ -M_{21} & M_{24} & M_{21} & M_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & M_{65} & M_{06} \end{bmatrix} \quad (11)$$

$$f(x) = \begin{bmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \\ f_5 \\ f_6 \end{bmatrix} = \begin{bmatrix} x \\ MLRx_4^2\sin x_3 + 2T_s \\ x \\ MgL\sin x_3 + ML^2x_6^2\sin x_3\cos x_3 \\ x \\ -2ML^2x_4x_6\sin x_3\cos x_3 \end{bmatrix} \quad (12)$$

$$u = \begin{bmatrix} 0 \\ u_2 \\ 0 \\ -u_2 \\ 0 \\ u_6 \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ \frac{nk_t}{R_m} & \frac{nk_t}{R_m} \\ 0 & 0 \\ \frac{nk_t}{R_m} & -\frac{nk_t}{R_m} \\ 0 & 0 \\ \frac{nk_t w}{2RR_m} & -\frac{nk_t w}{2RR_m} \end{bmatrix} \begin{bmatrix} v_r \\ v_l \end{bmatrix} \quad (13)$$

$u$  is the control input which is generated by the controllers in this study.

### III. CONTROLLER DESIGN AND SIMULATION

#### A. State feedback control having LQR

To stabilize the two-wheel inverted pendulum, the optimal SFC have been designed using LQR. Following is the linear quadratic regulator objective function:

$$J = \int_0^\infty x^T(t)Qx(t) + u^T(t)Ru(t)dt \quad (14)$$

The optimal control input to satisfy the above mentioned equation is:

$$u(t) = -Kx(t), \text{ where } K = R^{-1}B^TP \quad (15)$$

$P$  can be calculated by solving Riccati equation:

$$A^TP + PA - PBR^{-1}B^TP + C^TC = 0 \quad (16)$$

Where  $A$ ,  $B$  and  $C$  are state space matrices. Two optimal LQRs have been designed for left and right DC motors.

There are two measurements of the angle from two different sources. The measurement from accelerometer gets affected by sudden horizontal movements (it could be used to measure the  $\psi$ ) and the measurement from gyroscope gradually drifts away from actual value (it could be used to measure  $\theta$ ). In other words, the accelerometer reading gets affected by short duration signals and the gyroscope reading is affected by long duration signals. To stabilize the robot, two state feedback controllers work simultaneously to control the states of DC motors.

The state feedback controller has been applied to the simulated model which has been presented in the Eq. (15). Figure 2 is the block diagram of closed-loop states control for the TWIP. The gains details are given as in TABLE 2.

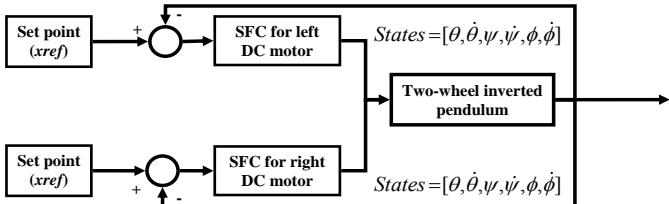

Figure 2. TWIP closed loop block diagram with LQRs

$x_{ref}$ : It represents the desired states, in this case to stabilize the TWIP the  $x_{ref}=0$  rad (Figure 2).

TABLE 2. SFC GAINS

	$[k_1, k_2, k_3, k_4, k_5, k_6]$
Left motor	[-0.7071 -0.3078 -11.3966 -1.6791 0.0000 0.2118]
Right motor	[-0.7071 -0.3078 -11.3966 -1.6791 0.0000 -0.2118]

The simulation of the closed-loop SFC has been done in SIMULINK using ode45 method with variable time step. As shown in Figure 3, two different initial pitch angles have been provided to evaluate the performance of LQR.

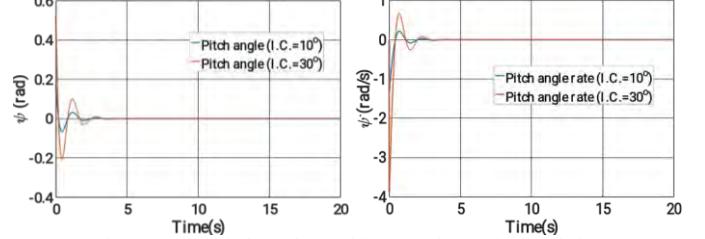

Figure 3. The pitch angle and its rate of LQR in simulation

#### A. Sliding mode controller

As the yaw motion and self-balancing of the robot need to be controlled properly, a sliding mode control is proposed and designed to achieve self-balancing and stabilizing. Due to the system's nonlinearity and uncertainty, LQR could not precisely balance the pendulum and reject the large disturbance within short time period. Hence, the sliding mode controller is designed to handle the nonlinearity of the system using the sliding surface approach.

The design of the wheel angle sliding mode controller is presented as follows:

$$s_1 = c_1\psi + c_2\dot{\psi} \quad (18)$$

$$\dot{s}_1 = -\varepsilon_1 \operatorname{sgn}(s_1) \quad (19)$$

$$\begin{aligned} u_2 &= \frac{c_1(M_{24}^2 - M_{22}M_{44})\psi + (M_{24}^2 + M_{22}M_{44})\varepsilon_1 \operatorname{sgn}(s_1)}{c_2(-M_{24} - M_{22})} + \\ &\quad \frac{C_2M_{24}f_2 - C_2M_{22}f_4}{C_2(-M_{24} - M_{22})} + \\ &\quad \frac{C_2M_{12}(-M_{24} + M_{22}) - C_2M_{21}(M_{24} + M_{22})\psi}{n} \end{aligned} \quad (20)$$

The design of the yaw motion sliding mode controller is presented as follows:

$$s_2 = c_3\phi + c_4\dot{\phi} \quad (21)$$

By substituting the equations to the robot dynamic, the second input can be calculated as:

$$u_6 = \frac{M_{66}\varepsilon_2 \operatorname{sgn}(s_2)}{-c_4} - f_6 + \dot{\phi}(M_{65} - C_3M_{66}) \quad (22)$$

where:

$$f_2 = MLRx_4^2\sin x_3 + 2T_s \quad (23)$$

$$f_4 = MgL\sin x_3 + ML^2x_6^2\sin x_3\cos x_3 \quad (24)$$

$$f_6 = -2ML^2x_4x_6\sin x_3 \cos x_3 \quad (25)$$

From Eq. 26 and Eq. 27, the inputs of left and right wheeels are:

$$v_r = \frac{RR_m}{nk_t w} u_6 - \frac{R_m}{2nk_t} u_2 \quad (26)$$

$$v_l = -\frac{RR_m}{nk_t w} u_6 - \frac{R_m}{2nk_t} u_2 \quad (27)$$

Figure 4 depicts the block diagram of closed look position control with sliding mode controller for the TWIP.

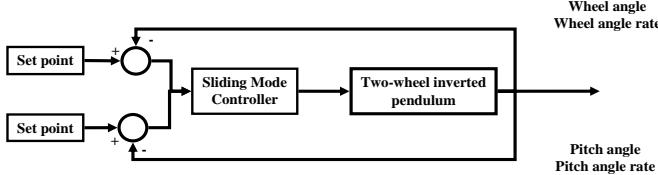

Figure 4. SMC block diagram for TWIP

The angular reaction of the wheels is presented in Figure 5:

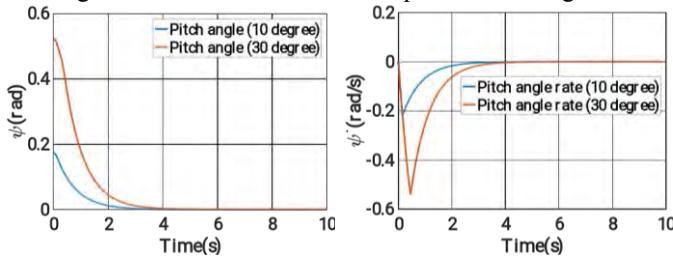

Figure 5. The pitch angle and its rate of SMC in simulation

TABLE 3. TRANSIENT PERFORMANCE OF SFC AND SMC IN SIMULATION

	LQR		SMC	
Initial condition	10°	30°	10°	30°
Rise Time (s)	0.181	0.166	3.144	4.374
Settling Time (s)	2.25	3.04	1.638	2.581
Percent of overshoot (%)	36.12	38.36	0	0

The simulation results are summarized in TABLE 3. From this table, one can see that the SMC has better transient performance than LQR does in terms of settling time and percent of overshoot.

#### IV. EXPERIMENT

This TWIP robot is built with four main parts: controller and sensors, gear DC motors, battery, and structure. Arduino Uno is the controller of the TWIP and allows the driver shield to drive gear DC motors. The gear DC motors of the robot could robustly keep the robot stable. The driver shield is L298, which is a dual full-bridge driver. It can transform the real time data from Arduino board to the DC motors. To record the angular position like pitch, yaw and wheel angles, Arduino has been connected to two different sensors. (i.e., IPU 6050 which has accelerometer sensors, gyroscope). As it contains 16-bits

analog to digital conversion hardware for each channel, it could be more precise.

In addition, using X-bee shield can wirelessly provide the data transmission to computer. The gear-DC-motors made by Faulhaber with maximum revolution of 350 rpm. Moreover, the power is supplied by Li-Po battery/4000 mA. The diameter of wheels is 120mm. the center mass of robot is located in the middle of the wheels' axis.

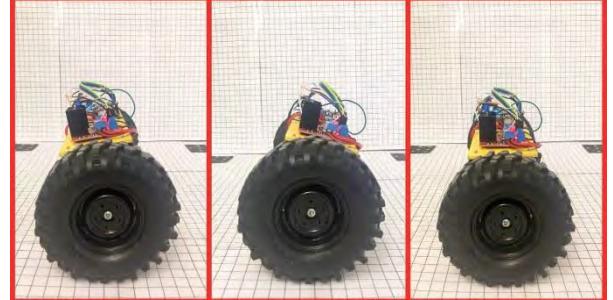

Figure 6. TWIP robot with different pitch angle

The experimental results of pitch angle and its rate of SFC controller are presented in Figure 7.

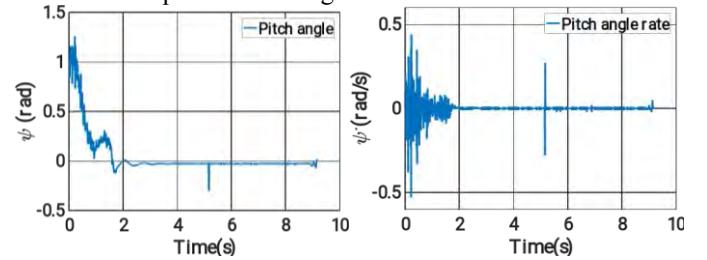

Figure 7. The experiment results of pitch angle and its rate of LQR

In the next, to evaluate the performance of the sliding mode control, the pitch angle and its rate have been illustrated in Figure 8.

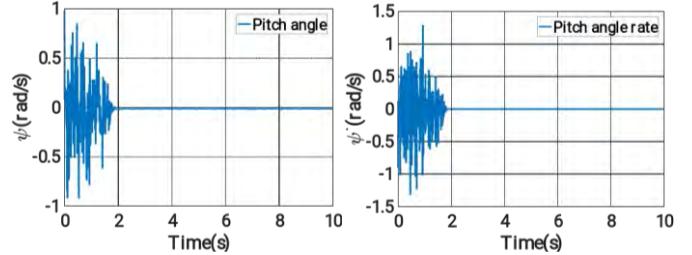

Figure 8. The experiment results of pitch angle and its rate of SMC

In both experimental tests, a big push has been applied to the TWIP robot around 1 second to test the disturbance rejection ability of both controllers. From Figs. 7 and 8, one can see that both SFC and SMC can recover from the push and achieve self-balancing. However, it takes SMC less than 2 seconds to settle in the zero angles position while SFC takes more than 2 seconds to reach the self-balancing state. [The video of the experiments is uploaded in Youtube.](#) <https://youtu.be/a6w5zxU8IBU>. The experimental tests demonstrate that SMC outperforms the LQR.

#### V. CONCLUSION

In this paper, a customer designed TWIP robot and its modeling and control are presented. The robot is an inherent

unstable and nonlinear system, which poses challenge for control design. A SMC for balancing and steering movement is designed based on the dynamic model derived by the Lagrangian function method. From simulation results of the LQR and SMC for the TWIP robot, it can be concluded that the SMC has better transient performance in stabilizing the TWIP robot. To further evaluate the SMC and LQR performances, experimental tests have been conducted and validated the effectiveness of the designed controllers. As it is presented in the aforementioned test results, the performances of SMC is superior to that of LQR in terms of settling time and robustness. The future work includes the further improvement of control performances considering the actuation constraints.

**Abstract**—This paper investigates the close formation control problem of multiple unmanned aerial vehicles (UAVs). A robust cooperative control algorithm is proposed in light of the uncertainty and disturbance estimation technique. In the proposed design, each UAV is assigned a virtual leader which defines the desired position for the corresponding UAV in close formation. Bidirectional communication topology is assumed for UAVs in close formation, based on which a cooperative control law is thereafter established on each UAV. Model uncertainties and formation aerodynamic disturbances are efficiently estimated and compensated using a uncertainty and disturbance estimator. Eventually, the efficacy of the proposed design will be validated via the close formation simulation of five aircraft.

**Keywords-component;** *close formation control; cooperative control; Multi-UAVs; uncertainty and disturbance estimation*

## I. INTRODUCTION

Close formation flight stems from the formation flight of migrating birds [1]. It has received extensive research attention in past decades [2, 3]. The research interest in close formation flight is motivated by its potential in drag reductions and fuel savings. When an aircraft is flying in air, trailing vortices—circular patterns of rotating air—will be left behind it. The trailing vortices are divided into downwash wake and upwash wake. If a follower aircraft is managed to fly at certain proper relative position to a leader aircraft, the upwash wake could be used to reduce the drag of the follower aircraft, thereby decreasing energy expenditure. According to flight tests by NASA, close formation flight can generate 13%-20% drag reductions and 14%-18% fuel savings on a follower aircraft [4]. Wind-tunnel experimental studies by Cho et al indicate 12% increase in the lift-to-drag ratio of a follower aircraft in close formation against solo flight [5].

However, close formation flight is always a challenging problem for unmanned aerial vehicles. Highly efficient and accurate formation control algorithms are indispensable, as close formation flight only makes sense when a follower is keeping a certain optimal position to its leader. The theoretical

analysis by the authors shows more 30% drag reduction by close formation flight could be lost, if a follower fails to track the optimal relative position by 10% wing span [6]. In addition, the trailing vortices, working like wind gusts, will induce other adverse aerodynamic disturbances on the follower aircraft, which increases the difficulty of the control design [6].

So far, the close formation control problem has been studied using different methods, such as PI controller [7], sliding mode control [8], LQR control [9], MPC control [10], adaptive control [11], and robust control [12]. However, all of them were developed under the leader-follower architecture, and there was no cooperation between two UAVs. The efficacy of the existing methods can only be guaranteed for close formation flight of two or three aircraft. Increase of formation size (number of UAVs) will result in dramatic loss of efficiency and accuracy for the existing methods. To deal with the deficiency of the existing methods in close formation flight of more than three UAVs, a cooperative control method is proposed in this paper. A bidirectional communication topology is employed. UAVs in close formation are required to communicate with some of their neighbors. To enhance the robustness against model uncertainties and formation aerodynamic disturbances, the uncertainty and disturbance estimation technique is employed and combined with the proposed cooperative formation controller. The efficiency of the proposed control algorithm is verified via the close formation simulation of five aircraft.

The paper is organized as follows. In section II, a nonlinear UAV model is introduced together with the close formation aerodynamics. Section III presents the robust cooperative control methods. The numerical simulations are given in Section IV. Eventually, some conclusion remarks are provided in Section V.

## II. PRELIMINARIES

### A. Aircraft model

The proposed cooperative control law will perform as an outer-loop formation tracking controller. Hence, a 6-state nonlinear UAV model is presented for the control design.

$$\begin{cases} \dot{x}_i = v_i \cos \chi_i, \dot{y}_i = v_i \sin \chi_i, \dot{h}_i = \eta_i \\ \dot{v}_i = (T_i - D_i - \Delta D_i) / m_i \\ \dot{\chi}_i = (L_i + \Delta L_i) \sin \mu_i / (m_i v_i) \\ \dot{\eta}_i = (L_i + \Delta L_i) \cos \mu_i / m_i - g \end{cases} \quad (1)$$

where  $x_i$ ,  $y_i$ , and  $h_i$  denote the position of the  $i$ -th UAV in the inertial frame,  $v_i$  is the ground speed projection on a horizontal plane,  $\eta_i$  is the climbing rate,  $\chi_i$  is the heading angle,  $\mu_i$  is the bank angle,  $L_i$  is the lift,  $D_i$  is the drag,  $T_i$  is the thrust,  $g$  is the gravity acceleration,  $\Delta D_i$  and  $\Delta L_i$  aerodynamic forces induced by the trailing vortices of leader aircraft. The control inputs are chosen to be  $T_i$ ,  $\mu_i$ , and  $L_i$ . The vortex-induced forces  $\Delta D_i$  and  $\Delta L_i$  are given by

$$\begin{aligned} \Delta L_i &= \int_{-\frac{b}{2}}^{\frac{b}{2}} q_\infty c(s) C_{l\alpha} \Delta \alpha(s) ds \\ \Delta D_i &= L'_i \sin(\overline{\Delta \alpha}) = (L_i + \Delta L_i) \sin(\overline{\Delta \alpha}) \end{aligned}$$

where  $\Delta \alpha$  is the vortex-induced change of the angle of attack along the wing span as shown in Figure 1, while  $\overline{\Delta \alpha}$  is the effective average change of the angle of attack. Notice that  $\Delta L_i$  and  $\Delta D_i$  are actually functions of the relative positions between a follower aircraft and its leader. Shown in Figure 2 and 3 are the relationships between non-dimensional lift and drag coefficients with respect to the lateral and vertical separations. More detailed results can be found at [6].

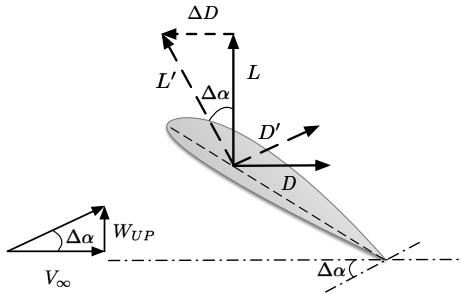

Figure 1: Lift rotation due to the upwash wake

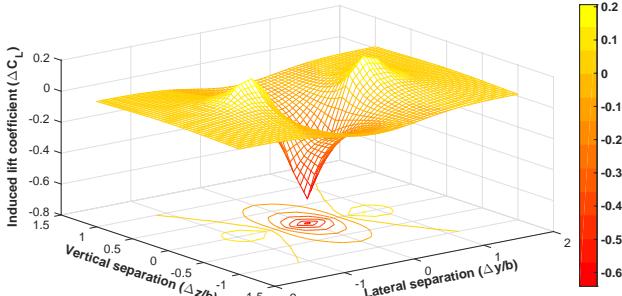

Figure 2: Vortex-induced lift coefficient variation

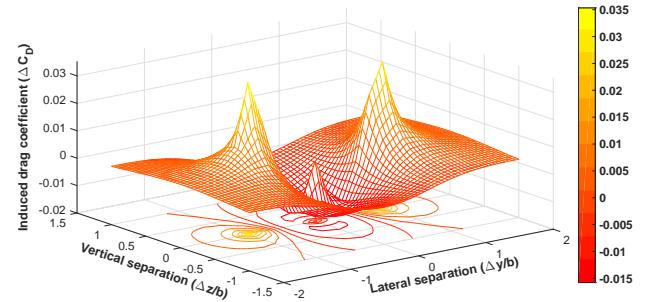

Figure 3: Vortex-induced drag coefficient variation

#### B. Control conversion

In the control design,  $D_i$  is taken as part of the model uncertainties. Differentiating the kinematic equations of Model (1) will yield

$$\begin{cases} \ddot{x}_i = \dot{v}_i \cos \chi_i - v_i \dot{\chi}_i \sin \chi_i \\ \ddot{y}_i = \dot{v}_i \sin \chi_i + v_i \dot{\chi}_i \cos \chi_i \\ \ddot{h}_i = \dot{\eta}_i \end{cases} \quad (2)$$

Define

$$\begin{aligned} u_{xi} &= \frac{T_i}{m_i} \cos \chi_i - \frac{L_i}{m_i} \sin \mu_i \sin \chi_i \\ u_{yi} &= \frac{T_i}{m_i} \sin \chi_i + \frac{L_i}{m_i} \sin \mu_i \cos \chi_i \\ u_{zi} &= \frac{L_i}{m_i} \cos \mu_i - g \\ d_{xi} &= -\frac{D_i + \Delta D_i}{m_i} \cos \chi_i - \frac{\Delta L_i}{m_i} \sin \mu_i \sin \chi_i \\ d_{yi} &= -\frac{D_i + \Delta D_i}{m_i} \sin \chi_i + \frac{\Delta L_i}{m_i} \sin \mu_i \cos \chi_i \\ d_{zi} &= \frac{\Delta L_i}{m_i} \cos \mu_i \end{aligned}$$

$$d_{zi} = \frac{\Delta L_i}{m_i} \cos \mu_i$$

Eventually, the nonlinear model is transformed into a standard 2<sup>nd</sup>-order integrator model as shown in (2).

$$\ddot{\rho}_i = u_{\rho i} + d_{\rho i} \quad (\rho \in \{x, y, z\}) \quad (3)$$

### III. ROBUST COOPERATIVE CONTROL

The entire control law is

$$u_{\rho i} = u_{\rho 0i} - \hat{d}_{\rho i} \quad (\rho \in \{x, y, z\}) \quad (4)$$

where  $u_{\rho 0i}$  is the baseline cooperative control,  $\hat{d}_{\rho i}$  is the estimation of the uncertainties and disturbances.

#### A. Baseline cooperative control

In this subsection, a cooperative baseline control law is proposed for close formation flight of N UAVs where  $N > 2$ . The major expectation is to increase the scalability, efficiency, and robustness of close formation flight by introducing certain cooperative mechanism. In the cooperative control method, a virtual leader together is introduced to generate the reference signals for each vehicle. All the virtual leaders together defines the optimal formation shape (usually, "V-shape") for a group of N UAVs, as shown in Figure 4. A bidirectional communication topology is employed.

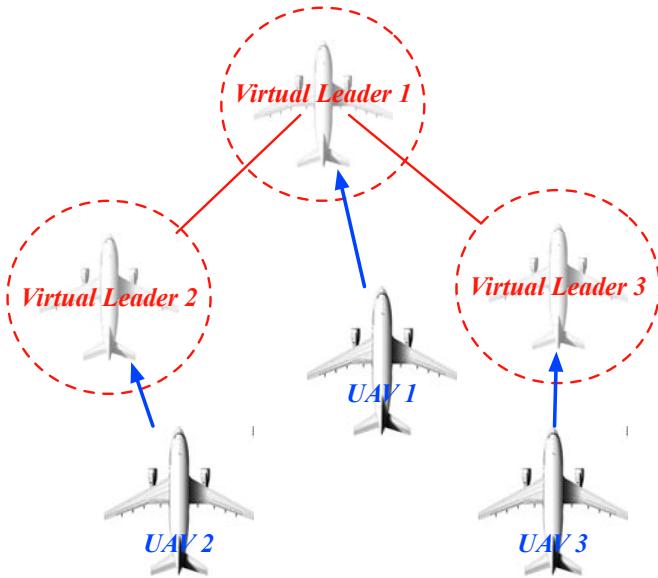

Figure 4 : Close formation organization

Define the position of each virtual leader as  $\vec{r}_i = \begin{bmatrix} r_{xi} & r_{yi} & r_{zi} \end{bmatrix}^T$ . Assume the 1<sup>st</sup> and 2<sup>nd</sup> of  $r_{xi}, r_{yi}$ , and  $r_{zi}$  are available. Define the position tracking error as  $e_{\rho i} = \rho_i - r_{\rho i}$ . The baseline cooperative control law for i-th UAV is

$$u_{\rho 0i} = \ddot{r}_{\rho i} - K_{P\rho} e_{\rho i} - K_{V\rho} \dot{e}_{\rho i} - \sum_{j \in \mathbb{N}_i} \left[ C_{P\rho} (e_{\rho i} - e_{\rho j}) + C_{V\rho} (\dot{e}_{\rho i} - \dot{e}_{\rho j}) \right]$$

where  $\rho \in \{x, y, z\}$ ,  $K_{P\rho}, K_{V\rho}, C_{P\rho}, C_{V\rho} > 0$ ,  $\mathbb{N}_i$  denotes the set of neighbors of i-th aircraft.

#### B. Uncertainty and disturbance estimator

The uncertainty and disturbance estimation term  $\hat{d}_{\rho i}$  is designed by applying (4) to (3).

$$\ddot{\rho}_i = u_{\rho 0i} - \hat{d}_{\rho i} + d_{\rho i} \quad (\rho \in \{x, y, z\}) \quad (5)$$

In terms of results in [],  $d_{\rho i}$  is estimated using a stable low-pass first-order filter  $G_{\rho i}(s)$ , where

$$G_{\rho i}(s) = \frac{1}{T_{\rho i}s + 1}$$

Hence,  $\hat{d}_{\rho i}$  is given by

$$\hat{d}_{\rho i} = \frac{1}{T_{\rho i}s + 1} d_{\rho i} \quad (6)$$

where  $T_{\rho i}$  is the time constant,  $d_{\rho i}$  is usually unavailable. However,  $d_{\rho i}$  is equal to  $\ddot{\rho}_i - u_{\rho 0i} + \hat{d}_{\rho i}$  according to Eq. (5). Replace  $d_{\rho i}$  by  $\ddot{\rho}_i - u_{\rho 0i} + \hat{d}_{\rho i}$  in (6). Via basic mathematical derivations, we can get

$$\hat{d}_{\rho i} = \frac{1}{T_{\rho i}s} (\ddot{\rho}_i - u_{\rho 0i}) \quad (7)$$

Specifying (7) in the time-domain will yield

$$\hat{d}_{\rho i} = \frac{1}{T_{\rho i}} \left( \dot{\rho}_i(t) - \dot{\rho}_i(0) - \int_0^t u_{\rho 0i} d\tau \right) \quad (8)$$

where  $\dot{\rho}_i(t)$  is a measurable speed signal which makes (8) always practically applicable.

#### IV. NUMERICAL SIMULATIONS

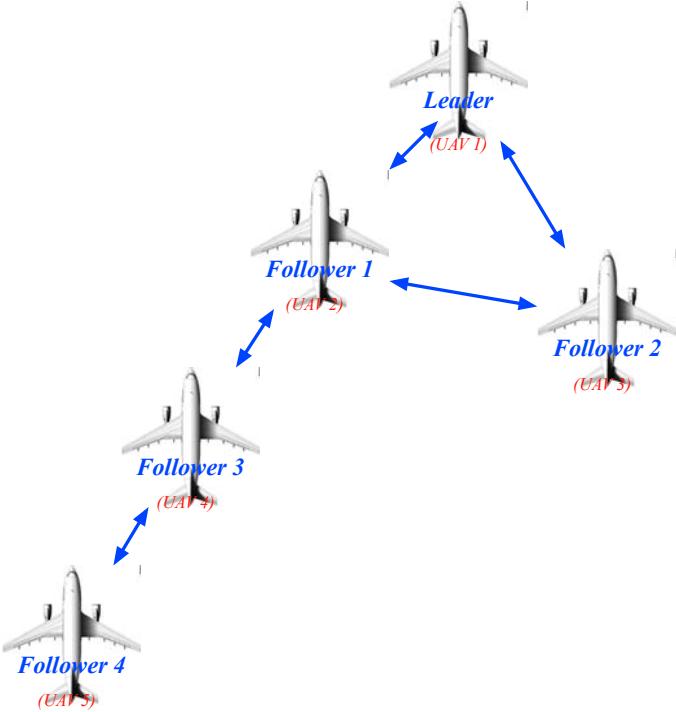

In the numerical simulations, close formation flight of 5 UAVs is considered. Among the 5 UAVs, one UAV performs as the very leader for the entire formation. This formation leader will be in charge of tracking the trajectory defined for the entire formation. The virtual leaders are defined according to the optimal relative position requirements to the formation leader. In the simulation results, the leader UAV for the entire formation is labelled to be "Leader", while the other UAVs are labelled to be "Follower 1", "Follower 2", "Follower 3", and "Follower 4", respectively. The control gains are

$$K_{Px} = K_{Py} = K_{Pz} = 1.5, \quad K_{Vx} = K_{Vy} = K_{Vz} = 3$$

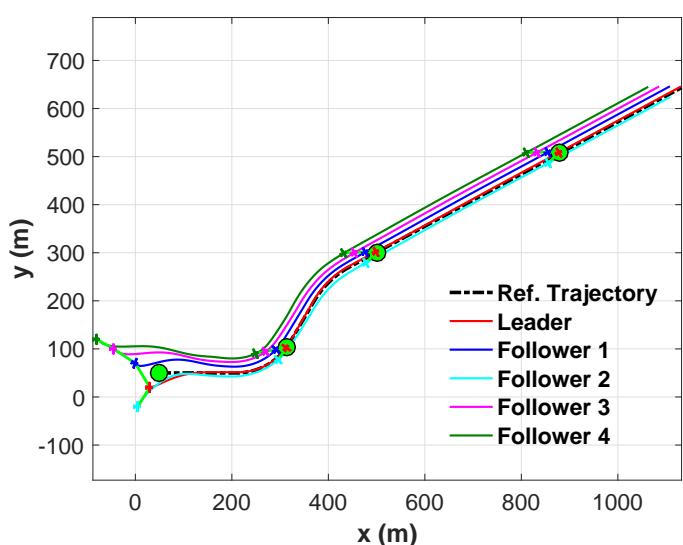

$$C_{Px} = C_{Py} = C_{Pz} = 1, \quad C_{Vx} = C_{Vy} = C_{Vz} = 2$$

$$T_x = T_y = T_z = 0.1$$

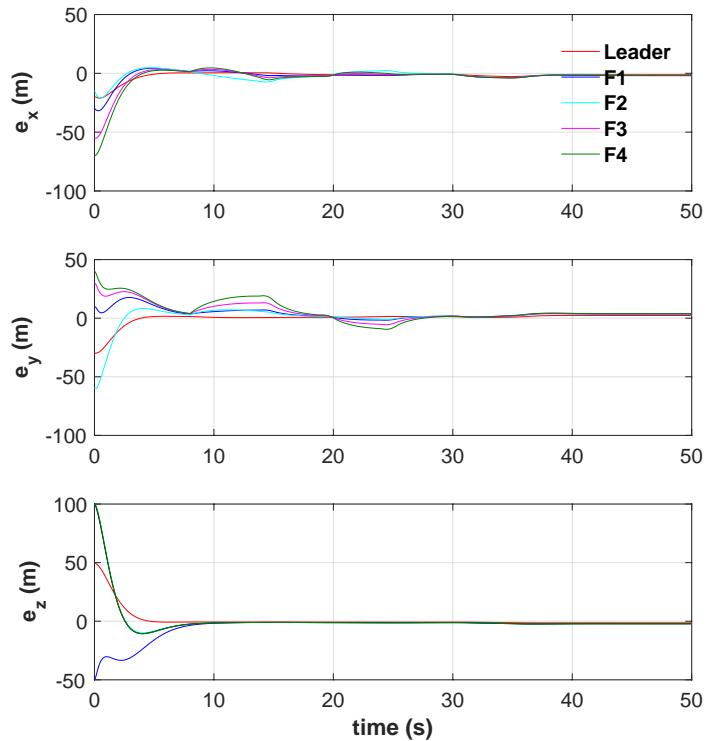

The communication topology of the five UAVs are shown in Figure 5. The formation trajectory tracking performance is shown in Figure 6 in which the 3-D trajectory is projected on a horizontal plane. Detailed tracking error responses are shown in Figure 7.

**Figure 5 : Communication Topology**

**Figure 6: Formation trajectory projection on a 2-D horizontal plane**

**Figure 7: Formation tracking error responses**

## V. CONCLUSION

This paper presents an efficient robust cooperative close formation control algorithms. Based on the proposed design, close formation flight can be easily extended to the case of more than three UAVs. The efficacy of the proposed design is verified via a close formation simulation of five UAVs.

**Abstract**—This paper presents mathematical modeling for thrust force and moments generated by a propeller. In particular, the effects of freestream on propeller's performance are investigated. We introduce some of the applications of the proposed model in modeling multi-rotor UAVs which helps to increase stability or maneuverability of the vehicle. In the end, simulation results for thrust force and moments of an example propeller in presence of a uniform freestream are presented.

**Keywords-component;** *propeller; aerodynamics; thrust force; unmanned aerial vehicles, freestream*

## I. INTRODUCTION (*HEADING 1*)

Multi-rotors have gained significant attention in recent years. Due to their simplicity and maneuverability, they have been used in a broad spectrum of applications such as bio-engineering [1], agronomy [2], sports [3] and inspection of infrastructures [4].

In modeling of UAVs, aerodynamic model of propellers plays an important role as it determines the majority of forces and moments in the system. Therefore, an accurate model for the propellers is crucial in analyzing such a system. In the literature, typically, the thrust force and moment generated by the propeller is assumed to be proportional to the square of its angular velocity and the effects of freestream on its performance is usually neglected by assuming small freestream velocities [5], [6], [7]. However, this model is not valid in high speed flight and its accuracy deteriorates as flight speed increases [8], [9].

The freestream may affect propeller's performance depending on its direction and magnitude. Generally, these effects could change propeller's performance in two ways: i) changing the effective angle of attack of the blades; and ii) changing the local airflow velocity over the blades. The former effect is caused when there is a freestream with its velocity vector parallel to the angular velocity vector of the propeller while the latter is caused by any freestream with its velocity vector perpendicular to the angular velocity vector of the propeller. Studying these effects not only helps us to derive a more realistic mathematical model for multi-rotors but also helps to find more stable and power-optimal configurations for

such vehicles. In this paper we use Blade Element Theory (BET) to calculate the thrust force and moment of each blade element.

The paper is organized as follows: Section II presents the effects of freestream on propeller's performance along with simulation results for thrust force and moments of an example propeller. Finally, the paper concludes in Section III followed by presenting some of the applications of the proposed model in multi-rotor UAV research.

## II. EFFECTS OF FREESTREAM ON PROPELLER'S PERFORMANCE

### A. Notation

The term  ${}^I\omega_p$  denotes that  $\omega$  belongs to  $p$  and is expressed in frame  $I$ . Angular velocity vector of the vehicle is represented by  $\omega_b = (p, q, r)^T$  where  $p$ ,  $q$  and  $r$  are roll, pitch and yaw rates respectively. Also, 2-Norm of  $\omega$  is represented by  $\|\omega\|$  and absolute value of  $s$  is shown by  $|s|$ .

### B. Effects of Freestream with Its Velocity Vector Perpendicular to Angular Velocity Vector of the Propeller

Suppose we have a propeller turning at angular velocity  $\omega_p$  as expressed in a frame attached to its COM as shown in Fig. 1. The propeller has two blades of radius  $R_b$  and is assumed to have constant chord  $c$ . For simplicity, first, we assume there is an almost uniform freestream with velocity vector  $V_{\infty_i}$ , as shown in blue in Fig. 1, which is parallel to the y-axis.

Consider a blade element (small hashed area in Fig. 2) of length  $c$  and differential width  $dr_b$  where  $r_b$  is the distance of the blade element from the root of the blade. As shown in Fig. 2, the rotation of the blade generates relative air flow velocity with magnitude  $r_b \|\omega_p\|$ , over each blade element. As the propeller is turning, the relative air flow velocity over the blade element could either be increased or decreased depending on the azimuth angle of the blade and direction of the freestream velocity. The azimuth angle  $\psi_p$  is defined as the angle between

the blade and the direction of  $V_{\infty_1}$ . Therefore, the resultant relative air flow velocity over each blade element can be written as:

$$v = r_b \|\omega_p\| + \|V_{\infty_1}\| \sin \psi_p \quad (1)$$

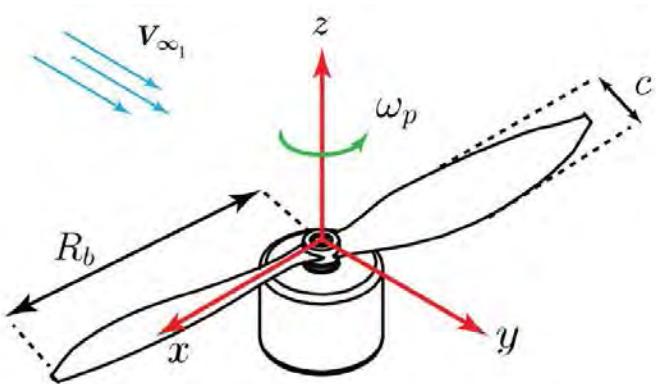

Figure 1: Schematic of a propeller with a frame attached to its COM.

It can be seen in Fig. 2, for the advancing blade ( $0 \leq \psi_p \leq \pi$ ), freestream velocity increases the relative air flow velocity over the blade and for the retreating blade ( $\pi \leq \psi_p \leq 2\pi$ ), it decreases the relative air flow velocity. The changes in the relative air flow velocity with azimuth angle affects the overall thrust of the propeller and it generates a moment in the direction of the freestream velocity as shown in blue.

Therefore, using (1) and according to *Blade Element Theory*, thrust force and moments of each blade element can be calculated as follows:

$$df_p = \frac{1}{2} \rho_a c C_L v^2 dr_b \quad (2)$$

$$d\tau_{dp} = \frac{1}{2} \rho_a c C_D v^2 r_b dr_b \quad (3)$$

$$d\tau_p = \frac{1}{2} \rho_a c C_L v^2 r_b \sin \psi_p dr_b \quad (4)$$

where  $\rho_a$  represents air density and  $C_L$  and  $C_D$  are the lift and drag coefficient of the airfoil of the blade respectively. Also,  $f_p$  represents thrust force of the blade element,  $\tau_{dp}$  represents the moment due to drag force of the blade element and  $\tau_p$  represents the moments due to change in thrust force with respect to the azimuth angle of the blade.

By integrating (2), (3) and (4) over blade radius  $r_b$  and azimuth angle  $\psi_p$ , average thrust force and the average moments for one blade as functions of freestream velocity and angular velocity of the propeller can be calculated as follows:

$$f_p = \frac{1}{2} \rho_a c C_L \left( \frac{2R_b^3}{3} \|\omega_p\|^2 + \|V_{\infty_1}\|^2 R_b \right) \quad (5)$$

$$\tau_{dp} = \frac{1}{4} \rho_a c C_D \left( R_b \|\omega_p\|^2 + \|V_{\infty_1}\|^2 R_b^2 \right) \quad (6)$$

$$\tau_p = \frac{1}{2} \rho_a c C_L R_b^3 \|\omega_p\| \|V_{\infty_1}\| \quad (7)$$

Note that by assuming zero freestream velocity, equations (5), (6) and (7) yield the simplified model for thrust force and moments of a propeller which is widely used in the literature (i.e., [3], [10], [11], [12]).

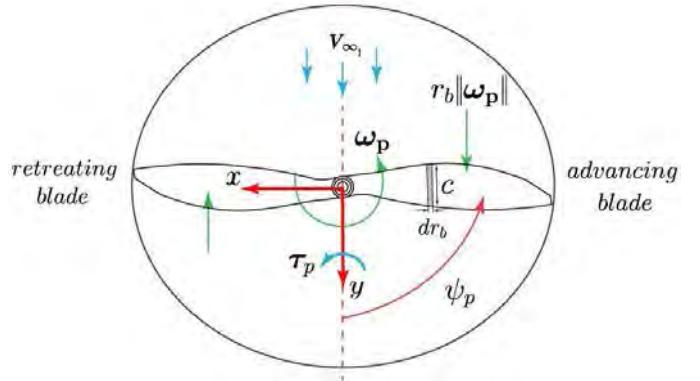

Figure 2: A propeller in presence of freestream.

Using the proposed model, simulation results for two complete turns of a propeller with angular velocity  $\|\omega_p\| = 900 \text{ rad/s}$  in presence of freestream velocity is presented in Fig. 3. Note that the direction of rotation and freestream velocity are the same as those in Fig. 2. The remaining parameters of the simulations are as follows:  $c = 0.03 \text{ m}$ ,  $C_L = 1.022$ ,  $C_D = 0.01$ ,  $R_b = 0.08 \text{ m}$  and  $\rho_a = 1.225 \text{ kg/m}^3$ . In Fig. 3, the top plot presents variations of thrust force with respect to blade azimuth. The red color represents the thrust force when  $\|V_{\infty_1}\| = 0$ , which is constant, meaning that the relative air flow velocity over the blade element is constant for all azimuth angles. The blue color, represents thrust force of the propeller as a function of azimuth angle when freestream velocity is nonzero,  $\|V_{\infty_1}\| = 10 \text{ m/s}$ . Comparing both scenarios, it can be seen that for nonzero freestream velocity and for  $0 \leq \psi_p \leq \pi$  thrust force is increased while for  $\pi \leq \psi_p \leq 2\pi$  it is decreased which is due to higher relative air flow velocities on the advancing blade than that over the retreating blade. The

yellow color shows the average of thrust force of the propeller when  $\|V_{\infty_1}\| = 10$  m/s. Results show that in presence of nonzero freestream velocity the average thrust force of the propeller increases.

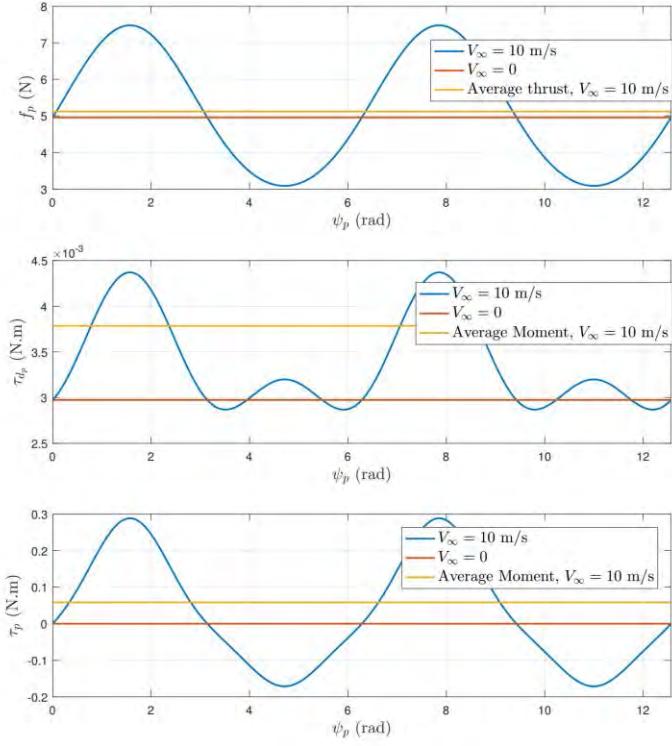

Figure 3: Simulation results for thrust force and moments of a propeller in presence of freestream.

The middle and bottom plots in Fig. 3 present variations of the moments due to drag and freestream ( $\tau_{d_p}$  and  $\tau_p$ ) versus azimuth angle respectively. The red color represents the moment when  $\|V_{\infty_1}\| = 0$  m/s, blue color represents variations of moment in presence of freestream velocity  $\|V_{\infty_1}\| = 10$  m/s and the yellow color represents the average moment of the propeller when  $\|V_{\infty_1}\| = 10$  m/s.

### C. Effects of Freestream with Its Velocity Vector in Parallel with Angular Velocity Vector of the Propeller

We continue investigating the effects of freestream on propeller's performance. However, as shown in Fig. 4, this time we assume the freestream velocity vector,  $V_{\infty_2}$ , is parallel to the angular velocity vector of the propeller,  $\omega_p$ , as expressed in the frame attached to it.

Suppose the propeller is turning at angular velocity  $\omega_p$  as shown in Fig. 5. In absence of freestream, there will be an airflow velocity vector  $r_b \omega_p$  over each blade element as shown in green. Also, for each blade element, the angle of attack (AOA)  $\Theta$  is defined as the angle between the chord of the blade element and the local airflow velocity vector  $r_b \omega_p$ .

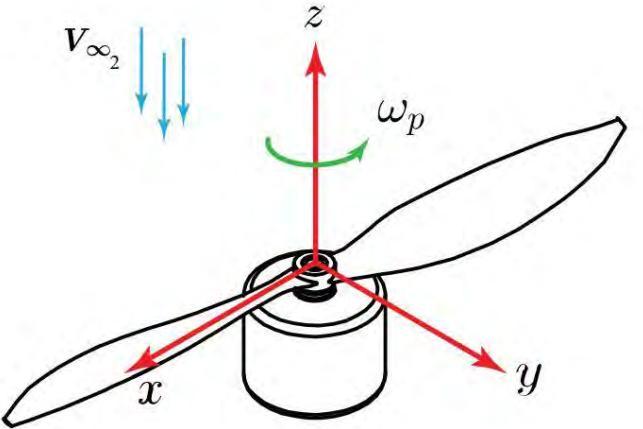

Figure 4: Propeller in presence of freestream. The freestream velocity vector  $V_{\infty_2}$  is assumed to be parallel with the angular velocity vector of the propeller  $\omega_p$ .

Now, consider an almost uniform freestream with velocity vector  $V_{\infty_2}$  in the positive direction of z-axis as shown in blue in Fig. 5 top. It can be seen that such a freestream changes the direction and magnitude of the resultant airflow velocity over the blade element as shown in red in Fig. 5 top. Therefore, the new angle of attack  $\Theta'$ , in presence of freestream is greater than that in absence of freestream ( $\Theta' \geq \Theta$ ).

However, if the freestream velocity vector is in the negative direction of z-axis (see Fig. 5 bottom), it changes the direction and magnitude of the resultant airflow velocity vector such that it decreases the effective angle of attack ( $\Theta' \leq \Theta$ ).

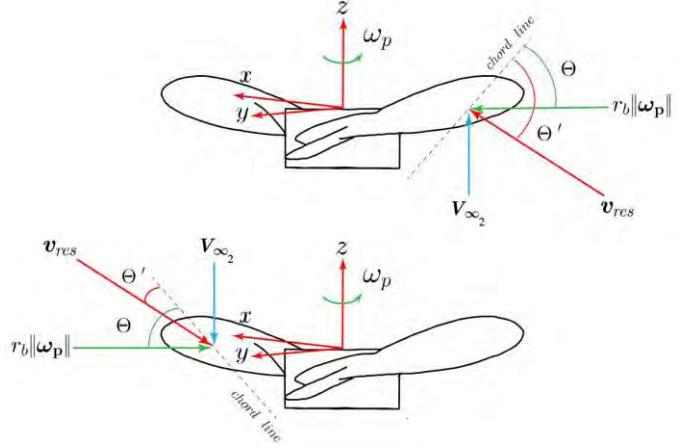

Figure 5: Propeller in presence of freestream. The freestream velocity vector  $V_{\infty_2}$  is assumed to be parallel with  $\omega_p$ . On top,  $V_{\infty_2}$  is the positive direction of z-axis and in bottom it is assumed to be in the opposite direction.

The importance of studying AOA is because it directly affects the lift coefficient of the blade element and consequently affects the thrust force generated by the propeller. At low speed flight (subsonic) and assuming small angles, the lift coefficient  $C_L$  changes almost linearly with AOA which can be written as follows [13]:

$$\frac{\Delta C_L}{\Delta \Theta} = \sigma \quad (8)$$

where  $\sigma$  is a constant which is determined through experiments in wind tunnel. From (2), we know that any increase (decrease) in  $C_L$  increases (decreases) the thrust force of the blade element. Therefore, one can summarize the results as follows:

- Any freestream with positive (negative) z-component velocity (expressed in the propeller's frame) increases (decreases) the AOA which increases (decreases) the thrust force.

Furthermore, to formulate the changes in thrust force of the propeller, first we can write the changes in AOA of each blade element as follows:

$$\Delta\Theta = \Theta - \Theta' = \arctan \frac{\|V_{\infty_2}\|}{\|r_b \omega_p\|} \quad (9)$$

Finally, using (2), (8) and (9), the changes in thrust force of the propeller can be written as follows:

$$\Delta f_p = \frac{1}{4} \rho_a c \sigma R_b^2 \|V_{\infty_2}\| \|\omega_p\| \quad (10)$$

From (10), it can be seen that the changes in thrust force is proportional to the magnitude of the freestream velocity vector  $V_{\infty_2}$ .

Table I presents the parameters involved in the modeling.

TABLE I. PROPELLER PARAMETERS

$\omega_p$	angular velocity vector of the propeller
$\Theta$	angle of attack
$C_L$ and $C_D$	lift and drag coefficients of the airfoil
$V_{\infty}$	freestream velocity vector
$\sigma$	slope of $C_L$ vs $C_D$ curve for the airfoil
$R_b$	blade radius of the propeller
$c$	chord of the blade
$\rho_a$	air density

### III. CONCLUSIONS

In summary, we presented the significance of the effects of freestream on performance of propellers. We formulated these effects as functions of propeller parameters and also the parameters of the freestream. Table I, presents all parameters involved in the proposed propeller model.

The proposed propeller model may be used in modeling multi-rotor UAVs. Such a model is used in quadcopters where it is shown that by tilting the rotors by a small angle as shown in Fig. 6, more stable or maneuverable configurations can be found [8]. The model is also used in modeling spinning-type multi-rotor UAVs to find optimal-power hover solutions. Fig. 7, presents a monospinner UAV with a single propeller where the spinning fuselage generates a freestream over the propeller [9].

For the future work, we plan to compare the proposed model with experimental results from experiments in wind tunnel for a particular propeller and investigate the accuracy and shortcomings of the model.

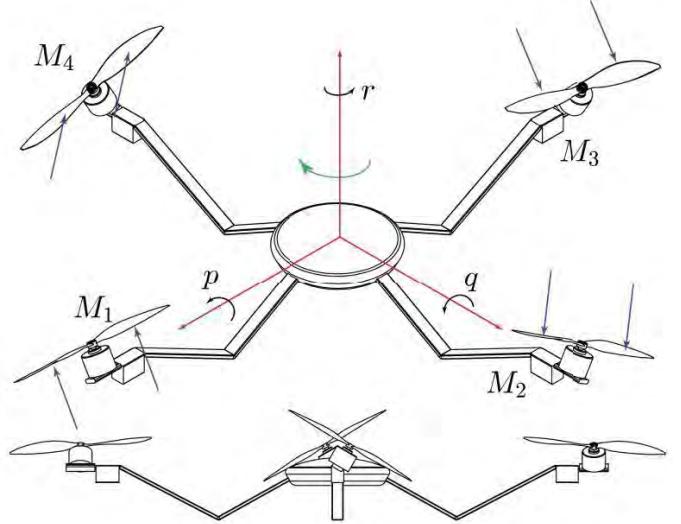

Figure 6: A quadcopter with tilted rotors. The blue arrows shows the direction of freestream velocity on each propeller as expressed in the body frame (red).

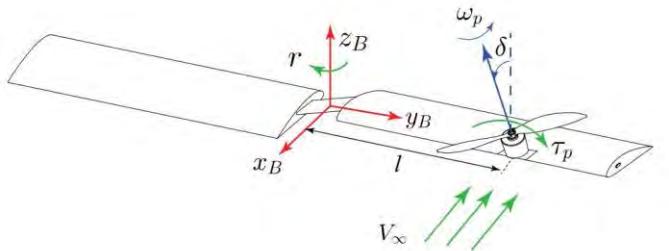

Figure 7: A monospinner UAV with tilted rotor. As the fuselage is spinning with yaw rate  $r$ , the propeller experiences a freestream, as shown in green.

**Abstract**— An experimental work has been conducted to investigate the ignition of n-heptane in the ignition quality tester (IQT™) by using fine gage thermocouples. A set of eight butt-welded exposed junction thermocouples (TCs) were inserted inside the chamber of IQT™ at different preselected locations to get the temperature variation spatially and temporally in the period prior to the fuel injection up to the mixture ignition. The data were recorded by using a high frequency data acquisition system with a sampling rate of 10 kHz per channel. The experimental data were characterized at set point temperature 584 °C and pressure 21.3 bar. For reproducibility purposes, 32 injections have been averaged and presented. A drop in temperature due to fuel spray cooling effects has been recorded by TCs at the chamber centerline whereas TCs near the chamber walls did not show a significant drop in temperature. Thus, there was no evidence that the fuel spray reached the chamber walls. The measurements showed that the combustion occurs in the main part of the chamber and the region near the fuel injector nozzle did not show a significant rise in temperature.

**Keywords-** heptane; combustion; injection; pressure; spray; thermocouple; temperature.

## I. INTRODUCTION

Diesel engines are more economical than gasoline engines but generate different toxic emissions (particulate matter, PM, in addition to elevated NOx, as well as CO, and hydrocarbons) in their exhaust gases, which present major risks on public health and environment. Extensive work has been conducted on combustion of diesel fuel and its influence on the performance of compression ignition engines [1]. Most studies discuss the measurement of the time interval between the start of fuel injection until the start of combustion which is called ignition delay (ID) period.

The ignition quality of diesel-like fuels is rated through their cetane number (CN) which is inversely proportional to the ID period. The Cooperative Fuel Research (CFR) test engine under designation number ASMT D613 [2] is commonly used to determine the CN of diesel fuels. Techniques which use

constant volume combustion chambers to analyze diesel ignition have been developed and the results have shown an excellent agreement with engines [3]. Therefore, three standard test methods [4] using constant volume combustion chambers have been developed to test diesel fuels and obtain their Ignition Delay (ID) or Derived Cetane Number (DCN). The Ignition Quality Tester (IQT™), the most precise device used to rate diesel fuels in the present [5], is one of these standards with designation number ASTM D6890.

Most of the experimental data involving the IQT™ are related to pressure measurements. There seems to be a void in temperature measurements, although temperature distributions inside the IQT™ during operation conditions have been obtained numerically [6, 7]. The present work aims to analyze n-heptane spray behavior and combustion in the IQT™ through temperature measurements by using multiple fine gage thermocouples located throughout the combustion chamber. These measurements have the potential to identify the regions within the chamber where fuel vaporization takes place and combustion is initiated.

## II. EXPERIMENTAL SETUP

### A. Ignition Quality Tester (IQT™) Overview and Setting

The IQT™ has been developed and automated by Advanced Engine Technology Ltd. (AET) [8] to make it a precise and accurate system for oil industry, research and regulatory applications [9, 10]. It is a bench-scale device which is mainly utilized to determine the ignition quality of diesel and alternative diesel fuels. It is comprised of a constant volume combustion chamber with intake/exhaust systems, a fuel injection system, temperature/pressure sensors and a data-acquisition system. Detailed information on the IQT™ can be found in [4].

There are six ports and holes on the walls of the IQT™ chamber as shown in Figure 1: nozzle body port on one end of the chamber, pressure transducer port on the other end, air inlet valve, exhaust outlet valve, and front & back thermocouple

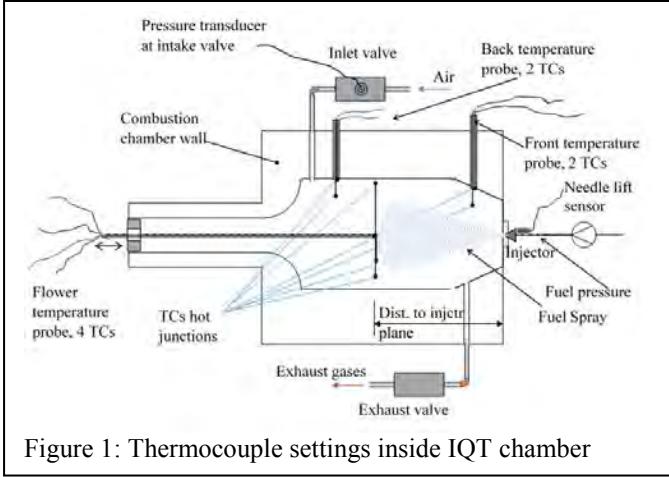

Figure 1: Thermocouple settings inside IQT chamber

holes. Nine electrical heaters of cartridge-type are embedded in the chamber walls and are used to heat chamber walls up to approximately  $600^{\circ}\text{C}$ . The combustion chamber is a cavity of cylindrical and conical shapes with total volume of  $0.213\pm 0.002$  liters. The charge-air gains the heat from the hot walls of the chamber. Both ends of the IQT™ chamber are maintained at a lower temperature compared to the temperature of main portion of the chamber to protect sensors located at the extremities.

The fuel is injected into the chamber as a hollow spray cone from an inward opening single-hole pintle-type nozzle. The spray characteristics from this nozzle design and others are well studied [11]. The nozzle needle starts to lift and the fuel is injected when the pressure of the liquid fuel line behind the nozzle reaches 17.92 MPa. The main injection duration lasts for approximately 2 ms [12].

#### B. Temperature Measurement Settings

Only three out of the six ports on chamber wall could be used to install temperature probes that would protrude into the chamber: front and back TC ports and pressure transducer port. An 1/8 inch probe with two TCs could be used with either front or back TC ports because those ports are already fitted for 1/8 inch temperature probes and they did not require any modifications.

Slight modifications have been made on the IQT™ chamber to allow adjustment of the axial temperature probe. The port of the pressure transducer was used to insert a probe with 4 TCs, which was named “flower” temperature probe (FTP). The coolant adapter of the pressure sensor was modified to accommodate 3/16 inch diameter probe. The pressure sensor was moved with its housing and fitted to the intake valve port. The data from the pressure sensor at the new location was verified against the standard location, showing adequate fidelity. Thus, a total of 8 TCs (2 at the front port, 2 at the back port, and 4 through the pressure transducer port) were fitted inside and near the wall of the combustion chamber as shown in Figure 1.

#### C. Thermocouple Selection and Temperature Probe Fabrication.

A robust temperature probe was required in order to withstand the harsh combustion environment presented by the high temperature, pressure and turbulence, and to track and record the instantaneous temperature variation. Thermocouples (TC) were selected for the present measurements due to their relative robustness, response time, and wide temperature range of operation [13, 14] compared to other temperature sensors.

Thermocouple of type K has been selected to be used in all experiments due to its high sensitivity ( $41 \mu\text{V/C}$ ) and availability [13].

Three sizes of TC wires (0.003", 0.005", and 0.010" of a butt welded hot junction end) were tested to achieve a compromise between response and durability. Although they exhibited good transient response, the 0.003" and 0.005" TCs did not withstand the harsh environment. They were damaged during warming-up time of the combustion chamber or at mid combustion. The 0.010" TC had a very good transient response to the temperature variations especially at discriminatory points (Start Of Injection (SOI) and Start Of Combustion (SOC)). Thus, 0.010" butt welded TC wires of type K from Omega were adopted for temperature measurements.

Based on the dimensions of the front and back TC ports and pressure transducer port, two sizes (1/8" and 3/16") of stainless steel sheath tubes were used to encase the temperature probes. An alumina ceramic insulator rod was used around the TCs before insertion of the probe into the sheath tubes [15]. The 1/8" probe contains two thermocouples and the 3/16" probe contains four thermocouples. Each thermocouple required two holes in the ceramic insulator rod. A maximum of 4 holes (2 TCs) and 8 holes could be created on the face of a 2.5 mm and 3.2 mm diameter ceramic rods, respectively.

#### D. Connections and Data logging

Tests were conducted in the laboratory at the AET facilities. All sensors were fitted to the chamber and connected to the data logger before the test as shown in Figure 2. Two temperature probes with 2 TCs each were fitted in the front and back TC ports. The flower temperature probe (FTP) with 4 TCs was inserted into the chamber from the pressure transducer port through a bored coolant adapter. All the TC wires of the hot junction side of the FTP were kept straight in the axial direction at first. Then, they were bent inside the chamber by  $90^{\circ}$  to be distributed radially (see Figure 1). TCs wires were bent manually by getting access to them from the injector nozzle side. For sealing purposes, a reusable Teflon ferrule was used with the stainless steel compression fittings to allow the FTP to be traversed inside the chamber.

All the sensors are connected to a laptop through a data acquisition system from Omega of model OMB-DAQ-3005. DAQ software (Daq view) settings are adjusted to synchronize the feedback from the sensors. The data were collected for the period beginning 10 ms before needle lift until the end of combustion, with a sampling interval of 0.1ms. The recorded

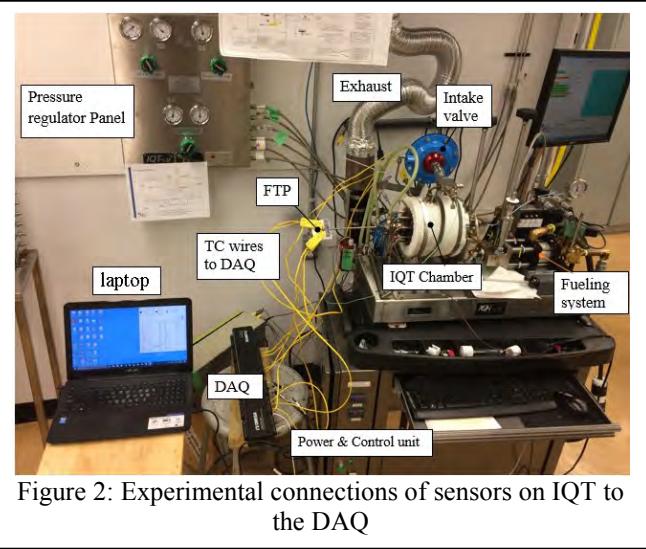

Figure 2: Experimental connections of sensors on IQT to the DAQ

data sets for all injections were saved automatically into the pre-selected file names. A Matlab code was created to analyze and present the collected data. The data of 32 test injections were low-pass filtered first and then the mean values were calculated for temperatures, pressure and needle lift as shown in the following figures below.

#### E. Points of Temperature Measurements

Temperature variations were captured at 20 different locations inside the IQT™ chamber as shown in Figure 3. The front or back TCs locations are: first TC was at the wall chamber plane, and the second TC was 8 mm from the wall in a radial direction. The 4 TCs of the FTP were distributed radially as follows: the first TC was at chamber centerline ( $r=0\text{mm}$ ), the second TC was 12 mm from center, the third was 18mm from center, and the fourth was 25mm from the center which is almost on the wall.

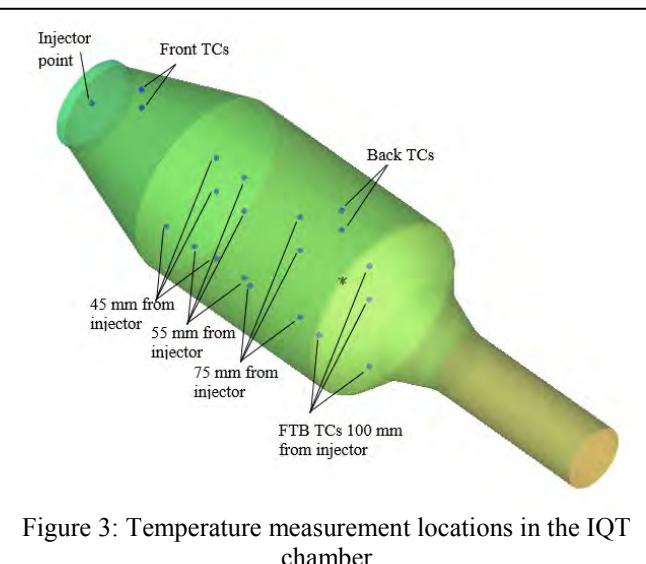

Figure 3: Temperature measurement locations in the IQT chamber

### III. RESULTS AND DISCUSSION

The IQT™ was calibrated first and the test conditions were  $584^\circ\text{C}$  for set point, 310 psi (21.3 bar) for charge air pressure and 0.8231 grams per 10 injections of heptane. Four runs on heptane were conducted at four different axial locations of the FTP, where the distances from the probe plane to the injector were 100, 75, 55, and 45 mm as shown in Figure 3. The three main parameters: nozzle needle position, combustion chamber pressure and spatial gas temperature are collected from needle lift sensor, pressure transducer (mounted in a new position) and TC probes, respectively.

#### A. Needle lift and Chamber Pressure

The nozzle needle lift position and the chamber pressure traces for 32 individual injections, along with their mean value trace (thick line) are presented in Figures 4 & 5, respectively. The ignition delay period begins when the needle lift signal begins to rise. All injections have the same starting point and the peak of needle lift is around 0.6mm. The main injection duration lasts in about 2 ms.

The chamber pressure (Figure 5) initially drops slightly due to cooling effects of evaporating spray. The required time for atomization, vaporization, mixing and heating of the injected fuel is called physical ignition delay period. During this period, the pressure and temperature inside the chamber decrease. This period is followed by a sudden increase in pressure and temperature due to heat released from the chemical reaction.

#### B. Temperature measurement results

The temperature variation at two locations were selected to be presented in this section: chamber centerline at a plane 55 mm from injector, and back port at chamber wall.

The time history of the gas temperature measured by FTP for 32 injections is given in Figure 6. The temperature drops initially due to the evaporation of the spray (as mentioned earlier), then the combustion will take place. The maximum temperature measured by FTP was around  $1300^\circ\text{C}$ . Notice the strong scatter of the temperature measurements from 25 to 500 ms, indicating significantly different combustion processes for each injection during this interval. Nevertheless, the onset of

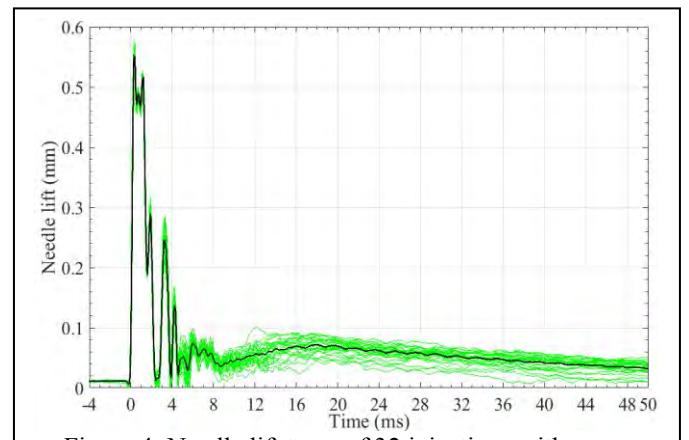

Figure 4: Needle lift trace of 32 injections with mean

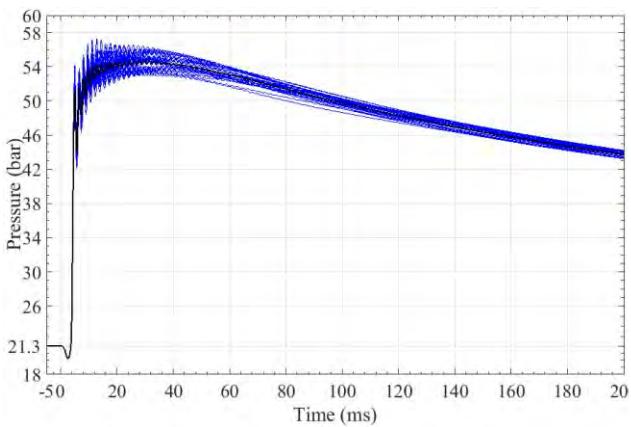

Figure 5: Chamber pressure trace of 32 injections with mean value

combustion (the region of interest from 0 to 5 ms) shows high reproducibility.

Temperature profiles at back port of chamber (Figure 7) are slightly different to that at the main part of the chamber (Figure 6). There was no drop in temperature recorded after fuel injection and before the sudden increase in temperature. In this case, a maximum temperature around 850 °C was recorded. The peak temperature at chamber wall, (Figure 7) continues for a very short period of time and then drops.

### C. Mean Temperature, Pressure and Needle lift Results at ID Period

To observe clearly temperature variation with pressure during the ID period, the mean values of 32 low pass filtered test injections are presented for the time prior to the fuel injection up to the fuel's IOC as shown in Figures 8 and 9. Three parameters (temperature, pressure and needle lift) are shown on the each figure.

Figure 8 gives temperature variations in four locations along the chamber centerline. The temperature of pressurized air prior to the fuel injection at locations 3 and 4 is higher than that at locations 1 and 2 by almost 10 °C and it drops when the released

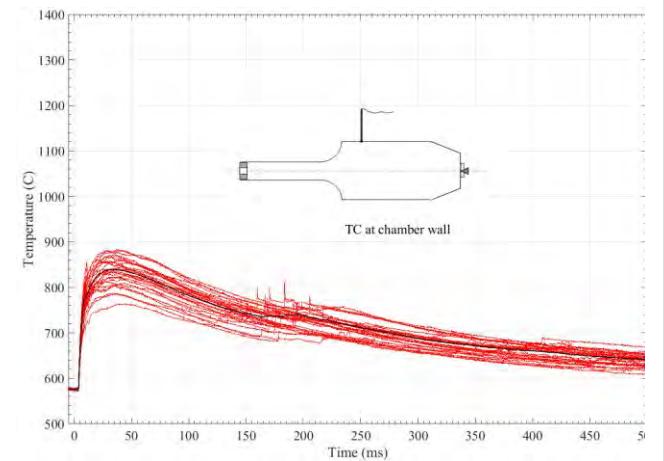

Figure 7: Temperature variation of 32 test injections with mean value at chamber wall, back port

spray from injector nozzle reaches the thermocouples. All four curves have shown a drop in temperature for various periods and are followed by that a sudden increase in temperature. The drop in temperature was due to the high vaporization rate of the fuel, which absorbs heat during that time. The starting point of that drop in temperature depends on the location of the thermocouple. Thus, the closest TC (line 4) to the injector nozzle sensed the spray first after SOI by 0.5ms whereas the farthest one (line 1) sensed the spray after almost 1.25 ms from SOI. The lowest temperature was measured at location 2. The rate of change in temperature ( $dT/dt$ ) in the rear part of the chamber (locations 1 and 2) was close to zero (temperature does not change with time) and remains at lowest point for a while (0.5 – 0.8 ms) before the sharp rapid increase which gives an indication of the IOC at that location. After that, the rate of increase in  $dT/dt$  is almost the same for all locations.

The results from the standard front and back TC locations of the IQT™ (at the wall and 8 mm from the wall) are presented

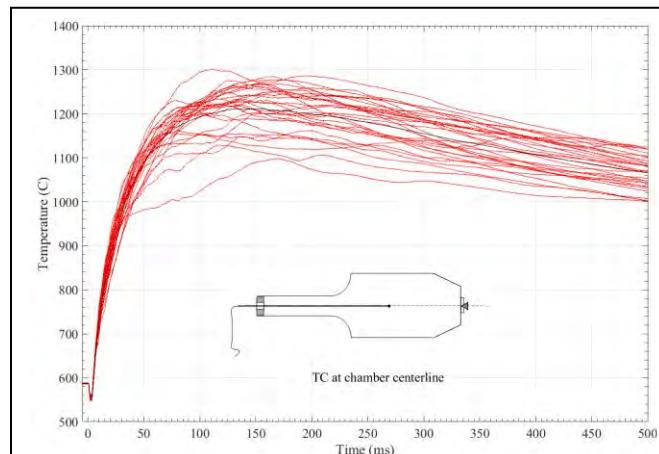

Figure 6: Temperature variation of 32 test injections with mean value from FTP

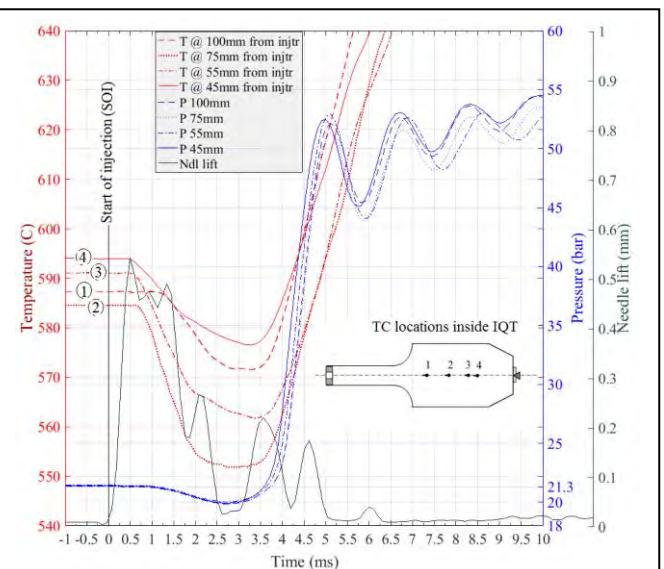

Figure 8: Temperature variation with time at chamber centerline with different locations from injector plane

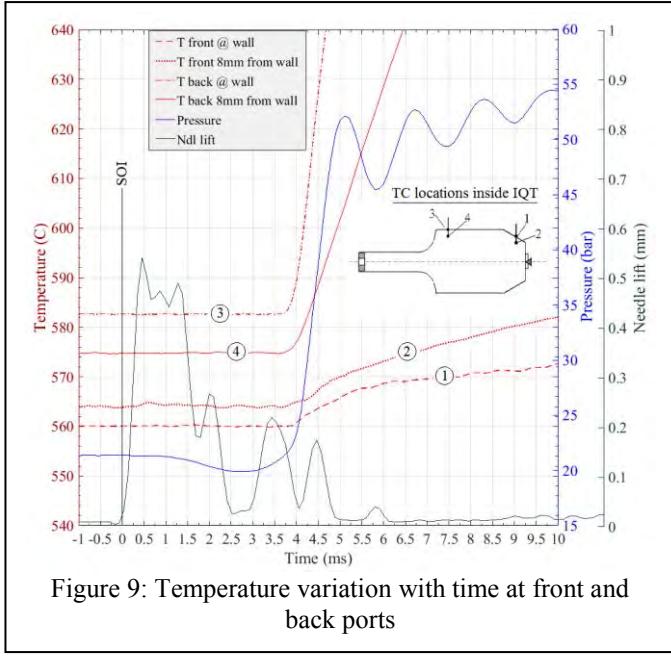

Figure 9: Temperature variation with time at front and back ports

in the Figure 9. None of these TC locations recorded a drop in temperature during the period between SOI and SOC. The temperatures at the front TC location showed only a minor increase after IOC whereas a sudden increase in temperature was measured from front port TCs. For the sake of conciseness, additional data at different locations are not shown here.

#### IV. CONCLUSIONS

Fine gage, exposed junction thermocouples were successfully used to trace temperature variations at twenty different locations in the combustion chamber of an ignition quality tester. The significant drop (about 30 °C) in temperature due to an evaporative cooling effect of the fuel spray was recorded at the region of chamber centerline. On the other hand, no evidence of cooling by fuel spray droplets was observed in measurements at and near the chamber walls, where only sudden rise in temperature (due to combustion) was recorded. These results indicate that fuel spray vaporization in the IQT™ takes place in the compressed, heated air within the combustion chamber rather than through contact with the hot chamber walls.

# A new mechanical band pass filter design for energy harvesting

Alireza Keshmiri, Nan Wu

Department of Mechanical Engineering

University of Manitoba

Winnipeg, Canada

[keshmira@myumanitoba.ca](mailto:keshmira@myumanitoba.ca), [Nan.Wu@umanitoba.ca](mailto:Nan.Wu@umanitoba.ca)

**Abstract**— This work presents an analytical methodology for development of a mechanical band pass filter for energy scavenging. The model is based on Adomian decomposition method to derive the dynamic response of the non-uniform smart structure with strain rate damping to external environmental excitations and efficiently harvest the subsequent vibrational energy. The steady state response of the nonlinearly tapered cantilever beam subjected to a harmonic base motion is obtained and electromechanical outputs in open circuit condition are analytically derived. In order to design a band pass filter, an array of cantilever beams with nonlinear geometry and surface bonded piezoelectric layers are considered. Therefore, the filter can choose one harvester to resonate at one particular ambient vibration frequency and reach the maximum electromechanical output. Compared with uniform beam design, it is also demonstrated that the proposed non-uniform configuration can generate higher electrical output over a wide frequency range.

**Keywords**— Band pass filter; Piezoelectric energy harvesting; Non-uniform structure; Adomian decomposition method.

## I. INTRODUCTION

Energy harvesting from ambient energy sources has become a dynamic research field and received so much attention in recent years because of huge number of applications. With decreasing electrical power requirements in wireless electronics and increasing utilization of sensors in different structures, energy harvesting to power sensors at the location without batteries limitations is appealing for various engineering automation and monitoring systems. Therefore, energy harvesters are designed to convert the environment energies into usable power form to supply the small wireless sensor systems throughout the sensor lifetime.

Alternatively, energy scavenging based on vibration is becoming more attractive. Conversion of mechanical vibration energy into electrical energy can be achieved through three conversion mechanisms: electrostatic, electromagnetic, and piezoelectric [1]. The small size, custom shape fabrication ability and high power conversion potential are the key and fundamental advantages of piezoelectric approach for vibration energy harvesting [2]. Even a small external excitation leads to

considerable amount of generated voltage without requiring any low-efficient initiation mechanical mechanism [3].

The most common energy harvester design is the cantilever beam with surface bonded piezoelectric layers transversely vibrating because of the base excitation. Although it is not essentially the best design in terms of output energy, it is well-known because of its simple and cost-efficient configuration. Furthermore, most of piezoelectric energy harvesters work on the resonance mechanism to raise the strain distribution in the piezoelectric layer and eventually increase the output electrical power. Due to the small size factor, resonance frequency of the harvester increases and makes it undesirable for low frequency vibrations. The common response to this problem is adding a proof mass at the free end [4,5]. But, this optimal resonance condition is not given in most of the environmental cases with variable vibration conditions. Given this, having a single harvester design capable of operating over a range of vibration frequencies would be desirable. Additionally, refining the geometry of the scavenger is itself a major improvement area. A trapezoidal profile can distribute the strain evenly such that maximum strain is obtained at every point in the piezoelectric energy harvester. A harvester with trapezoidal geometry can generate more than twice energy than a harvester with rectangular shape [6].

One of the biggest disadvantages of common vibration energy harvesters is the very limited practical bandwidths over which energy can be scavenged. In order to increase the frequency range of vibration energy harvesters, two approaches of tuning the resonant frequency and widening the bandwidth are suggested in the literature [7]. Based on the widen bandwidth methodology, the operational frequency range of the vibration energy generator can be extended by using an array of harvesters with different natural frequencies. In other words, the piezoelectric energy harvester should have appropriate bandwidth in the range of peak-power frequencies of the ambient vibrations. This frequency range can be easily measured in different environments. Such a device with this particular characteristic can be called a piezoelectric band pass filter [5].

The work presented in this research endeavors to challenge previous energy harvesting designs and fabricate a novel and advanced energy harvester system that possesses enough bandwidth in the range of ambient vibration frequencies. The model developed in this paper has included nonlinear geometry

rather than a simple uniform pattern. The dynamic steady state solution of the harmonic base excitation problem for lateral vibration of the non-uniform smart structure with strain rate damping is presented and electromechanical outputs of the piezoelectric patches in open circuit condition are analytically derived. The mathematical process is based on Adomian decomposition method (ADM) and the mechanical model is applicable to any slender beam which allows neglecting shear deformation and rotatory inertia effects. Finally, it is demonstrated that such an arrangement of non-uniform cantilever piezoelectric coupled beams can be made into a band pass filter when the dimensions are selected properly.

## II. THEORETICAL MODEL

The proposed bimorph piezoelectric energy harvester configuration consists of a nonlinearly tapered cantilever beam with piezoelectric patches bonded on the top and bottom surfaces, Fig. 1. The geometry of the structure is described by  $L$  length of the beam,  $2b_0$  width of the beam at the fixed end,  $2h_0$  thickness of the beam at the fixed end,  $L_p$  the piezoelectric patch length and  $h_p$  thickness of the piezoelectric layer. The energy harvesting efficiency of the piezoelectric coupled cantilever beam can be investigated by setting the mechanical vibration input for the system in the form of  $f(t)=Ye^{j\omega t}$  where  $Y$  is the amplitude of the base displacement,  $\varphi$  is the angular frequency of the vibration and  $j$  is the unit imaginary number. The differential equation that describes the forced lateral vibration of a smart beam with non-uniform geometry and structural strain rate damping can be expressed by,

$$\rho A(x) \frac{\partial^2 w(x,t)}{\partial t^2} + \frac{\partial^2}{\partial x^2} EI(x) \frac{\partial^2 w(x,t)}{\partial x^2} + C_s I(x) \frac{\partial^3 w(x,t)}{\partial x^2 \partial t} = -\rho A(x) \phi^2 Y e^{j\omega t} \quad (1)$$

where  $x$  is position variable along length of the beam,  $t$  is time variable,  $\rho$  is the equivalent mass density,  $A(x)$  is cross-sectional area,  $w(x,t)$  is the deflection function,  $E$  is the equivalent elasticity modulus,  $I(x)$  is the second moment of area and  $C_s$  is the strain-rate damping coefficient. Moreover, boundary conditions for the non-uniform cantilever beam are defined as,

$$\begin{aligned} [w(x,t)]_{x=0} &= 0, \left[ \frac{\partial w(x,t)}{\partial x} \right]_{x=0} = 0, \\ \left[ EI(x) \frac{\partial^2 w(x,t)}{\partial x^2} \right]_{x=L} &+ C_s I(x) \frac{\partial w(x,t)}{\partial x} \Big|_{x=L} = 0, \\ \left[ \frac{\partial}{\partial x} \left( EI(x) \frac{\partial^2 w(x,t)}{\partial x^2} \right) \right]_{x=L} &+ C_s I(x) \frac{\partial^2 w(x,t)}{\partial x^2} \Big|_{x=L} = 0. \end{aligned} \quad (2)$$

Using the normal mode approach, the solution of Eq. (1) is assumed to be a linear combination of the normal modes of the beam denoted by a convergent series as,

$$w(x,t) = \sum_{i=1}^{\infty} X_i(x) T_i(t), \quad (3)$$

where  $X_i(x)$  are mass normalized modes and  $T_i(t)$  are modal participation coefficients for the  $i$ th vibration mode. Since the system is proportionally damped, eigenfunctions represented by  $X_i(x)$  are normal mode eigenfunctions of the corresponding undamped free vibration problem [8,9].

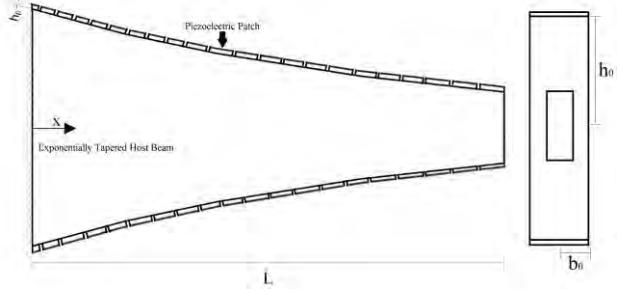

Figure 1. A nonlinearly tapered cantilever beam with piezoelectric patches mounted on its surface, side and front views.

Consequently, normal modes can be calculated by solving,

$$EI(x) \frac{d^4 X_i(x)}{dx^4} + 2E \frac{dI(x)}{dx} \frac{d^3 X_i(x)}{dx^3} + E \frac{d^2 I(x)}{dx^2} \frac{d^2 X_i(x)}{dx^2} - \omega_i^2 \rho A(x) X_i(x) = 0 \quad (4)$$

where  $\omega_i^2$  are the undamped natural frequencies of the structure.

In order to solve the Eq. (4), ADM is used. The solution obtained by ADM is an infinite series; an  $n$ -term approximation usually serves as a practical solution. Since the methodology itself is not the main focus of this research and it is perfectly addressed in [10,11], more details will not be discussed here. Hence, by applying ADM, solution of Eq. (4) which is the mode shape function in the recurrence format can be expressed as,

$$\left. \begin{aligned} X_i(x) &= \sum_k^{\infty} X_{k_i}(x) = X_0 - L_x^{-1} \left[ \frac{dI(x)}{I(x)} \sum_{k=0}^{\infty} \frac{d^3 X_{k_i}(x)}{dx^3} \right] \\ &\quad + \frac{d^2 I(x)}{I(x)} \sum_{k=0}^{\infty} \frac{d^2 X_{k_i}(x)}{dx^2} \\ &\quad - \omega_i^2 \frac{\rho}{EI(x)} \sum_{k=0}^{\infty} X_{k_i}(x) \end{aligned} \right\} \quad (5)$$

where the inverse operator  $L_x^{-1}$  is a four fold integration with respect to  $x$ . Additionally,  $X_0 = C_1 + C_2 x + C_3 x^2/2! + C_4 x^3/3!$  and  $C_1$  to  $C_4$  are constants which can be evaluated from the system boundary conditions. Thus, all  $X_k$  components are evaluated and the mode shape function is obtained. As many terms as required to obtain a more accurate shape function can be considered.

Clearly, normal mode eigenfunctions satisfy the orthogonality conditions,

$$\int_{x=0}^L \rho A(x) X_m(x) X_n(x) dx = \begin{cases} 1 \rightarrow m = n \\ 0 \rightarrow m \neq n \end{cases}, \quad (6)$$

$$\int_{x=0}^L \frac{d^2}{dx^2} \left[ EI(x) \frac{d^2 X_m(x)}{dx^2} \right] X_n(x) dx = \begin{cases} \omega_m^2 \rightarrow m = n \\ 0 \rightarrow m \neq n \end{cases}.$$

Therefore, the modal participation coefficients  $T_i(t)$  are the solution of the ordinary differential equation,

$$\frac{d^2T_i(t)}{dt^2} + 2\xi_i\omega_i \frac{dT_i(t)}{dt} + \omega_i^2 T_i(t) = Q_i(t) = \rho\phi^2 Y \left[ \int_0^L X_i(x) A(x) dx \right] e^{j\phi t}, \quad (7)$$

where  $2\xi_i\omega_i = C_s\omega_i^2/E$  and  $\xi_i$  is the structural strain-rate damping ratio of  $i$ th vibration mode. Finally, the modal response can be obtained by Duhamel integral,

$$T_i(t) = \frac{1}{\omega_{di}} \int_0^t Q_i(\tau) e^{-\xi_i\omega_i(t-\tau)} \sin \omega_{di}(t-\tau) d\tau, \quad (8)$$

where  $\omega_{di} = \omega_i [1 - \xi_i^2]^{0.5}$  is the  $i$ th mode damped natural frequency. However, the steady state solution of Eq. (7) can be expressed as,

$$T_i(t) = \frac{\rho\phi^2 Y \int_0^L X_i(x) A(x) dx}{\omega_i^2 - \phi^2 - j2\xi_i\omega_i\phi} e^{j\phi t}. \quad (9)$$

As a result, normal mode eigenfunctions given by Eq. (5) and modal participation coefficients obtained by Eq. (9) can be used in Eq. (3) to represent the dynamic steady state response of the smart structure relative to its base as,

$$w(x, t) = \sum_{i=1}^{\infty} X_i(x) T_i(t) = \sum_{i=1}^{\infty} X_i(x) \frac{\rho\phi^2 Y \int_0^L X_i(x) A(x) dx}{\omega_i^2 - \phi^2 + j2\xi_i\omega_i\phi} e^{j\phi t}. \quad (10)$$

In order to obtain the electrical outputs of the piezoelectric energy harvester, the following piezoelectric constitutive equation is considered,

$$D_3(x, t) = d_{31}\sigma_1(x, t) + e_{33}^\sigma E_3(t), \quad (11)$$

where  $D_3$  is the electrical displacement,  $d_{31}$  (Coulomb/N or m/V) is the piezoelectric coefficient with polarization in direction 3 due to the external stress in direction 1,  $\sigma_1$  is the axial stress along 1-axis,  $e_{33}^\sigma$  is the permittivity at constant stress and  $E_3$  is the electrical field along 3-axis [12]. It should be noted that 1, 2 and 3 directions are aligned with  $x$ ,  $y$  and  $z$  axes, respectively.

By replacing the axial stress  $\sigma_1$  with bending strain  $\varepsilon_1$  and knowing that there is no applied electric field on the piezoelectric patch  $E_3(t)=0$ , Eq. (11) can be rewritten as,

$$D_3(x, t) = d_{31}E_p \varepsilon_1(x, t), \quad (12)$$

where  $E_p$  is the piezoelectric elasticity modulus and  $V(t)$  is the electric voltage over the piezoelectric area. Furthermore, the longitudinal bending strain  $\varepsilon_1(x, t)$  in the structure can be calculated as,

$$\varepsilon_1(x, t) = -h_c \frac{w(x, t)}{\left( h(x) + \frac{h_p}{2} \right) \frac{\partial^2 w(x, t)}{\partial x^2}}, \quad (13)$$

where  $h_c$  is the distance between center of the piezoelectric layer and the beam's neutral axis and  $\frac{\partial^2 w(x, t)}{\partial x^2}$  is the curvature of the structure. Consequently, the electric displacement becomes,

$$D_3(x, t) = -d_{31}E_p \left( h(x) + \frac{h_p}{2} \right) \frac{\partial^2 w(x, t)}{\partial x^2}. \quad (14)$$

The electric displacement  $D_3(x, t)$  is related to the output electric charge  $q(t)$  by integration over the electrode area. Since the vibration mode of the energy harvester is not restricted to the first mode, segmented piezoelectric patches and electrodes in order to harvest the maximum output charge are utilized. This is due to the fact that using continuous electrodes results in phase difference in the strain distribution which leads to charge cancellation [8].

$$q(t) = -\sum_{k=1}^{N_p} \int_{x=(k-1)L_p}^{kL_p} d_{31}E_p b(x) \left( h(x) + \frac{h_p}{2} \right) \frac{\partial^2 w(x, t)}{\partial x^2} dx, \quad (15)$$

where  $N_p$  is the total number of piezoelectric patches mounted on the surface of the beam and obviously  $N_p L_p = L$ .

The generated voltage  $v(t)$  can be calculated by dividing the produced electric charge to the capacitance as,

$$v(t) = \frac{q(t)}{C_p} = -\frac{d_{31}E_p}{C_p} \sum_{k=1}^{N_p} \left\{ \int_{(k-1)L_p}^{kL_p} b(x) \left( h(x) + \frac{h_p}{2} \right) \frac{\partial^2 w(x, t)}{\partial x^2} dx \right\}, \quad (16)$$

where  $C_p = e_{33}^\sigma L b_0 / h_p$  is the capacitance of the piezoelectric layer.

The goal of this research is to estimate the open circuit voltage across the piezoelectric layers. So the backward coupling in the relations is ignored. Finally, steady state voltage can be obtained by using Eq. (10) in Eq. (16) as,

$$v(t) = -\frac{d_{31}E_p \rho\phi^2 Y}{C_p} \sum_1^{\infty} \left\{ \sum_{k=1}^{N_p} \int_{(k-1)L_p}^{kL_p} b(x) \left( h(x) + \frac{h_p}{2} \right) \frac{d^2 X_i(x)}{dx^2} dx \right\} \frac{\int_0^L X_i(x) A(x) dx}{\omega_i^2 - \phi^2 + j2\xi_i\omega_i\phi} e^{j\phi t}. \quad (17)$$

In order to provide a more general form of steady state response and not considering specific  $Y$  and  $\phi$  values, frequency response functions (FRFs) of the electromechanical outputs are obtained and presented. Firstly, the voltage FRF is defined as the ratio of the steady state voltage output to the base acceleration. Hence, voltage FRF is described as,

$$\frac{v(t)}{-Y\phi^2 e^{j\phi t}} = \frac{d_{31}E_p \rho}{C_p} \sum_1^{\infty} \left\{ \sum_{k=1}^{N_p} \int_{(k-1)L_p}^{kL_p} b(x) \left( h(x) + \frac{h_p}{2} \right) \frac{d^2 X_i(x)}{dx^2} dx \right\} \frac{\int_0^L X_i(x) A(x) dx}{\omega_i^2 - \phi^2 + j2\xi_i\omega_i\phi} e^{j\phi t}. \quad (18)$$

Secondly, the relative tip motion FRF is presented as ratio of the beam vibration amplitude at the tip to the amplitude of the base excitation. It is worth mentioning that the presented model is not limited to the motion at the tip and can be applied to any point along the beam. By using Eq. (10), tip motion FRF is defined as,

$$\frac{w(L, t)}{Y e^{j\phi t}} = \rho\phi^2 \sum_{i=1}^{\infty} \left\{ (L) \frac{\int_0^L X_i(x) A(x) dx}{\omega_i^2 - \phi^2 + j2\xi_i\omega_i\phi} \right\}. \quad (19)$$

When the excitation frequency is equal to the natural frequency of the  $i$ th mode ( $\phi = \omega_i$ ), all the terms in the FRF

relations other than the mode of interest can be ignored. As a result, the amplitude of voltage output and tip motion FRFs are rewritten as,

$$\left\| \frac{(t)}{-Y\phi^2 e^{j\omega t}} \right\| = \frac{d_{31}E_p\rho}{\xi_i\omega_i^2 C_p} \left\{ \sum_{k=1}^{N_p} \int_{(k-1)L_p}^{kL_p} b(x) \left( h(x) + \frac{h_p}{2} \right) \frac{d^2 X_i(x)}{dx^2} dx \right\} \left[ \int_0^L X_i(x) A(x) dx \right]. \quad (20)$$

$$\left\| w(L,t) \right\| = \frac{\rho\phi^2}{2\xi_i} X_i(L) \int_0^L X_i(x) A(x) dx. \quad (21)$$

### III. MECHANICAL BAND PASS FILTER

In this section, the probability of designing a mechanical band pass filter from an array of non-uniform beams is investigated. The material properties and electromechanical coefficients are listed in Table 1. The excitation of the piezoelectric energy harvester is due to the harmonic base translation and the steady state dynamic behavior of the system is of interest. Furthermore, structural strain-rate damping ratios for the first and second vibration modes are assumed to be  $\xi_1=\xi_2=0.03$ . Finally, two steady state electromechanical FRFs, voltage output and beam tip motion, are examined.

TABLE I. GEOMETRY AND MATERIAL PROPERTIES OF THE PIEZOELECTRIC ENERGY HARVESTER.

In order to design a mechanical band pass filter, an array of non-uniform beams is considered. The idea of an ensemble of beam-mass system working as a band pass filter is borrowed from [5] and further developed in here. The system consists of several nonlinearly tapered piezoelectric coupled cantilever beams, each of which has different geometrical taper ratio and hence different resonance frequencies. Consequently, the assembled system has a wide operational frequency range and the filter can automatically choose one harvester to resonate at one particular ambient vibration frequency. When the natural frequency of the energy harvester matches the peak power frequency of the source, the output power is the most efficient. Additionally, to partially overcome the stability and size drawbacks, all the harvesters in the system have similar length, volume and mass. As a result, the entire system can work as a mechanical band pass filter depending on geometrical dimensions and taper ratios. Although the non-uniformity function in the presented model is not constrained to any specific type of function and is a general definition, here an exponential variation function  $g(x)=g_0e^{-mx/L}$  is considered where  $g_0$  is the initial value,  $m$  is the taper ratio and  $0 \leq x \leq L$ .

Fig. 2 represents the nonlinear geometry effect on the electric voltage output in frequency domain. As can be seen, the amplitude of the voltage output drastically increases when the excitation frequency is close to the fundamental natural frequency of the harvester. It is worthwhile to mention that for every excitation frequency, maximum electrical output is

gained when the piezoelectric energy harvester is working in open circuit condition [13]. As shown, higher nonlinearity in geometry of the harvester results in substantial increase of the voltage amplitude. For instance, by increasing the geometry taper ratio from 0 to 0.8, the voltage output for the first two vibration modes show up to 15.46 times higher outputs, Fig. 2. Therefore, a system comprising only five non-uniform energy harvesters with different taper ratios and same volume/mass can function like a band pass filter over a wide frequency band [ $\omega_{\min}-\omega_{\max}$ ]=[290-550]rad/s≈[45-90]Hz. Besides, the proposed non-uniform design substantially increases the voltage output of the system compared to the uniform one [5].

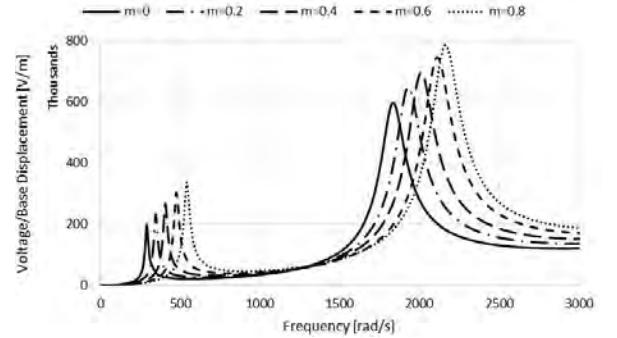

Figure 2. Voltage output FRF for an array of non-uniform piezoelectric energy harvesters with five different geometrical taper ratios.

Finally, the tip displacement in frequency domain for various nonlinear geometries is shown in Fig. 3. Likewise, increasing the nonlinearity in the geometry of the harvesters leads to higher natural frequencies and tip displacements. As mentioned earlier, trapezoidal profile can distribute the strain evenly such that maximum strain is obtained at every point in the piezoelectric energy harvester.

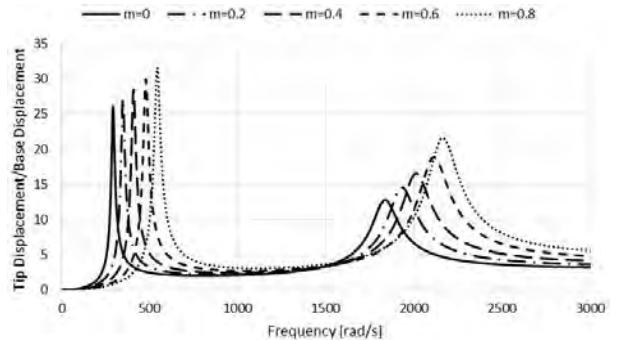

Figure 3. Beam tip motion FRF for an array of non-uniform piezoelectric energy harvesters with five different geometrical taper ratios.

### IV. CONCLUSION

In this paper, an analytic electromechanical model for a nonlinearly tapered cantilever piezoelectric energy harvester is presented. The non-uniform piezoelectric harvester is assumed to be excited by harmonic base motion in the transverse direction. By using ADM, the steady state dynamic behavior of the smart structure with non-uniform geometry and structural strain-rate damping is obtained and closed-form expressions for the electromechanical parameters are derived. Analytically

obtained equations are used to determine the electric charge, voltage output and tip motion FRFs to be able to see the frequency response of the non-uniform harvesters. The electromechanical FRFs are plotted against frequency in open circuit condition which leads to the maximum output. Finally, a mechanical band pass filter including an array of nonlinearly tapered piezoelectric bimorph cantilever beams, each of which has different geometrical taper ratio and hence different resonance frequencies is designed and presented.

In summary, a new approach to increase the frequency range and electrical outputs of vibration energy harvesters by widening the bandwidth of the generator and introducing nonlinear structural geometry design is developed and presented. This is achieved through employing an array of non-uniform harvesters with different resonance frequencies. The new nonlinear geometry design has demonstrated to be promising to considerably increase the electromechanical outputs of the band pass filter in a wide frequency domain. This research challenges previous energy harvesting designs and formulates an innovative harvester configuration which functions optimally and efficiently on extensive range of ambient vibration sources.

#### ACKNOWLEDGMENT

This research was undertaken, in part, thanks to funding supports from University of Manitoba, Research Manitoba and Natural Sciences and Engineering Research Council of Canada (NSERC).

szwang94212@gmail.com

**Abstract**—This paper reports a numerical analysis of solar-driven seawater desalination systems with two configurations: a floating photo-thermal film at the air-water interface with and without an insulation layer located beneath its surface. Heat transfer processes from the film including conduction, convection and radiation have been evaluated at different film temperatures to determine the relative contributions of different heat loss mechanisms from the film. Convective heat transferred to the bulk seawater is found to be the dominant heat loss path, and can be reduced from  $6.95 \times 10^7 \text{ J/m}^2\cdot\text{h}$  to  $8.77 \times 10^5 \text{ J/m}^2\cdot\text{h}$ , a difference of almost two orders of magnitude, by inserting an insulation layer beneath the photo-thermal film. Thus, the addition of an insulating layer is suggested as an important design component to effectively minimize heat losses in air-water interfacial solar heating systems.

**Keywords**-solar interfacial heating; desalination; heat transfer

## I. INTRODUCTION

Worldwide freshwater scarcity has been a longstanding issue due to the demands of an ever-growing population. In addition to environmental conservation, freshwater production is an important solution for meeting this urgent need. Seawater covers most of the earth's surface, and is considered to be a sustainable source of continuous freshwater supply. However, the predominant methods used to desalinate seawater, such as multi-stage flash distillation (MSF) and reverse osmosis (RO), typically consume 5 ~ 26 times as much energy as the latent heat of water (about 2400 kJ/kg) [1], [2]. A promising alternative approach is solar-driven seawater desalination, whereby heat generated from the solar irradiance is used to evaporate water, which minimizes the need for fossil fuels and electric power. However, traditional solar-driven water desalination systems exhibit low efficiencies (typically 34 - 40% for a single basin solar still [3]) due to large heat losses to the bulk water reservoir.

To improve solar distillation systems, numerous photo-thermal materials with different morphologies and surface properties have been investigated for their performance of absorbing solar irradiance and producing heat to enhance evaporation. In this regard, plasmon resonance phenomena in metallic materials, such as Au [4], [5], Ag [6] and Cu [7], [8],

have been investigated in terms of light absorption and localized heat generation for accelerated water evaporation. For example, Jin et al. achieved a the solar-thermal conversion efficiency (the ratio of the thermal energy used for evaporation and the total incident solar irradiance) of 80.3% using Au nanoparticles dispersions under 220 sun illumination ( $1 \text{ sun} \approx 1 \text{ kW/m}^2$ ) [4]. Besides, carbon-based materials such as graphene and reduced graphene oxide have gained popularity for solar-driven distillation applications in the past few decades on account of their excellent photo-thermal properties. Y. Ito et al. found that nitrogen doped nano-porous graphene sheets floating on the air-water interface were heated to 100 °C under concentrated solar irradiation while the bulk water remained at 35 °C, reaching an 80% conversion efficiency of received solar radiation to the latent heat of water [9]. This strategy of using a photo-thermal film located at the air-water interface has promising potential to increase the efficiency of solar desalination systems because heat generated from the absorbed solar energy is localized at the air-water interface where the evaporation process occurs.

To date, simulations and mathematical analysis of heat and mass transfer in traditional solar distillation plants [10]–[13] and molecular dynamic modeling for general evaporation [14], [15] have been reported in the literature. However, few studies have investigated heat loss mechanisms in photo-thermal films used for air-water interfacial solar heating from a heat transfer perspective to seek quantitative explanations for their superior performance. Herein, numerical analysis is performed to investigate the performance of two air-water interfacial solar heating configurations, wherein 1) a thin film of black photo-thermal material (e.g. graphene and its derivatives) floats directly on the air-water interface, and 2) the film structure is similar to the first configuration but with a thermal-insulation layer inserted between the photo-thermal film and the bulk water. Simplified models are used to study the convective, conductive and radiative heat transfer losses from the photo-thermal film to its surrounding environment. Comparisons between these heat losses and the energy contributed to evaporate water are made in order to provide recommendations for optimizing the design of solar-driven water desalination systems.

## II. MATHEMATICAL MODEL AND ANALYSIS

### A. General Assumptions

Herein we model two air-water interfacial solar heating configurations, namely 1) floating photo-thermal film without an insulation layer and 2) floating photo-thermal film with an insulation layer. In practice, the photo-thermal film has a thickness at the micron scale and exhibits high absorptivity towards solar irradiance such that its temperature is sufficiently increased to provide thermal energy to facilitate the water evaporation process. In this work, to simplify the heat transfer analysis, it is assumed that the solar irradiance heats the film isothermally to a constant temperature  $T_f$ , which is reasonable considering the high thermal conductivity and small thickness of the film. Furthermore, in practice the photo-thermal film would be porous to allow for vapour to escape from the reservoir. However, an assumption is made that the photo-thermal film is flat on both its upper and lower surfaces and has zero thickness for simplification. Also, small turbulence induced by mass transfer (replenishment) from the bulk to the heat-up zone below the film is not considered. Moreover, the analysis presented herein assumes a one-dimensional, quasi-steady state case, and horizontal heat diffusion along the planar direction of the film is not considered. It is also assumed that the thermal properties of the film are independent of temperature and its heat capacity is negligible. The air is quiescent and remains at constant temperature,  $T_a$ , at distances far above the photo-thermal film. Both the air and water vapor behave as ideal gases. It is assumed that sidewalls of the tank are thermal-insulated without edge effects and the temperature of the water far beneath the air-water interface is at a constant value,  $T_{w0}$ . The parameters considered in the analysis as well as the dimensions and related physical properties are provided in Table I.

### B. Floating Photo-Thermal Film without an Insulation Layer

In this model the photo-thermal film floats on the air-water interface and is in direct contact with the water (as shown in Fig. 1 (a) and Fig. 1 (b)). A thermal resistance network for the heat transferred from the photo-thermal film is provided in Fig. 1 (c). This thermal resistance network is consistent with the assumption that evaporation takes place in an ultra-thin layer at the air-water interface where the porous photo-thermal film (with zero thickness) resides. Except for evaporating water, heat is lost from the photo-thermal film due to convection to the air,  $Q_{va}$ , radiation to the air,  $Q_{ra}$ , convection to the bulk water,  $Q_{vw}$ ,

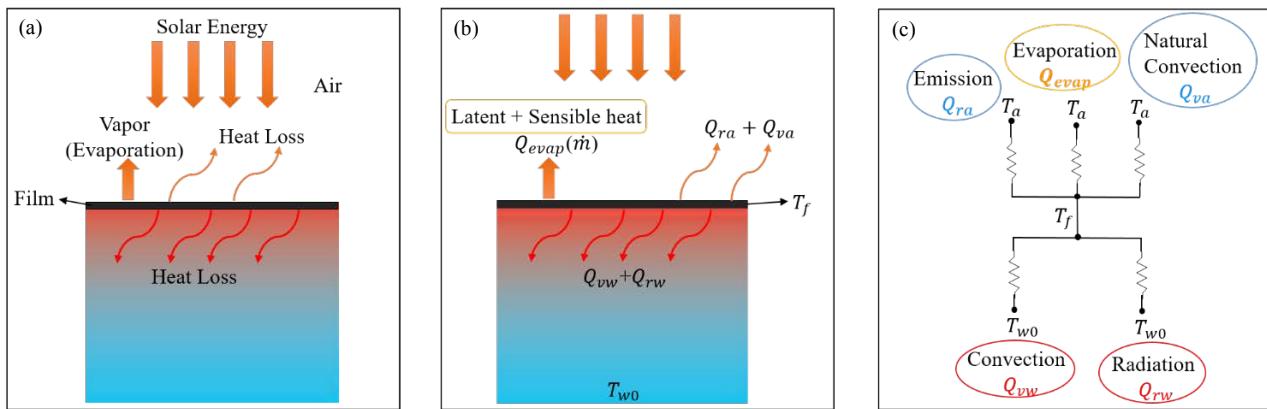

Figure 1. (a) (b) Simplified heat transfer model for a solar interfacial heating model using a floating photo-thermal film.  
(c) Thermal resistance network for the floating photo-thermal film.

and radiation to the bulk water  $Q_{rw}$ . The surface area of the film,  $A$ , is assumed to be  $0.3 \text{ m} \times 0.3 \text{ m}$ .

Convective heat losses are through natural convection mainly, and are calculated using Newton's Law of cooling:

$$Q_{va} = A\overline{h_a}(T_f - T_a) \quad (1)$$

$$Q_{vw} = A\overline{h_w}(T_f - T_{w0}) \quad (2)$$

where  $\overline{h_a}$  and  $\overline{h_w}$  are the heat transfer coefficients for convection to the air and water, respectively, and are determined by the following empirical correlations:

$$Ra_L = \frac{g\beta\Delta TL_c^3}{\alpha\gamma} \quad (3)$$

$$\overline{Nu_L} = \begin{cases} 0.54Ra_L^{1/4} & (\text{upper surface } 10^7 \leq Ra_L \leq 10^{11}) \\ 0.27Ra_L^{1/4} & (\text{lower surface } 10^5 \leq Ra_L \leq 10^{10}) \end{cases} \quad (4)$$

$$\bar{h} = \frac{k\overline{Nu_L}}{L_c} \quad (5)$$

where  $\Delta T$  is the relevant temperature difference.

Radiative heat transfer losses are determined using the Stefan-Boltzmann Law:

$$Q_{ra} = A\varepsilon\sigma(T_f^4 - T_a^4) \quad (6)$$

$$Q_{rw} = A\varepsilon\sigma(T_f^4 - T_{w0}^4) \quad (7)$$

Thermal energy transferred from the film for evaporation consists of both the sensible and latent heat of water, and is given by the following formula:

$$Q_{evap} = A\dot{m}[\Delta H + C(T_f - T_{w0})] \quad (8)$$

The temperature of the vapor is assumed to be the same as that of the film, so the sensible heat for a rise of water temperature from the initial temperature  $T_{w0}$  to  $T_f$  is included in the calculation for  $Q_{evap}$ . Methods used to determine the evaporation rate,  $\dot{m}$ , are discussed in Section III with reference to Fig. 3.

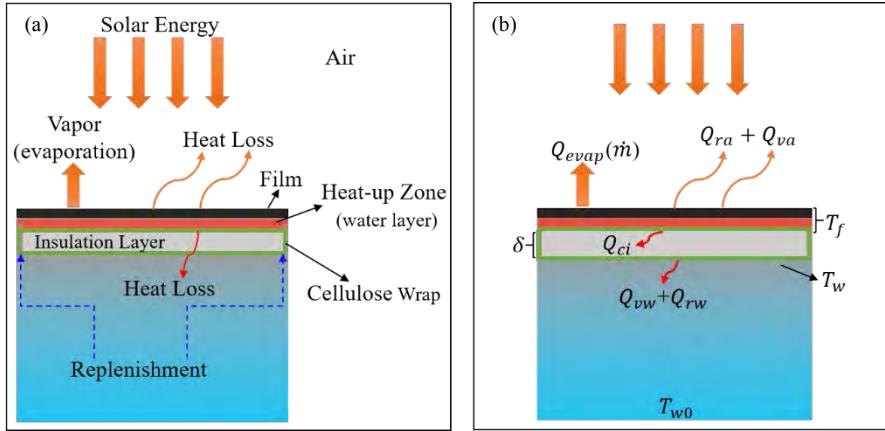

Figure 2. (a)(b) Simplified heat transfer model for solar interfacial heating model using photo-thermal film with an insulation layer underneath.

### C. Floating Photo-Thermal Film with an Insulation Layer

In the second air-water interfacial solar heating configuration, an insulation layer (such as cellular glass or polystyrene foam with a low thermal conductivity of about  $0.05 \text{ W/m}\cdot\text{K}$ ) with a thickness of  $\delta$  is inserted below the photo-thermal film to reduce convective loss to the bulk water (Fig. 2 (a) and Fig. 2 (b)).

In this configuration, a structure similar to that of a cellulose wrap [16] is applied for replenishment during evaporation, i.e. water is driven by capillary forces from the bulk. A thin water layer (with a thickness of  $\sim 0.1 \text{ mm}$ ), herein referred to as the “heat-up zone” in Fig. 2 (a), is thus created and resides on top of the insulating layer, right below the photo-thermal film. It is assumed that the temperature of the heat-up zone is equal to that of the film,  $T_f$ . The amount of thermal energy transferred from the film downwards through the insulator is equal to the sum of the convective and radiative heat losses from the bottom of the insulation layer to the bulk water:

$$Q_{ci} = Q_{vw} + Q_{rw} \quad (9)$$

Thus, it is assumed that the total heat loss from the photo-thermal film is the sum of three heat loss mechanisms: radiation and convection to the air, and conduction to the insulator. Equation

(1) - (7) are used again to determine the heat losses in the second configuration, except the temperature at the insulating layer-bulk water interface,  $T_w$ , is used to calculate the radiative and convective heat losses to the water.  $T_w$  is determined using (9). Conduction through the insulator is given by the following equation:

$$Q_{ci} = \frac{\Delta k_i(T_f - T_w)}{\delta} \quad (10)$$

where  $k_i$  is the thermal conductivity of the insulator.

### III. RESULTS AND DISCUSSION

To determine the evaporation rate at the air-water interface as a function of the photo-thermal film temperature,  $T_f$ , an empirical relationship has been determined using experimental data reported in the literature [17]–[21]. That is, based on evaporation rates reported for air-water interfacial solar heating employing various photo-thermal sheet-like carbon materials such as graphene, rGO (reduced graphene oxide) and graphite, an exponential curve fitting for the evaporation rate has been applied and the results are shown in Fig. 3 (a). The evaporation rates achieved are between  $0.92 \text{ kg/m}^2\cdot\text{h}$  and  $3.5 \text{ kg/m}^2\cdot\text{h}$  in most studies.

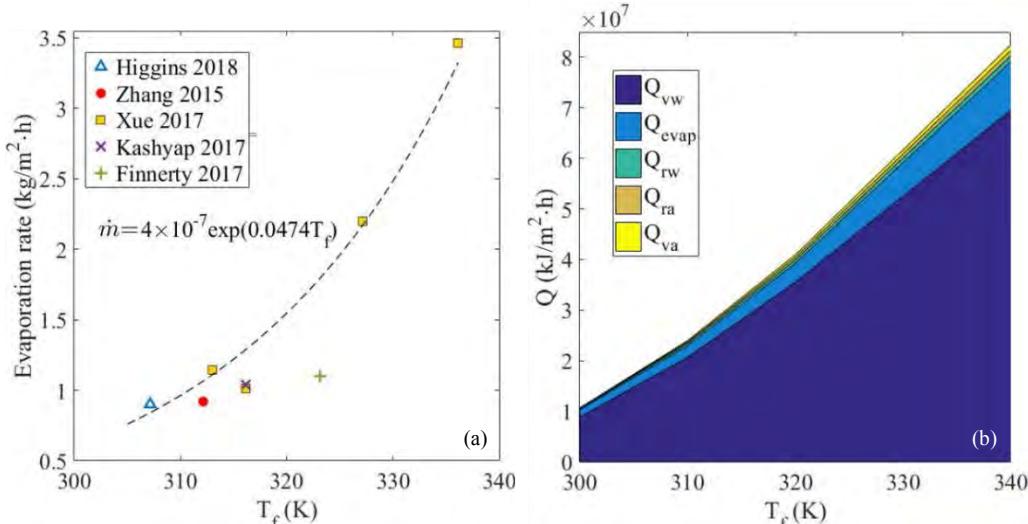

Figure 3. (a) Exponential fitting of the data from previous work ( $R^2 = 0.8415$ ) [17]–[21]. (b) Thermal energy transferred from the photo-thermal film due to water evaporation, convection and radiation to the water, and convection and radiation to ambient air in the floating film without an insulation layer configuration.

For the first configuration, *floating photo-thermal film without an insulation layer*, thermal energy transferred through the different paths are plotted in Fig. 3 (b). Every heat transfer pathway steadily increases with increasing  $T_f$ , as the temperature difference between the photo-thermal film and its surrounding environment increases. When the photo-thermal film is at a temperature of 340 K, the amount of energy used to evaporate water ( $Q_{evap}$ ) is  $\sim 9.6 \times 10^6 \text{ J/m}^2\cdot\text{h}$ , whereas the convective loss to the bulk water,  $Q_{vw}$ , is almost 7 times larger than  $Q_{evap}$ , and dominates over other heat transfer processes. Thus, natural convection to the bulk water is the major heat loss mechanism, limiting the efficiency of air-water interfacial solar heating evaporation systems. It can be noted that the sum of the heat lost to the air ( $Q_{ra}$  and  $Q_{va}$ ) and radiation to the bulk water ( $Q_{rw}$ ) is only 4%.

The effectiveness of placing an insulation layer beneath the photo-thermal film to mitigate convective heat losses from the film to the bulk water is analyzed in the second configuration, *floating photo-thermal film with an insulation layer*. The results show the addition of an insulating layer significantly alters the thermal energy loss distribution. As shown in Fig. 4 (a), for an insulating layer with a thickness of 0.001 m, the convective heat  $Q_{vw}$  is reduced dramatically because the thermal insulation layer reduces the heat transfer lost from the photo-thermal film to the underlying bulk water. For example, for a photo-thermal film temperature of  $T_f = 340 \text{ K}$ ,  $Q_{vw} = 8.77 \times 10^5 \text{ J/m}^2\cdot\text{h}$ , which is just 1.26% of its former value of  $6.95 \times 10^7 \text{ J/m}^2\cdot\text{h}$  for the configuration where the insulating layer is absent. Consequently, the percentage of heat used in evaporating water,  $Q_{evap}$ , increases from 11% to 76% of the total energy transferred from the photo-thermal film. Moreover, the influence of the insulator layer thickness on  $Q_{vw}$  is also shown in Fig. 4 (b). As the thickness of the insulating layer increases the convective heat transfer losses to the bulk water are further decreased. For the thickest insulator layer considered in this study,  $\delta = 0.1 \text{ m}$ , convective loss to the bulk water decreases below 9000  $\text{J/m}^2\cdot\text{h}$ , which is even lower than  $Q_{ra}$  and  $Q_{va}$  when  $300 \text{ K} < T_f < 340 \text{ K}$ . Thermal energy dissipations to the air, namely  $Q_{ra}$  and  $Q_{va}$ ,

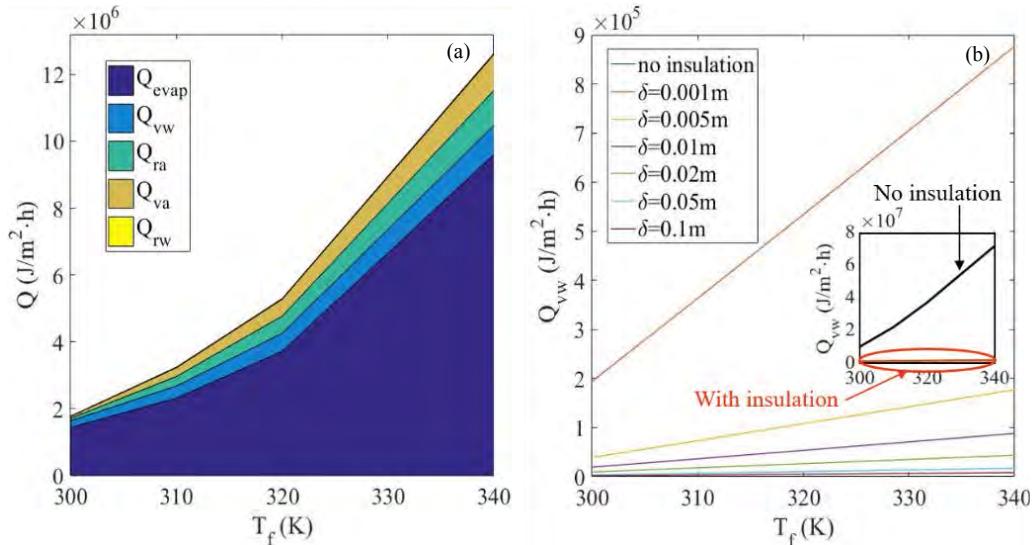

Figure 4. (a) Thermal energy transfer from the photo-thermal film as a function of its temperature due to water evaporation, convection and radiation to the water, and convection and radiation to the ambient air for the configuration with an insulating layer ( $\delta=0.001 \text{ m}$ ). (b) Convective heat losses to the bulk water as a function of the photo-thermal film temperature for different thicknesses,  $\delta$ , of the insulating layer situated beneath the film. The inset shows that convective losses to the bulk water for the configuration with an insulation layer is almost two orders of magnitude less than that of the configuration without an insulation layer.

stay unchanged because they only depend on  $T_f$  and  $T_a$ , regardless of the presence of an insulation layer under the film.

In conclusion, numerical analysis of the thermal energy losses in air-water interfacial solar heating systems shows that convection to the bulk water is the dominant loss mechanism, wasting up to over 80% of the available thermal energy. To improve the overall performance of interfacial air-water solar desalination systems, the application of an insulation layer beneath the photo-thermal film is recommended to effectively suppress heat losses to the bulk of the reservoir.

TABLE I. PARAMETERS AND PHOTO-THERMAL FILM DIMENSIONS

Nomenclature			
$T_f$	Temperature of the photo-thermal film	$\sigma$	Stefan-Boltzmann constant ( $\text{W/m}^2\cdot\text{K}^4$ )
$T_a$	Temperature of the air (296 K)	$g$	Acceleration of gravity ( $\text{N/m}^2\cdot\text{s}$ )
$T_{wo}$	Initial temperature of the water (288 K)	$Nu_L$	Nusselt number
$Q_{va}$	Convective heat transfer to the air ( $\text{J/m}^2\cdot\text{s}$ )	$h_{fg}$	Latent heat of water ( $\text{kJ/kg}$ )
$Q_{vw}$	Convective heat transfer to the bulk water ( $\text{J/m}^2\cdot\text{s}$ )	$\varepsilon$	Emissivity of the film ( $\approx 0.9$ )
$Q_{ra}$	Radiative heat transfer to the air ( $\text{J/m}^2\cdot\text{s}$ )	$\beta$	Volume thermal expansion coefficient ( $/\text{K}$ )
$Q_{rw}$	Radiative heat transfer to the bulk water ( $\text{J/m}^2\cdot\text{s}$ )	$\alpha$	Thermal diffusivity ( $\text{m}^2/\text{s}$ )
$Q_{ci}$	Conductive heat transfer to the insulation layer ( $\text{J/m}^2\cdot\text{s}$ )	$\gamma$	Kinetic viscosity ( $\text{m}^2/\text{s}$ )
$\delta$	Thickness of the insulation layer (m)	$\dot{m}$	Evaporation rate or vapor flux close to film surface in the air ( $\text{kg/m}^2\cdot\text{h}$ )
$L_c$	Characteristic length of the film (A/Perimeter = 0.075 m)	$k$	Thermal conductivity ( $\text{W/m}\cdot\text{K}$ )
$Ra_L$	Rayleigh number	$C$	Specific heat capacity of water ( $\text{kJ/kg}\cdot\text{K}$ )

**Abstract**—The Archimedes screw is one of the oldest machines in the world, and has been used for various applications including hydroelectric power generation. This project investigated the effect of inlet conditions on a laboratory-scale Archimedes screw as a generator. The performance of the Archimedes screw was measured with both a narrow inlet channel and a wider inlet basin. The required inlet water depth was experimentally determined for both the channel and the basin, for a range of operating flow rates and screw rotation speeds. The tests with and without the channel were conducted at 9 different speeds and 9 different flows. The data was analyzed and plotted for efficiency, head, inlet depth, non-dimensional inlet depth with the respective flow and speed associated to each data point. The experimental data was used to develop an inlet depth model. The data was analyzed and plotted for efficiency, head, inlet depth, non-dimensional inlet depth with the respective flow and speed associated to each data point. It was found that there was a notable efficiency difference between the basin and channel inlets only at low volume flow rates and high rotation speeds.

**Keywords**-Archimedes screw; inlet channel; efficiency; head

## I. INTRODUCTION

The Archimedes screw is an ancient machine that has been used continually for millennia. Initially the Archimedes screw was used for drainage and irrigation purposes [1]. Applications of the Archimedes screw today include, but are not limited to, wastewater treatment plant pumps, low-lying land pumping stations, irrigation systems, fish conveyors, and generators [2].

An Archimedes screw consists of a set of helical planes, or flights, which are connected to a cylindrical central shaft, and supported on bearings that allow it turn within a close-fitting cylindrical trough or enclosure [3]. The design of the Archimedes screw is such that when the screw is tilted, the blades of the screw trap water discrete volumes of water called buckets [1]. The rotation of the screw allows the water to travel within the blades. The Archimedes screw can be used either as a pump or a generator. When water is moving from the bottom to the top, work is done turning the screw and it is being used as a pump. When water is moving from the top to the bottom, work is done by the rotating Archimedes screw and it can be used to turn a generator to produce electricity.

In the 1930's there were over 300 Archimedes screws in the Netherlands being used as drainage pumps in low-lying regions [4]. Use of the Archimedes screw for power generation began with experimental tests conducted at the University of Prague between 1993 and 1995 by Brada [2]. These experiments demonstrated that an Archimedes screw used for power generation could have more than 80% efficient converting hydraulic energy into mechanical energy [2]. It has been shown and proven that better conversion efficiencies can be attained by using larger screws as per Hellmann and Kleemann [2].

Currently over 400 Archimedes screw generators (ASGs) have been installed in Europe, with the first being installed only in 1993 [5]. Archimedes screw generators remain rare outside Europe. The first connection of an Archimedes screw generator to a power grid in North America was in 2013 by Greenbug Energy near Waterford, Ontario, Canada [5]. Unlike most hydro turbines, fish can pass through an operating Archimedes screw unharmed [5]. Additional advantages of Archimedes screws include straightforward design, good efficiency at non-optimum flows, ease of use, and low environmental impacts [6].

Water for an ASG is typically supplied by an inlet channel that conveys water from a reservoir or other source to the inlet of the screw. During design of an ASG installation, it is essential to ensure that the water depth that can be supplied at the inlet to the screw will be sufficient to provide the desired flow rate and amount of filling once the water enters the screw. If the inlet basin level is too low, for example, it will not be possible to fill the buckets in the operating screw.

The required inlet water level will be a function of both the screw rotation speed and the volume flow rate of water to be supplied. For example, if the screw is turning very quickly, there will be insufficient time to fill each bucket of the operating screw, and the screw will be unable to produce the desired power.

The goal of this project was to experimentally investigate the impact of volume flow rate and screw rotation speed on the inlet basin water depth. Two cases were tested to check the effect of inlet channel geometry on this relationship: one with a narrow inlet channel and the other with a much wider

A range of cross-sections can be used in an inlet channel. The channel used for this experiment had a rectangular cross-section, with a flat bottom and vertical, parallel side walls.

The project involved the use of an inlet channel for the testing to develop a relationship of a non-dimensional model which can predict head, flow, and speed. The outlet channel losses were held constant for all tests during the experiment because the depth of the water at the screw outlet was always below the screw in the lower basin. The inlet channel losses depend upon the depth of water entering the screw and leaving the screw. It should be noted that the Borda-Carnot entrance loss technique can be used for calculating the inlet channel head loss and has been done by [2]. Kozyn found that the actual power loss at the entrance was small relative to other losses in an ASG.

This project involved the construction of a rectangular cross section channel which was connected to the Archimedes screw generator. This connecting channel was used to develop relationships with respect to the flow, head, torque, and speed of an Archimedes screw generator. The objective of the project was to determine the required water depth to achieve a specific volume flow rate through the Archimedes screw generator over a range of screw speeds within the operating range of the Archimedes screw generator.

## II. EXPERIMENTAL METHODOLOGY

Experiments were conducted at the University of Guelph Archimedes screw testing facility with, and without the rectangular inlet channel installed within the upper supply basin to the Archimedes screw. Tests were conducted on a three-bladed screw with a 31.6 cm outer diameter, 16.8 cm inner cylinder diameter, 31.8 cm pitch and 122 cm flighted length.

The setup of the testing facility involved an upper basin that fed the Archimedes screw with water and that water would output to a lower basin (Fig. 1). The water from the lower basin was fed to the upper basin through a pipe. There was a pump which allowed for the water to flow through the pipe to get to the upper basin. Upon completion of the experiments with just the Archimedes screw, a rectangular cross-section inlet channel was designed with width of 31.8 cm, length of 122 cm from upstream channel entrance to screw entrance. The sides of the channel entrance were designed with a radius of 2.5 cm to reduce channel entrance losses. The floor of the channel was aligned with the bottom-most edge of the screw inlet. This channel was machined by a local machining company in Guelph and installed in the Archimedes screw testing facility. The channel was installed and then tests were conducted at the 9 different flows and 9 different rotation speeds. The flows and speeds that were tested were the same with and without the channel in place.

The screw was operated at an inclination angle  $\beta$  of 24.5°, at rotation speeds of RPM, 25 RPM, 30 RPM, 35 RPM, 40 RPM, 50 RPM, 60 RPM, 70 RPM, and 80 RPM. At each rotation speed, torque and inlet basin depth were recorded for flows of 6 L/s to 14 L/s in one L/s increments. These ranges of speed and flow were chosen to provide a range of results across the performance envelope of the screw.

The Archimedes screw was operated in generator mode and the instruments which were available in the University of Guelph Archimedes screw testing facility were used for the measurements of flow, head, torque, and speed [3,8].

The shaft power generated by the screw  $P$  was calculated from the angular rotation speed of the screw  $\omega$  and torque  $T$ :

Figure 1. Archimedes screw (left) and inlet channel (right).

Figure 2. Upper basin with channel installed, with top of screw frame including gear motor and torque arm.

$$P = \omega T \quad (1)$$

The rotational speed of the screw was measured with a magnetic switch which was positioned just above the shaft at the inlet of the screw. A magnet secured on the screw shaft caused the magnetic switch to close once revolution [3]. The switch state was recorded by a National Instruments (NI) USB-6009 Data Acquisition (DAQ) unit connected to a laptop computer running NI LabVIEW. The magnetic switch data was recorded at a frequency of 1000 Hz.

It should be noted that ASGs rotate relatively slowly. In practice, most full-scale ASGs used for power generator rotate at a speed close to

$$\omega_m = \frac{5\pi}{3D_o^{2/3}} \quad (2)$$

where  $D_o$  is the screw outer diameter in meters and  $\omega_m$  is rotation speed in radians per second.

Screw torque was measured by an Omegadyne LC703-25 load cell with one end fixed to an arm attached to a variable-frequency drive that regulated rotation speed, and the other end fixed to a stationary point on the support frame of the screw [8].

Figure 4. Efficiency vs Speed at Specified Flows

The load cell was installed so that the line of action through the cell was 26.5 cm from the screw axis of rotation.

The maximum power available to the screw is

$$P_{max} = \rho g h Q \quad (3)$$

where  $\rho$  is water density,  $g$  is the gravitational constant ( $9.81 \text{ m/s}^2$ ),  $h$  is the height difference between the free surfaces in the upper and lower basin, and  $Q$  is volume flow rate of water. The screw was operated with the receiving basin water level below the outlet of the screw to ensure consistence, so  $h$  was taken as the vertical distance from the inlet basin free surface, to the lowermost point on the screw outlet. The heights of the screw as tested are shown in Fig. 3. The efficiency of the screw is then

$$\eta = \frac{P}{P_{max}} \quad (4)$$

The water level in the inlet basin was measured using a Keller Valueline depth gauge and visually confirmed. Volume flow rate was measured with an Omega FTB740 flow meter

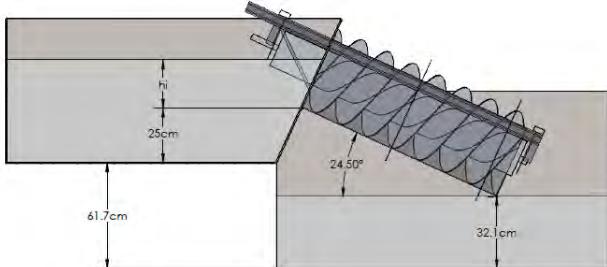

Figure 3. Heads and vertical distances as tested.

installed in the return pipe that through which water is pumped from the lower basin back to the inlet basin. All flow through the system also passes through the screw, so this measurement also reflects the flow rate through the screw.

Non-dimensional inlet depth was calculated as

$$\zeta = \frac{h_i}{D_o \cos \beta} \quad (5)$$

where  $h_i$  is vertical distance between the inlet basin free surface, and the lowest point of the screw inlet opening (Fig. 3).

### III. ERROR ANALYSIS

An error analysis was performed in which observed sensor errors and uncertainties were propagated through the calculations to determine the uncertainty of calculated efficiency and power. Power generated by the screw is the product of torque and angular velocity. The magnetic switch observing rotation was recorded at a frequency of 1000 Hz, and rotation rate was based on the precise time between the series of full rotations within the one minute sampling period. This allowed for the uncertainty in angular velocity to be negligible relative to the torque measurement [3]. The uncertainty for the torque measurements was previously found to be 0.22 Nm [8]. The overall result was that under nominal conditions, the uncertainty of the calculated power was  $\pm 1.0 \text{ W}$  and efficiency uncertainty at nominal conditions is  $\pm 0.015$ .

### IV. RESULTS AND DISCUSSION

The effect of supplying water to the screw through a narrow inlet channel, rather than directly from a wide supply basin, was

relatively minor. Figs. 4 and 5 show that across much of the tested range, the efficiency of the screw was effectively the same whether it was operating with a narrow inlet channel or the wider inlet basin. The effect of the inlet channel only becomes apparent at low volume flow rates and higher rotational speeds. Above 40 RPM the efficiency of the screw is higher with the channel than without the channel for 6 L/s. A similar trend occurred at 7 L/s, while at all higher flow rates there were no significant differences in efficiency given the uncertainty in the calculated efficiency.

Interestingly, in low flow, high rotation conditions, the efficiency of the screw was higher with the narrow channel in place than it was without the channel. This was not expected: it was anticipated that the presence of the channel would result in decreased overall efficiency. The overall head across the screw is measured in the upstream area of the basin, and so any channel losses with the inlet channel would be expected to produce additional head loss, reducing system efficiency relative to the case of operating with the screw being supplied directly from the wide inlet basin.

It was determined that the efficiency difference was due to entrance effects when water enters the screw. Figs. 6 to 9 show the water surface at the entrance to the operating Archimedes screw. With the channel in place there is a relatively linear surface, and flow is relatively uniform into the screw. Without the channel, water enters the screw from the wide basin from both the front and sides of the inlet. Fig. 10 shows a notable variation in water level at the entrance, due to the flow from the basin sides turning around the sharp edged inlet and into the screw entrance. This was seen for both the 6 L/s and 7 L/s flows. This additional entrance loss without the channel in place results in an increased head loss. At higher flow rates, there was little apparent difference in the water surface at the entrance with and without the channel in place.

Note that the data point with 8 L/s and 60 RPM may be subject to experimental error. It is believed that some air was drawn by the pump into the return pipe while this data point was taken, causing the flow meter to erroneously measure a slightly lower-than-actual flow.

Considering inlet depth generally (with or without the narrow inlet channel present), it was found that higher inlet basin depth was required in order to increase flow rates or decrease rotation speeds. Fig. 5 graphically shows this relationship.

Simple models of inlet depth were developed by first noting that screw rotation speed and volume flow rate would be the dominant dependent variables:

$$h_i = f(\omega, Q) \quad (6)$$

$$\zeta = f\left(\frac{\omega}{\omega_m}, \frac{Q}{Q_m}\right) \quad (7)$$

where

$$Q_m = \left[ \frac{\pi}{4} (D_o^2 - D_i^2) \right] \left[ \frac{S\omega}{2\pi} \right] \quad (8)$$

is a theoretical rate at which material would pass through the full cylindrical volume of the screw (excluding the inner cylinder) due to screw rotation only.

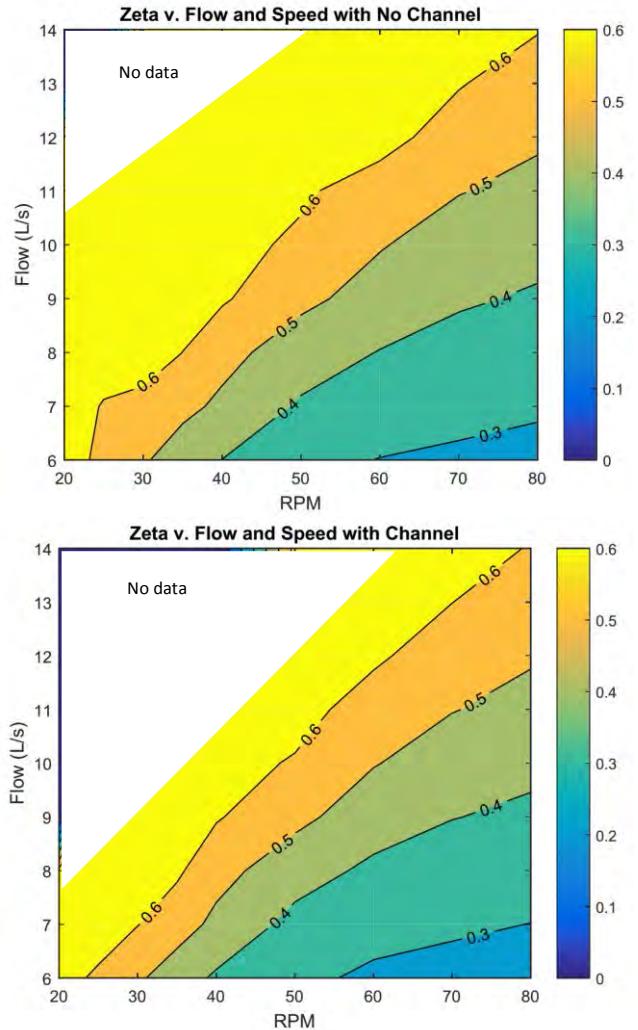

Figure 5. Contours of non-dimensional inlet depth vs. flow and rotation speed without channel installed (top) and with channel in place (bottom)

Simple predictive models were then developed by fitting the measured data (e.g. Fig. 4) to Eqns. 6 and 7. The resulting model for the inlet depth in dimensional form is

$$h_i = \frac{Q}{[15.51 \text{ L}^1 \text{ m}^{-1} \text{ rad}^{-1}] \times \omega} \quad (9)$$

This equation gives a fairly accurate representation of the inlet depth with a mean absolute error of 3.3%. Similarly, a non-dimensionalized relationship was found as

$$\zeta = \frac{\omega Q}{6.84(\omega_m Q_m)} \quad (10)$$

The equation developed for the non-dimensional inlet depth with respect to the flow and speed was found by trial and error. This equation gives a representation of the non-dimensional inlet depth with a mean absolute error of 9.4%.

It should be noted that scaling between lab ASGs and full scale ASGs has been identified as an issue in need of further study [3]. While Eqn. 10 is cast non-dimensionally, it should be noted that entrance Reynolds number and Froude number will

Figure 6. Flow of 6 L/s with no channel (left) and channel (right) at 80 RPM at the inlet of the screw

Figure 7. Flow of 7 L/s with no channel (left) and channel (right) at 80 RPM at the inlet of the screw

Figure 8. Flow of 8 L/s with no channel (left) and channel (right) at 80 RPM at the inlet of the screw

Figure 9. Flow of 9 L/s with no channel (left) and channel (right) at 80 RPM at the inlet of the screw

change with ASG scale, and effects such as the criticality of the entrance flow are not included in this simple model. Therefore, Eqn. 10 should be used with caution in differing situations.

## V. CONCLUSION

The Archimedes screw is a practical device that has been used for many years with various applications. There are still many things to learn about the Archimedes screw. This project

investigated the inlet water depth to required achieve a specific volume flow rate through the Archimedes screw generator over a range of screw speeds. Tests were conducted with both a narrow inlet channel and wider inlet basin at the entrance to the screw. The measured efficiency was higher with the channel than without the channel for the 6 L/s and 7 L/s cases above 40 RPM. Entrance effects at the screw were identified as a possible cause of the reduced efficiency without channel present. There can be other reasons which would require further research into this topic. Relationships were developed for both the dimensional and non-dimensional inlet depth required to provide a specified volume flow rate across a range of rotational speeds. Additional testing of these relationships with data from other Archimedes screws is needed to verify prediction accuracy and determine if the relationships are broadly applicable to all Archimedes screws.

## ACKNOWLEDGMENTS

The work documented in this study was completed as part of a much larger project financially supported by Greenbug Energy Inc. and the Natural Sciences and Engineering Research Council (NSERC) of Canada through the Collaborative Research and Development (CRD) program.

**Abstract** — Proton exchange membrane (PEM) fuel cells have been progressively designed to become suitable for high-temperature operation to achieve further performance improvements. However, the current state-of-the-art fuel cell materials, such as long-side-chain (LSC) ionomers and membranes, are not suitable for high-temperature operation, requiring development and investigation of alternative materials. In this study, short-side-chain (SSC) membrane and ionomer are considered as potential materials, and performance of a membrane-electrode assembly (MEA) manufactured with the SSC ionomer and membrane is experimentally investigated in a scaled-up fuel cell ( $45\text{ cm}^2$ ). Comparison is made with an MEA based on the LSC ionomer and membrane under identical preparation and testing conditions. The catalyst layers (CLs) made of either SSC or LSC ionomer are characterized through scanning electron microscopy (SEM) to understand their surface morphology and microstructure. Results show that the SSC ionomer embedded in the CL provides much more uniform surface morphology and well-proportioned microstructural characteristics than its LSC counterpart. Further, the MEA based on SSC ionomer and membrane demonstrates considerable performance superiorities under all the applied operating conditions. Furthermore, the performance of the MEA based on the SSC ionomer and membrane is found to be less sensitive to changes in operating conditions.

## I. INTRODUCTION

Proton exchange membrane (PEM) fuel cells are an energy-conversion device that converts the chemical energy of hydrogen and oxygen into electricity through electrochemical reactions. In recent years, PEM fuel cell technology has perceptively advanced and reached the early stage of

commercialization, but along with remaining technical challenges to be overcome for further improvements in performance [1–3]. To overcome many of these challenges, fuel cells have been gradually designed to provide trouble-free performance at high operating temperatures.

Fuel cells adopted for low-temperature operation are highly susceptible to carbon monoxide (CO) poisoning, since the adsorption of CO on the catalyst nanoparticles is favored at low temperatures [4]. Thus, high-temperature operation would certainly increase the CO tolerance, which can in turn eliminate prohibitive technological costs through catalyst loading reduction. Further, a fuel cell generates a considerable amount of heat due to electrochemical reactions and associated irreversibilities that needs to be effectively removed to maintain the operating temperature, requiring the development of effective cooling strategies. Thus, if the cell is adopted for high-temperature operation, there will be no necessity for well-planned cooling strategies. Besides, the overall system efficiency can be substantially boosted through recovering of excess heat as steam for direct heating or pressurized conditions. High-temperature operation can also substantially minimize the damage caused by fuel impurities [5], as it does not require high-level of humidification for pressurization, unlike low-temperature operation, and hence the problems associated with water management can also be mitigated. High-temperature operation can also simultaneously increase the diffusion rate of the reactants and simplify detachment of water molecules from the catalyst layer (CL) – which would consequently facilitate the diffusion of the reactants into the three-phase boundary.

Although high-temperature operation provides the aforementioned promises, today's fuel cells perform only well at low temperatures, typically  $60\text{--}80^\circ\text{C}$  [6]. This restriction originates from unsuitability of the archetypal membranes and ionomers for high-temperature operation (i.e., long-side chain (LSC) membranes and ionomers), since they are

typically made of perfluorosulfonic acid. Dupont's Nafion® can be given as a good example of these ionomers and membranes, in which proton transport is governed by "Vehicular" and "Grotthus" mechanisms [7,8] – the mechanisms function only well in the presence of adequate water, unlikely to be seen at high temperatures [9]. Recently, several alternatives, known as short-side chain (SSC) ionomers and membranes, have been introduced into the fuel cell market to make fuel cells viable for high-temperature operation (see [10], for example). The SSC ionomers and membranes can provide favorable thermal transition temperature and ion exchange capacity (EIC), without facing any swelling and/or dissolution [11]. These characteristics also enable them to absorb and retain water even at elevated temperatures. Even though the SSC ionomers and membranes are popular owing to their suitability for high-temperature operation, their cell performance characteristics are still under vehement investigations.

The objective of the present work is therefore to investigate cell performances of the SSC ionomers and membranes under different cell conditions: varied cell temperatures, varied anode and cathode flow rates, and varied anode and cathode relative humidities (RHs). To understand the morphological and microstructural differences between the SSC and LSC ionomers, scanning electron microscopy (SEM) analyses of the CLs made of these ionomers are performed. For comparison, cell performances of the membrane-electrode assemblies (MEAs) with the SSC ionomer-based CLs and membranes are evaluated. Cell performances are compared with those of the MEAs based on the LSC-based ionomers and membranes under the same conditions.

## II. EXPERIMENTAL

The catalyst inks are prepared by using carbon-supported platinum (50% Pt to C ratio, Tanaka Kikinzoku Kogyo K.K.) as a catalyst, either short-side-chain ionomer (Aquivion® with equivalent weight of 790 g eq<sup>-1</sup>) or long side chain ionomer (Nafion (EW) 1100 g eq<sup>-1</sup>) as a binding agent, and 2-proponal (IPA, 99.9%, Sigma®-Aldrich) as a solvent. Proper amount of these materials is mixed in a 20 ml vial, followed by mechanical mixing in an ultrasonic bath for 1 h. The Pt/C/ionomer ratio in the electrodes is kept constant as 3.0/1.0. The ink prepared is deposited onto the selected membrane (either Aquivion E87-05S with equivalent weight of 890 g eq<sup>-1</sup> or Nafion 211) via catalyst-coated membrane (CCM) method. The CCM is then sandwiched between the anode and cathode gas diffusion layers (GDLs, Avcarb GDS 3250) to obtain the MEA. The electrode active areas of the MEAs are 45 cm<sup>2</sup>, and the Pt loadings in the anode and cathode electrodes are kept constant as 0.10 mg/cm<sup>2</sup> and 0.40 mg/cm<sup>2</sup>, respectively. Cell performances of the MEAs based on different ionomers and membranes are obtained under the same conditions: a varied cell temperature, varied anode and cathode flow rates, and varied anode and cathode relative humidities. The polarization curves are obtained by potentiostatically reducing the cell voltage and recording the corresponding current values. Each polarization curve is the average of three polarization curves obtained on three different days, with a standard deviation no more than 5%.

## III. RESULTS AND DISCUSSION

### A. Morphological and Microstructural Characteristics of the Catalyst Layers

Figs. 1 (a) and (b) present the top view of the CLs made of the SSC and LSC ionomers. Both the CLs have similar compact and porous surface characteristics – such characteristics are quite common for the CLs made of Pt-C catalyst. Since the CLs are subjected to gold coating prior to SEM analyses, the cracks apparent on the surface could be associated with the gold deposition. Darker particles in the images show the Pt-C particles, while black holes represent the pores existing in the regions near the surface. Ionomer surrounding the Pt-C particles is shown by lighter contrast in the images. Clearly, both the CLs have homogeneous surface characteristics, but the SSC ionomer-based CL seems to have relatively more open pores, along with virtually no ionomer agglomeration (see Fig. 1(a)), clearly indicating the SSC ionomer's compatibility with the Pt-C particles. Such compatibility could be related to inherent binding characteristics of the SSC ionomer. In contrast, in the LSC ionomer-based CL, the ionomer films are more prone to accumulate and build up bigger ionomer-ionomer agglomerates (see Fig. 1(b)), which is not so desirable, because such agglomerates shrink the available pores that are available for mass transport. Therefore, compared to the LSC ionomer-based CL, the SSC ionomer-based one has relatively more open pores. The pore characteristics of the electrodes based on these CLs are investigated by the Method of Standard Porosimetry (MSP) under identical testing conditions, and results are in good agreement with the SEM images. It is seen that the SSC ionomer-based CL has relatively a relatively higher porosity (73.10%) than the LSC ionomer-based one (68.80%).

### B. Fuel Cell Performance Testing

Scaled-up single cell performance tests are conducted to provide practical insights into the differences between the CLs and membranes made of the SSC and LSC ionomers, under various operating conditions, i.e., different cell temperatures and different flow rates, and relative humidities (RHs) of air and hydrogen. For the virtue of repeatability, each polarization curve is obtained from measurements conducted on three different days under identical conditions. Figs. 2 (a) and (c) compare the polarization and power density curves of the MEAs with the CLs made of two different ionomers – SSC and LSC – as polymeric binders and membranes as a function of varying air and hydrogen flow rates. The other testing parameters are held constant, such that the cell temperature is set as 75°C, while the back pressures and RHs of the hydrogen and air streams are set as 35 kPag and 100%, respectively. Two different flow rates of hydrogen and air are applied. Fixed anode and cathode flow rates of 4.45 and 9.00 l/min applied is named as "high flow", while the anode and cathode stoichiometries of 1.20/2.00 is named as "low flow", throughout the rest of this paper. As evident from Fig. 2 (a), the MEA with the SSC-ionomer based CLs and membrane is relatively less sensitive to flow rates of the reactants. The open circuit voltages (OCVs) obtained from this MEA at the high- and low-flow rates are almost the same, while there is a slight

difference between the current densities when the cell voltage is decreased, such that the maximum power densities obtained under high- and low-flow conditions are  $0.96 \text{ W/cm}^2$  and  $0.94 \text{ W/cm}^2$ , respectively. On the other hand, the MEA with the LSC-based CLs and membrane shows almost the same performance at low current densities under both the high- and low-flow conditions, as seen in Fig. 2 (b). However, a noticeable reduction in cell performance is observed, as the cell is operated at high current densities, and the reactants are supplied under low-flow conditions. This trend indicates that the LSC-based CL and membrane provide condition-dependent performance, further suggesting that the LSC-based components are highly sensitive to changes in operating conditions. This sensitivity probably originates from the dimensional changes in the LSC ionomer; the LSC ionomer potentially experiences severe swelling at high current densities, blocking the pores available for the mass transport. In contrast, the MEA with the SSC ionomer-based CLs and membrane shows almost the same performance, regardless of flow conditions, indicating the stability of this ionomer, which potentially experiences less swelling, as the current density is increased. Such behaviour probably preserves the porosity of the electrode, thus almost the same mass transport capability is

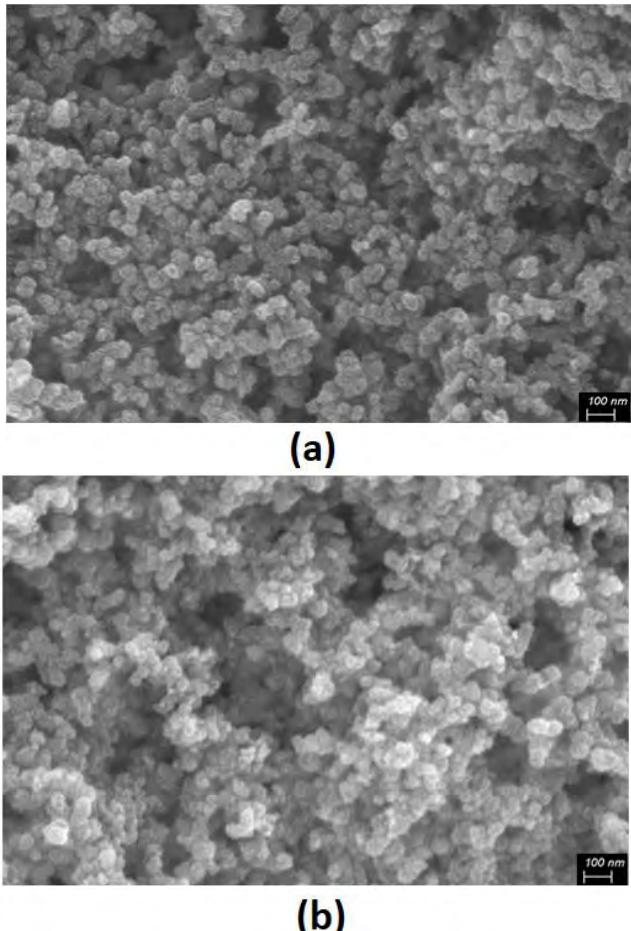

Figure 1. Scanning electron microscopy (SEM) images of the catalyst layers (CLs) made of (a) short-side chain (SSC) ionomer and (b) long-side-chain (LSC) ionomer.

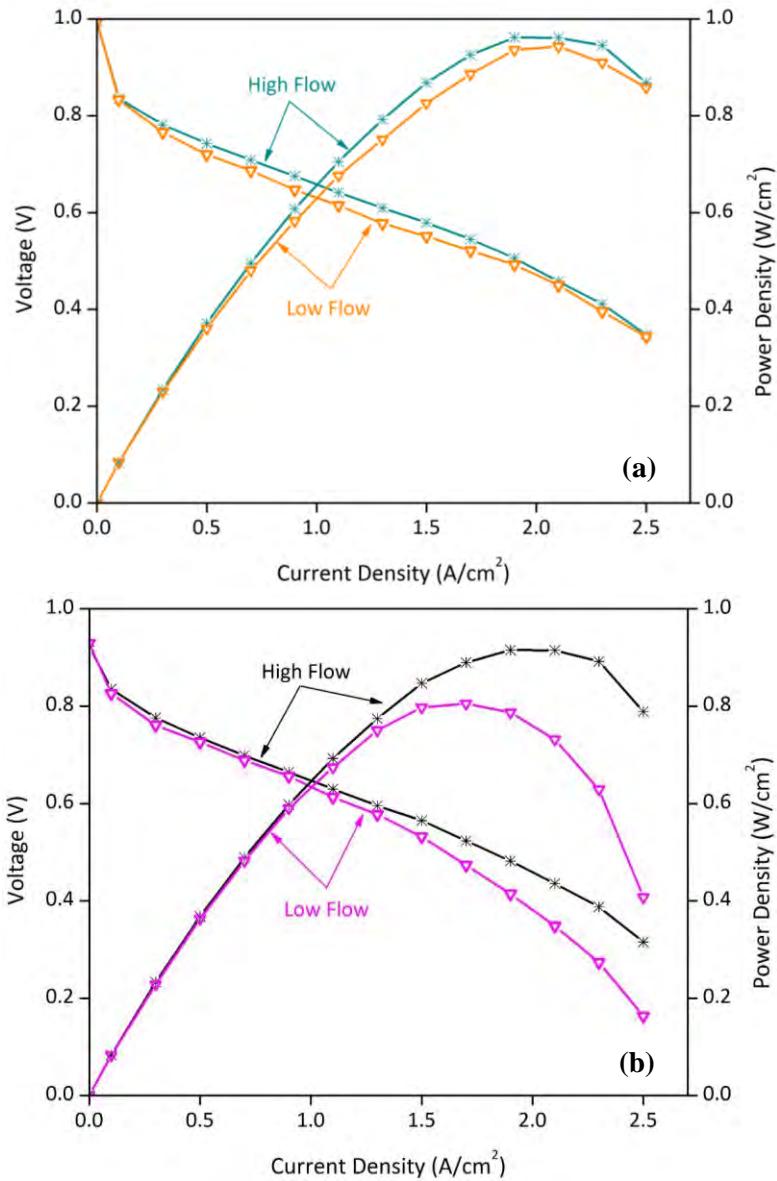

Figure 2. Polarization and power curves of the MEAs with the catalyst layers (CLs) and membranes made of either (a) SSC or (b) LSC ionomers under low and high flow conditions.

maintained, regardless of the flow conditions. By comparing Figs. 2 (a) and 2 (b), it can be concluded that the MEA with the SSC ionomer-based CLs and membrane yields better cell performance under high- and low-flow conditions than its LSC ionomer-based counterpart; such a performance superiority may be attributed to the SSC-based components' higher stability, crystallinity, and proton-transport capability [11].

Cell temperature is another critical parameter affecting the capability of the constituents in dealing with mass, heat, and electron transport. Thus, performances of the MEAs with the CLs and membranes based on either SSC or LSC ionomers are investigated at two different cell temperatures, namely, at  $75^\circ\text{C}$  and  $95^\circ\text{C}$ . These temperatures are specifically chosen, because the LSC-ionomers and membranes demonstrate the best performance at the cell temperature of  $75^\circ\text{C}$ ; meanwhile, it is also known that their effective operation is limited to  $100^\circ\text{C}$ . Hence, temperatures chosen are expected to provide a better understanding of the differences between the SSC and

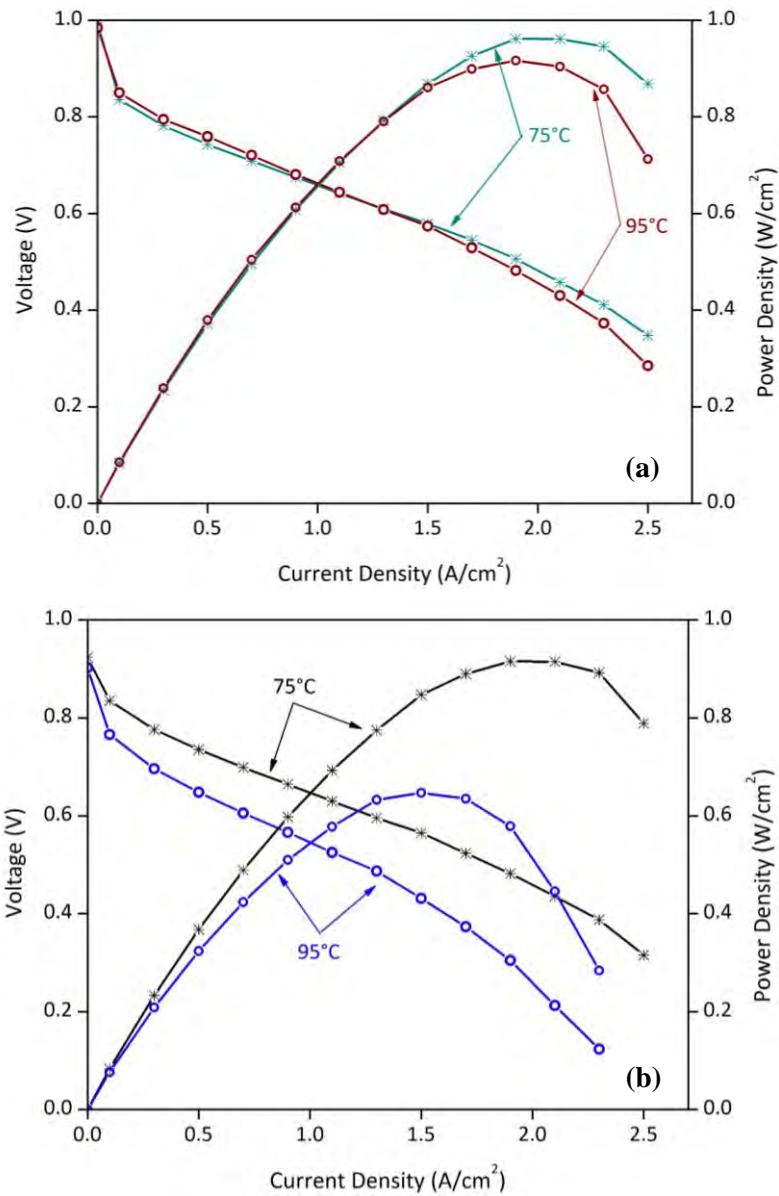

Figure 3. Polarization and power curves of the MEAs with the catalyst layers (CLs) and membranes made of either (a) SSC or (b) LSC ionomers at 75° and 95°C.

LSC ionomers and membranes. For a proper comparison, the other operating parameters are held constant during performance testing, such that the flow rates, back pressures, and RHs of the air and hydrogen streams are set to 4.45 and 9.00 l/min, 35 kPag, and 100%, respectively. As seen from Fig. 3, the MEA with the SSC ionomer-based CLs and membrane shows virtually the same performance in activation-polarization and ohmic-polarization dominant regions, as the operating temperature is increased from 75°C to 95°C, while a slight drop in cell voltage is detected at high current densities. For example, at the constant current density of 2.50 A/cm<sup>2</sup>, the performance of the MEA with the SSC-based ionomer and membrane drops almost 17%, as the cell temperature is increased from 75°C to 95°C. However, the MEA with the LSC ionomer-based CLs and membrane performs quite differently in activation-, ohmic-, and concentration-polarization dominant regions with increasing cell temperature (see Fig. 3(b)). The drop in cell voltage is

even more substantial at high current densities, such that at the current density of 2.30 A/cm<sup>2</sup>, a voltage drop of about 68% is detected. The performance differences between the two MEAs may be better understood by taking a closer look at the maximum power densities obtained at the cell temperatures of 75°C and 95°C. The MEA with the SSC ionomer-based CLs and membrane yields the maximum power densities of 0.96 W/cm<sup>2</sup> and 0.92 W/cm<sup>2</sup> at the cell temperatures of 75°C and 95°C, respectively. However, the maximum power densities obtained at the cell temperatures of 75°C and 95°C from the MEA with the LSC ionomer-based CLs and membrane are 0.92 W/cm<sup>2</sup> and 0.65 W/cm<sup>2</sup>, respectively. Clearly, increasing cell temperature results in severe deterioration in performance of the MEA with the LSC ionomer-based CLs and membrane, but only slight deterioration in performance of the MEA with the SSC ionomer-based CLs and membrane – a finding indicating that the SSC ionomer-based cell components are far less sensitive to changes in the operating temperature; or alternatively, the proton transport in the SSC ionomer and membrane is effectively maintained at elevated temperatures. This behaviour could be related to the high crystallinity and better proton transport capability of the SSC ionomer at elevated temperatures. Further, owing to their higher crystallinity and lower equivalent weight, the SSC ionomer and membrane experience less swelling, which is not only useful for preserving the interfacial characteristics at the three-phase boundary but also for maintaining the electrode microstructural characteristics over a wide range of cell temperature. Furthermore, due to their lower equivalent weight, the SSC ionomer and membrane probably retain adequate water, which in turn enables them not to suffer from membrane dehydration, hence function well even at elevated temperatures. In the case of the MEA with the LSC ionomer-based CLs and membrane, high-temperature operation probably leads to degradation in the LSC-ionomer based components, i.e., excessive swelling, and thus both the interfacial and microstructural characteristics may not be maintained at high cell temperatures. The joint effect of these changes in turn leads to significant deterioration in the cell performance in both ohmic- and concentration-polarization dominant regions (see Fig. 3).

The effect of the RHs of the air and hydrogen streams on performances of the MEAs with the CLs and membranes made of either SSC or LSC ionomers are also investigated. Fig. 4 shows the power and polarization curves of the MEAs under the RHs of 55% and 100%. Clearly, a decrease in the RHs of the air and hydrogen streams negatively impacts performances of both the MEAs. However, the MEA with the SSC ionomer-based CLs and membrane seems to experience less performance drop with decreasing RHs, compared to the one with the LSC ionomer-based CLs and membrane. For example, the MEA with the SSC ionomer-based CLs and membrane experiences a cell voltage drop of 13% at the constant current density of 1.50 A/cm<sup>2</sup>, as the RHs are decreased from 100% to 55%, while drop in cell voltage of the MEA with the LSC-based CLs and membrane is almost 46%. The maximum power densities obtained for the SSC- and LSC-based MEAs at 55% RH are 0.76 W/cm<sup>2</sup> and 0.55 W/cm<sup>2</sup>, respectively. A noticeably better cell performance of the SSC-based MEA is probably due to the higher water-retention capability of the SSC ionomer and membrane,

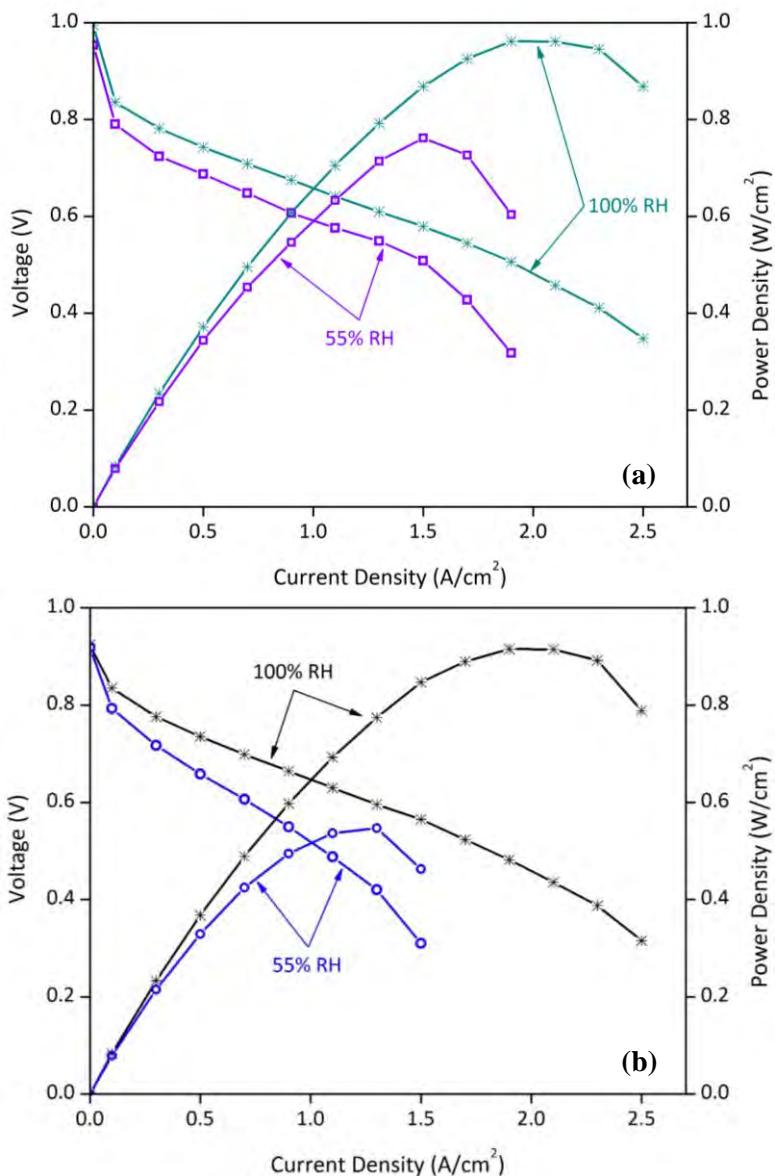

Figure 4. Power and polarization curves of the MEAs with the catalyst layers (CLs) and membranes made of either (a) SSC or (b) LSC ionomer under different RHs of air and hydrogen streams.

compared to their LSC counterparts, since being able to operate well under low-humidity conditions requires effective proton-transport capability. This advanced proton-transport capability is probably due to its lower equivalent weight than the LSC ionomer, which provides relatively higher number of hydrophilic sulfonic acid groups. The presence of more sulfonic acid groups inside both the ionomer and membrane yields effective proton transport even when the cell is operated under low RHs, thus the cell suffers less from ohmic polarization and performs much better.

#### IV. CONCLUSIONS

In this study, the effect of ionomer structure in the membrane and catalyst layer (CL) on the performance of proton exchange membrane (PEM) fuel cells is experimentally investigated in a scaled-up cell ( $45\text{ cm}^2$ ). Short-side-chain (SSC) ionomer and membrane are applied in a membrane-electrode assembly

(MEA), and cell performance of this MEA is investigated over a wide range of operating conditions: different cell temperatures ( $75^\circ\text{C}$  and  $95^\circ\text{C}$ ), air and hydrogen flow rates (low- and high-flow conditions), and air and hydrogen relative humidities (100% RH and 55% RH). Comparison is made with an MEA based on long-side-chain (LSC) ionomer-based CLs and membrane. The morphological and microstructural characteristics of the SSC ionomer-based CLs are investigated, and comparison is made with the LSC ionomer-based CLs. The pore characteristics of the electrodes with these CLs are also investigated. Results indicate that the SSC ionomer not only offers more uniform surface morphology and microstructure, but also provides desirable coverage characteristics; adequate Pt-C coverage without blocking the pores. Thus, the SSC ionomer-based electrode has a relatively higher porosity (73.10%) than the LSC ionomer-based electrode (68.80%). The performance test indicates that the MEA with the SSC ionomer-based CLs and membrane shows superior performance than the one with the LSC ionomer-based CLs and membrane under all the studied conditions. In particular, the SSC ionomer and membrane are found to be quite suitable for high-temperature operation, due to their favorable water-retention capability (hence proton-transport capability) at high temperatures. Lastly, the MEA based on SSC-ionomer and membrane is found to be less sensitive to variations in operating conditions.

# Thermal Management for Efficient Fast Refill of Compressed Natural Gas

Aiqing Lan, Guoyu Zhang, Ri Li\*, Joshua Brinkerhoff

School of Engineering  
The University of British Columbia, Okanagan campus  
Kelowna, Canada

**Abstract**— As an alternative fuel, compressed natural gas (CNG) plays an important role fueling transportation. Like driving other types of vehicles, drivers of CNG-powered vehicles prefer to refill on-board CNG tanks in a short time, which is referred to as fast refill. Accompanied by a fast pressure increase in the cylinder, temperature will also rise significantly due to re-compression work with limited time for the heat to dissipate. This phenomenon ends with a common problem referred to as under-refill, which means less mass filled than the standards. This article presents a summary of the research works to solve this problem and improve fill efficiency by thermal management. Two-dimensional axisymmetric CFD (computational fluid dynamics) simulations of unsteady, compressible, turbulent flow in fast refill process are conducted. Three different types of thermal management concepts are discussed, including active cooling, pre-chilling and real-time chilling. The results show that thermal management is a promising way to mitigate the under-refill problem with a maximum of 7% increase of fill efficiency achieved by active cooling. These provide guidelines for future research on improving fill efficiency through cooling strategies in which real-time chilling should be firstly focused on.

## I. INTRODUCTION

Natural gas [1] has become an important alternative fuel for transportation. The number of natural gas vehicles (NGVs) has escalated speedily at an annual rate of 24% since 2005 [2] and now it powers roughly 22.4 million vehicles around the world [3]. Due to the comparatively low density, natural gas is carried either as liquefied low-temperature LNG (liquefied natural gas) or as high-pressure CNG (compressed natural gas) with the latter currently having higher market share [4].

For CNG fuelled vehicles, a common problem is under-refill when the on-car gas cylinder is fast filled (<5 mins) at CNG station. It is caused by temperature rise in the filling process followed by earlier reaching the standard pressure. This means less mass of CNG filled as the temperature inside

finally recovers to ambient temperature and the pressure inside drops. The temperature rise is a result of the heat generated by recompression work and inadequate time for the heat to be removed out naturally through cylinder wall with material of low conductivity. It is at least about 10°C above the ambient temperature at the end of fast refill [5]. Fill efficiency is thus typically only 80% for ambient temperature at 20 °C when the efficiency is defined as the ratio of the actual filled mass to the capacity at the rated pressure and ambient temperature [6].

To mitigate the under-refill problem, the simplest idea is to over-pressurise the cylinder when refilling it, which has a risk of safety issues. The second way that has been considered is to develop good strategy with modified feeding conditions to minimize the re-compression heat. Farzaneh-Gord et al. [7] showed that existing procedure proposed [8] requires appropriate controlling facilities, limiting the applicability. Compared to the above two methods, thermal management is a more promising way to achieve higher filling efficiency, in which cooling technique and strategies are introduced to lower the CNG cylinder's temperature before or during the refilling process. Zhang et al. [9] numerically investigated an active cooling concept and achieved a 7% increase of fill efficiency at the expense of utilizing a simple cooling loop, which shows good prospect for thermal management in improving the fill efficiency of CNG.

There are very few previous studies focusing on thermal management of efficient fast refill of CNGs. The article presents a summary of the work done on thermal management to improve fill efficiency of CNG cylinder, involving three types of thermal management method: active cooling, pre-chilling and real-time chilling. The effects of these methods on thermal behaviour and fill efficiency of the CNG fast refill process are presented and discussed.

## II. NUMERICAL MODEL AND THERMAL BEHAVIOUR OF THE FAST REFILL PROCESS

To quantify the temperature rise and its effect on the fill efficiency, a 2-D CFD model is built for the fast fill process, employing ANSYS Fluent®, a commercial CFD package. Gas inside the cylinder is modelled as an axisymmetric flow. For simplicity, the working fluid is pure methane with real

\*Corresponding author: sunny.li@ubc.ca

gas properties determined using the Redlich-Kwong equation of state [10]. The standard  $k-\epsilon$  turbulence model with enhanced wall treatment is applied with modified coefficients ( $C_{le}=1.52$ ,  $C_{te}=1.92$ ,  $C_\mu=0.09$ ) [11]. As shown in Fig 1, model geometry is based on a type-III cylinder which is one of the four types of cylinder commonly used for natural gas vehicles. The type-III cylinder wall consists of the aluminum liner and the carbon fiber wrap. The dimensions of the cylinder follow the model used by Nahavandi [12]. The gas enters the cylinder through a converging nozzle that has an entrance diameter of 0.01 m and an exit diameter of 0.005 m. Figure 2 shows the unstructured mesh applied in conventional fast filling case. Mesh is refined near the inlet region where there expect big gas property changes and gradients.

A convection boundary condition is imposed on the outer wall of the cylinder with a constant heat transfer coefficient of 10 W/m<sup>2</sup>·K, and the ambient air temperature is kept constant at 300 K throughout the filling process. At the inner wall, a no-slip boundary condition is imposed. The initial pressure of the gas inside the cylinder is 2 MPa. A constant total enthalpy boundary condition is applied corresponding to a total temperature of 300 K. A total pressure that linearly ramps from 4 to 20.6 MPa in the first 3 seconds of the fill process and then is maintained at 20.6 MPa for the remainder of the fill. The refill is considered to end at time  $t$  when the average gas pressure  $p_g(t)$  satisfies the following equation:

$$\frac{p_g(t) - p_i}{p_s - p_i} = 95\% \quad (1)$$

where  $p_s$  and  $p_i$  are the total supply pressure and initial pressure, respectively.

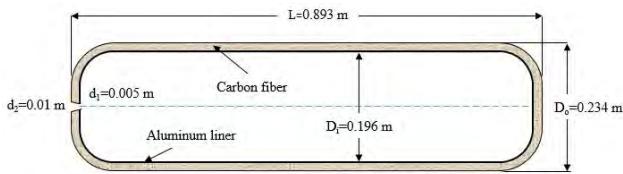

Figure 1. The computational domain for conventional fast filling process

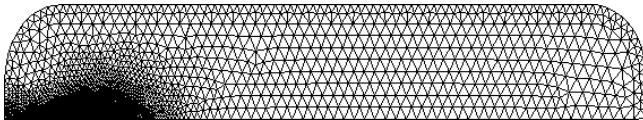

Figure 2. The computational mesh used for fast refill process without cooling

Figures 3-4 present the temporal variation of the average temperature and mass filled, respectively, within the cylinder during conventional fast refill process. The temperature rises quickly in the first 5 seconds, and after that, the temperature increase slows down and ends at a final temperature 29K higher than the ambient temperature. Totally, 3.35 kg natural

gas is filled into the cylinder. Potential of reducing the final temperature and increasing the final mass can be seen related to different thermal management concepts.

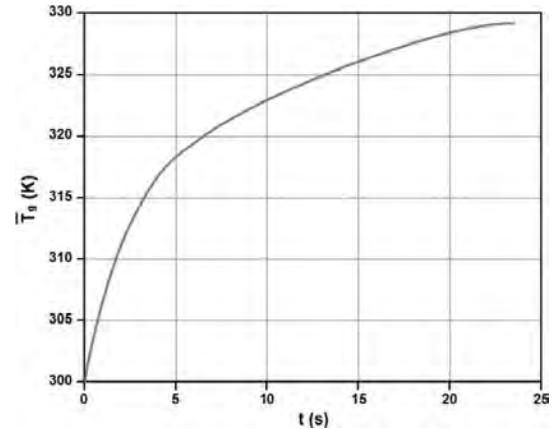

Figure 3. Dynamic change in gas average temperature

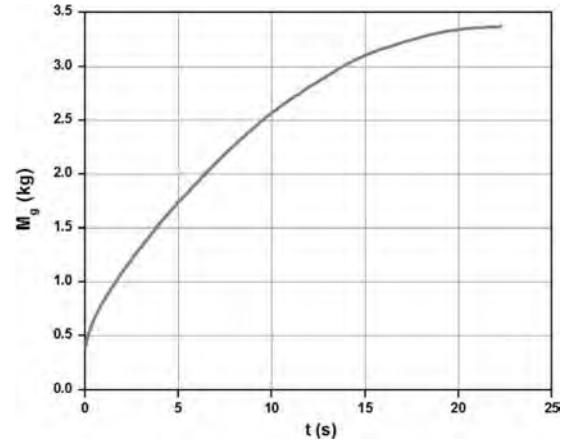

Figure 4. Dynamic change in mass filled

### III. IMPROVING FILL EFFICIENCY BY ACTIVE COOLING

In the concept of active cooling, the natural gas is filled and cooled simultaneously in the filling process with coolant loop used to help remove heat to the ambient environment. There are two important features of the active cooling. The first is that the feeding flow rate of coolant can be adjusted so it can actively adjust the target temperature of the cooling, which is different from some passive heat removal device as heat pipes. The second feature is that the ultimate low temperature it can reach is the ambient temperature.

The heat removal performance of active cooling is investigated by using 2-D axisymmetric CFD simulation on a simplified model with location effects considered. The cooling system is expected to be composed of cooling coils installed inside the cylinder (Fig 5) which are connected to a coolant pump and a heat exchanger, which are not displayed in Fig 5. For simplicity, only the inside cooling coils are considered in the model (Fig 6) and they are placed in the front or back part of the cylinder. A uniform and constant temperature 300 K is applied at the coil surface. It represents

the ideal extreme temperature that the cooling loop can reach assuming an ambient temperature of 300K.

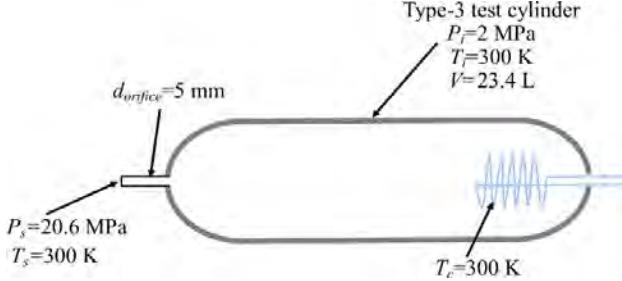

Figure 5. Schematics on the active cooling concept

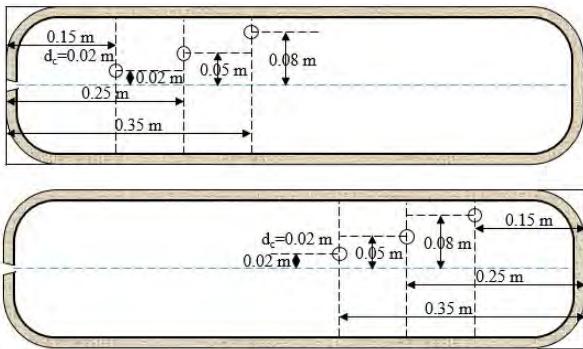

Figure 6. The computational domain for filling process with active cooling in the front and back

Figures 7-8 present the temporal variation of the average gas temperature and mass within the cylinder during the fill, respectively, with active heat removal via the cooling coils in the front and the back. Comparison has been made with conventional fast refuelling without cooling. As shown in Fig 7, different from the monotonic increase of the temperature for the case without cooling, the temperature for the active cooling cases starts to go down after the first 5 seconds' increase. This results from a stronger effect of cooling than that of recompression heating. The maximum average temperatures are 313.3K and 310 K, respectively, for front cooling and back cooling, while the maximum value could be as high as 329K for no cooling. Through active cooling, 7% more mass of gas is filled into a cylinder when cooling happens at the back part of the gas cylinder, while the fill efficiency only increases by 4.5% when the cooling coils are placed at the front. Apparently, fast refill is more efficient when active cooling is conducted in the back of the cylinder. These improvements are accompanied by longer fill time, which, however, is still comparable to that of conventional liquid fuel.

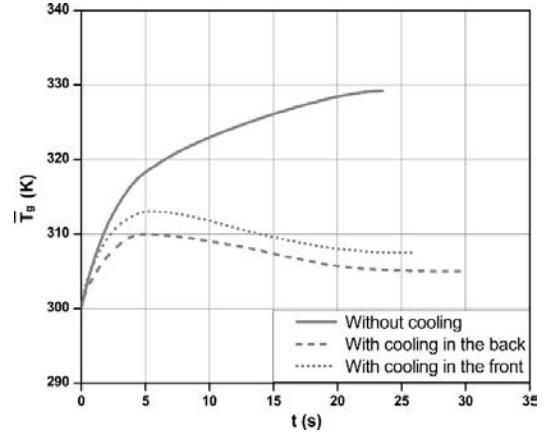

Figure 7. Dynamic change in gas average temperature

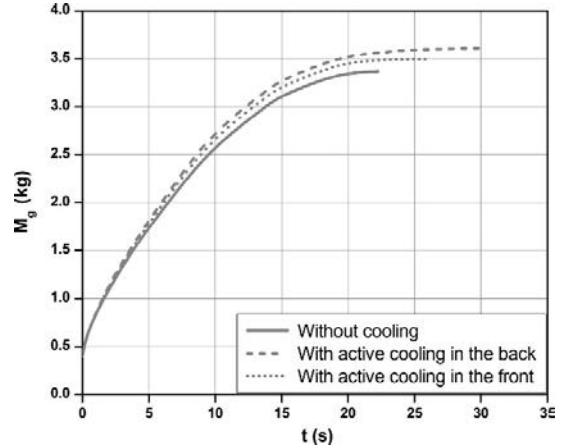

Figure 8. Dynamic change in the mass of gas filled

#### IV. IMPROVING FILL EFFICIENCY BY PRE-CHILLING

Although active cooling can help improve the fill efficiency by 7%, there are still two limitations for this method. Firstly, the coolant temperature is no lower than the ambient temperature, leading to limited maximum cooling ability. Secondly, excessively high pressure difference across the coil wall requires material of high mechanical strength and possible leakage will reduce the fuel quality. A new concept named pre-chilling is then considered in this section. As displayed by Fig 9, a pre-chilled mass block made of aluminium alloy is designed to be placed in the back side of the cylinder. There is a coolant circulation to chill the mass to a temperature below the ambient temperature prior to the beginning of gas filling. The chilled mass is then responsible for cooling the gas filled in the filling process. The liquid refrigerant (R134a) from truck air conditioning system [13] can be used to cool down the aluminium mass prior to the filling process.

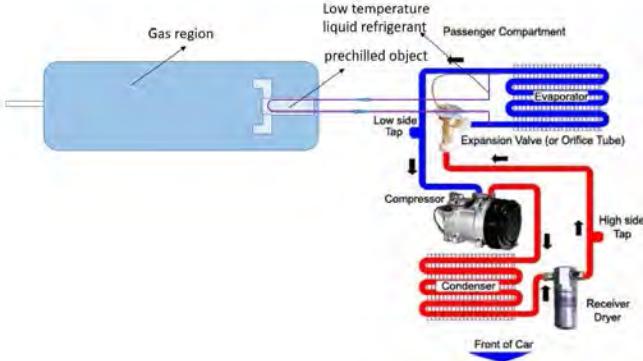

Figure 9. Schematic diagram of pre-chilling achieved by refrigerant circulation

The geometry of model used in simulation is designed with fins, as displayed in Fig 10. The pre-chilled mass takes 5% of the gas volume. Saturated liquid refrigerant flow with temperature of  $-1.2^{\circ}\text{C}$  and pressure of 275.79 kPa [14] is used to chill the mass with 4 different refrigerant mass flow rates tested ranging from 0.0035 kg/s to 0.014 kg/s. For comparison, another case is also simulated with a constant temperature boundary condition ( $-1.2^{\circ}\text{C}$ ) applied at the wall of the channel, which corresponds to infinite flow rate.

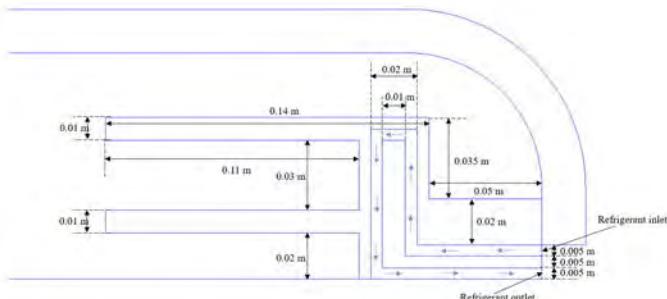

Figure 10. Dimension and location of the redesigned pre-chilled device

The first step in simulation is to pre-chill the mass attached to the bottom before starting gas filling. The change of average temperature of the pre-chilled mass is plotted in Fig 11. The duration of the chilling is 30 minutes and increasing the refrigerant flow rate means lower temperature within a fixed time. For this ideal case with infinite flow rate, the heat sink can be chilled to  $0^{\circ}\text{C}$  in only 5 minutes, this is the shortest time that pre-chilling takes with current inlet conditions in the model.

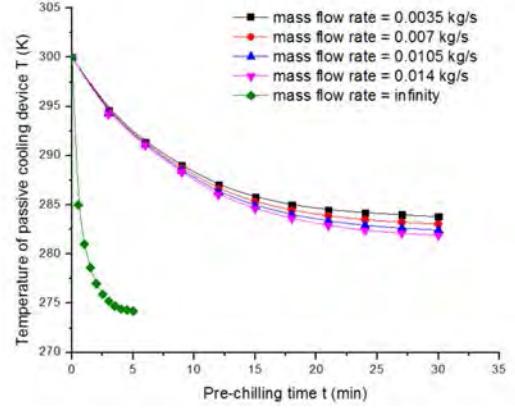

Figure 11. Average temperature of the pre-chilled device vs. pre-chilling time

Second step is to fill the CNG into the cylinder with refrigerant loop stopped. Two pre-chilled cases are presented in Fig. 12. In case (a), the heatsink has been pre-chilled by a refrigerant mass flow rate of 0.0035 kg/s for 30 minutes. Case (b) is pre-chilled by constant boundary temperature for 5 minutes. At the end of the refill, compared with the case without cooling, pre-chilling achieved with constant boundary temperature increases the filled mass by 6.6%, while the number drops to 5% for case (a), for which a refrigerant flow rate of 0.0035kg/s is applied. This indicates that pre-chilling is also an effective way to improve fill efficiency.

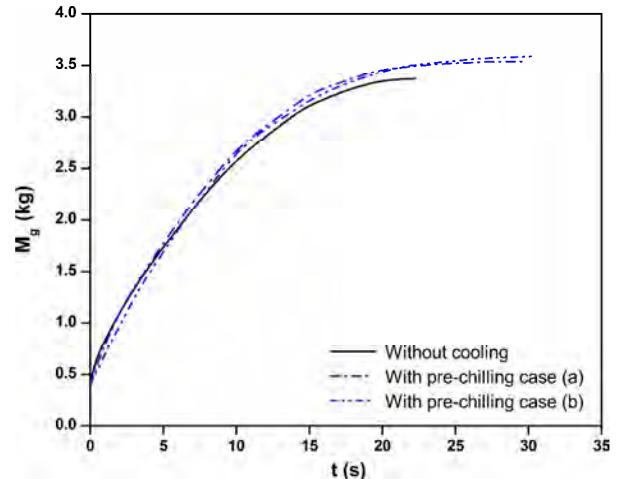

Figure 12. Dynamic change in the mass of gas filled

## V. IMPROVING FILL EFFICIENCY WITH REAL-TIME CHILLING

One disadvantage for pre-chilling is that the total filling time exceeds the fast refill regime. Increasing mass flow rate to a high enough value is a possible way to reduce the time, but mass flow rate can also be restricted by the power of coolant supplying system. A new concept called real-time chilling is proposed to avoid the long pre-chilling time. While the gas inside the cylinder is heated by compression

work done by the incoming gas flow, it is possible to utilize the expansion (the Joule–Thomson effect) of another flow of CNG outside the cylinder to cool the gas inside the cylinder. As shown in Fig. 13, there is cavity at the outside of the rear heat sink. Another flow of natural gas only for chilling expands with gas temperature lowered. The low temperature expansion flow removes heat from the gas inside the cylinder actively. This chilling flow starts simultaneously with the filling flow into the cylinder. The low pressure chilling flow coming out of the cavity can be transported to other natural gas systems or re-compressed to the gas reservoir. This concept and related model still need to be investigated as a main future work to verify its effect on efficient fast refill.

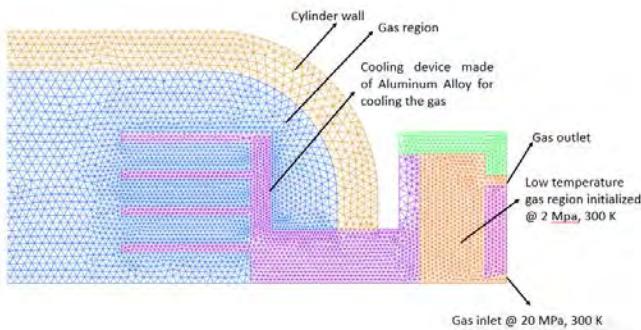

Figure 13. The rear part of the cylinder model for real-time chilling

## VI. CONCLUSION

In this paper, in terms of improving the fill efficiency of CNG fast refill, three different thermal management methods are presented with some research results displayed, giving a whole map of cooling strategies including the effects on the thermal behaviour and fill efficiency of the CNG fast refill process.

Some conclusions can be drawn from the results of research on active cooling and pre-chilling. Both methods can effectively increase the fill efficiency of the fast refill process for CNG. For active cooling, the best improvement that can be achieved with the current design is 7%, which is higher than 4.5% with active cooling conducted at the front part of the cylinder. This location effect indicates that it is better to apply cooling to the rear part of the cylinder. For pre-chilling, time spent and results from this method are dependent on the mass flow rate of supplying refrigerant flow when inlet conditions are fixed. For the ideal case with infinite flow rate, the pre-chilling can achieve a maximum improvement on fill efficiency by 6.6%, which is slightly lower than that of active cooling. Pre-chilling also takes much more time to cool the thermal mass before filling the cylinder, which is less time-economic than active cooling.

Compared with the first two methods researched, the real-time chilling concept can balance the time efficiency and cooling effects. It presents good prospect and need further work to verify this idea. Among the three thermal

management concepts discussed in this paper, each of them has its advantages and disadvantages. Proper thermal management method should be chosen based on comprehensive assessment of the compatibility and practicality of each method in a specific scenario.

Current research has provided important guidelines for thermal management on efficient fast refill combining the advantage of acceptable computation time by using 2-D axisymmetric model. In the future, real-time chilling concept will be firstly examined based on current model. After that, as the 2-D model may cause abnormal shape of the coolant loop and the fins of the heat sink, a 3-D model will be built for better realization of the cooling strategies and better understanding of the thermal and flow field. Also, basic experiment will be done to verify certain thermal management concepts.

# **Energy Benefits of Integrating Transportation Energy with a Net Zero Energy Solar Building Using Captured Waste Hydrogen from Electrochemical Plants and Biogas from Various Bio Gasification Processes**

Shahryar Garmsiri, Marc A. Rosen

Faculty of Engineering and Applied Science  
University of Ontario Institute of Technology  
Oshawa, Ontario, Canada

**Abstract**— When considering a net zero energy building, the transportation energy sector is often viewed as a separate entity. Currently, hydrocarbons are the main source of energy used in the transportation sector. In an effort to reduce greenhouse gas emissions, more automotive manufacturers are moving towards alternatively fueled vehicles that are electric or fuel cell powered. Electrochemical and other process industries frequently vent or flare hydrogen into the atmosphere and most community municipal waste is buried underground (landfill) or burned to generate electricity resulting in greenhouse gas emissions. Energy benefits and the methods of achieving net zero energy status for a solar building and reduction of greenhouse gas emissions through the integration of these waste streams and transportation energy are discussed.

## I. INTRODUCTION

Hydrocarbon fuels that are responsible for a relatively large proportion of the overall greenhouse gas (GHG) emissions are the main source of energy used in the transportation sector. An overview of 2015 reported emissions by sector was published in 2017 by Environment and Climate Change Canada [1]. Emissions reported in 2014 by sector in the City of Toronto [2] indicate that the transportation sector contributes 35% of overall emissions while 53% of the overall emissions are produced by buildings. The City of Toronto has committed to reducing GHG emissions by 80% of 1990 levels by 2050, through increases of renewable and district power generation [2]. To this end the City of Toronto has developed a zero emissions building framework, which targets building performance to near-zero emissions level by the year 2030 [2].

A net zero energy building (NZEB) is a building that offsets all of its energy consumption by using renewable energy sources within the building's built environment [3]. Most net zero energy buildings use the electrical grid as a buffer to avoid the need for energy storage. The building's energy demand is typically generated on-site through a

renewable energy source such as solar. A net zero energy building's performance is increased through efficiency measures and waste energy recovery so that the balance of energy needed within the building, both thermal and electrical, is usually met by the renewable source of energy. However, solar energy is intermittent due to weather conditions and the balance is not met through the renewable source of energy; hence the building relies on the electrical grid for the energy demand.

Climate change has become an important topic world-wide, as have reduction targets for GHG emissions. The transport sector is identified as one of the key sectors contributing to climate change [4,5]. Along with the growing gap between oil supply and demand globally, and the need to reduce GHG emissions, the use of alternative fuels and energy efficiency improvements are receiving increased attention [6].

In an effort to meet emission targets set out by each country, alternative methods of energy production must be considered such as solar power, wind energy, bio gasification, and waste energy recovery techniques. Although hydrogen energy technology has received much attention in the last decade with significant progress in performance, reliability, cost and efficiency, producing hydrogen from fossil fuels is not a clean, sustainable approach. There are also economic, intermittency and efficiency implications of hydrogen production from renewable energy sources. One method of addressing these implications is through the recovery of waste energy in a community.

Electrochemical and other process industries such as chlor-alkali plants frequently vent or flare hydrogen process gas into the atmosphere. The sodium chlorate used as a reactant for water purification and paper bleaching processes in a chlor-alkali plant produces hydrogen as a by-product. This waste hydrogen can be captured and purified for use in a hydrogen proton exchange membrane (PEM) fuel cell for transportation or stationary power generation.

A study of the economics of hydrogen production, storage and delivery was conducted by International Energy Agency (IEA) [7] for transportation use. The environmental benefits were outlined, with key points demonstrating the potential benefits of renewable hydrogen production, and utilization for

various modes of transportation. The Integrated Waste Hydrogen Utilization Project (IWHUP), the world's first waste-hydrogen capture system for fuel cell applications, was installed at a chemical plant in North Vancouver, British Columbia [8]. Additional waste-hydrogen capture systems are in development.

When considering a net zero energy building or community, the transportation energy sector is often viewed as independent from the building sector of the community. In this paper, the integration of transportation energy with a net zero energy building utilizing captured waste hydrogen from chlor-alkali plants and biogas from various bio gasification processes is examined.

Energy benefits and the methods of achieving net zero energy status for a solar building, and the reduction of greenhouse gas emissions through the integration of transportation energy are described. The objective of this paper is to demonstrate usable waste gas reduction and community waste energy recovery for use in the building and transportation sectors while utilizing a fuel cell vehicle's energy storage and production capabilities.

## II. BACKGROUND

### A. Net zero energy building

A net zero energy building (NZEB) is a building that offsets all of its energy consumption by using renewable energy sources within the building's built environment [3]. Net zero energy performance may be achieved by a combination of reducing building energy demand and generating electricity through the increased use of renewables, efficiency measures, waste energy recovery methods and integration of transportation energy.

Most net zero energy buildings use the electrical grid as a buffer to avoid the need for energy storage. The building's energy demand is typically generated on-site through a renewable energy source such as solar. Because solar energy remains intermittent due to the weather conditions, it may not be considered as a dependable source of energy to meet the building's energy demands.

### B. Solar energy

In a photovoltaic (PV) module, a portion of the incident solar energy is converted into useful electricity, while the rest is either reflected or dissipated as heat. There are two methods of installing PV modules on a building. A building added photovoltaic (BAPV) system has the PV modules installed as an addition to the building envelope. A building integrated photovoltaic (BIPV) system has the PV modules forming part of the building installation. When adding a heat recovery system for module cooling purposes and to capture generated waste heat by the BIPV solar module, the system is referred to as a building integrated photovoltaic/thermal (BIPV/T) system. The BIPV/T system not only generates electricity, but also provides useful heat that allows for a reduction in the building heating loads [9,10].

### C. Electrochemical chlor-alkali industry plants

In a chlor-alkali facility, chlorine ( $\text{Cl}_2$ ) and sodium hydroxide ( $\text{NaOH}$ ) are manufactured by electrolysis of brine, a salt solution [11]. The main technologies applied for chlor-alkali production are mercury cell, diaphragm and membrane cell electrolysis, mainly using sodium chloride ( $\text{NaCl}$ ) as feed [11]. Each of these processes represents a different method of keeping the chlorine that is produced at the anode separate from the caustic soda and hydrogen that are produced at the cathode.

The inputs are primarily salt and water; acids and chemical precipitants are used to remove impurities and output chlorine and caustic solution [11]. The main pollutant outputs are chlorine gas emissions to air, free oxidants to water, spent acids, cooling agents, and impurities removed from the input brine salt and hydrogen gas.

### D. Waste hydrogen gas

The chlor-alkali industry produces chlorine and caustic solution (sodium or potassium hydroxide) simultaneously through decomposition of salt in water. The basic principle in the electrolysis of a sodium chloride solution occurs at the anode and cathode. At the anode, chloride ions are oxidized and chlorine ( $\text{Cl}_2$ ) is formed. At the cathode, hydrogen ( $\text{H}_2$ ) and hydroxide ions ( $\text{OH}^-$ ) are formed by the reaction of the sodium in the amalgam with water.

During chlorine gas compression and cooling, most of the chlorine gas is condensed. However, by diluting the remaining chlorine gas with air, the concentration of non-condensable gases such as hydrogen can be kept below the explosion limit. The remaining gases after liquefaction have to be purged from the system and are led to a chlorine absorption unit. The remaining impurities in the gases in the chlorine absorption unit is absorbed and the remaining gas is 97.5–99.9% pure hydrogen [12].

This pure hydrogen gas can be used in hydrogen proton exchange membrane (PEM) fuel cells for stationary or vehicle use applications. Often times the gas is either sold to merchants or vent/flared into the atmosphere. In this study, the focus is made on the vent/flared hydrogen gas into the atmosphere.

In a chlor-alkali electrochemical plant, hydrogen is produced in a fixed ratio of 28 kg per tonne of chlorine used or approximately 1200 kg per day ranging up to approximately 2700 kg per day [11].

### E. Biogasification processes

There are a variety of ways to use wastes and to convert them into useful energy. Some of these include gasification processes that uses wood or coal, and anaerobic digesters that use biodegradable material such as municipal solid waste and sewage sludge to create a biogas that is useful for combustion to generate power. This useful gas can be further processed and converted to hydrogen to be used in fuel cells.

Gasification is a process of converting organic materials into carbon monoxide ( $\text{CO}$ ), hydrogen ( $\text{H}_2$ ), and carbon dioxide ( $\text{CO}_2$ ). The process involves burning of solid fuels like wood or coal to complete combustion with inadequate air supply,

creating an output gas called synthesis gas with potential for combustion. The power produced from gasification and combustion of the synthesis gas obtained from biomass is considered to be a source of renewable energy [13,14,15,16]. This synthesis gas can further be processed in a steam reformer for subsequent conversion to hydrogen.

Some examples of demonstration projects include the 20 MW synthesis gas from forest residues by GoBiGas project in Gothenburg, Sweden [18], a 2 MW electricity production facility in Güssing, Austria by the Renewable Energy Network Austria (RENA) [19] and the US Air Force in Hurlburt Field, Florida [17].

#### *F. Integration of transportation and renewable sources of energy*

Several studies concerning the possibilities of integrating renewable sources of energy with the transportation sector have been pursued. Some of these studies include electricity produced by wind turbines in combination to plug-in hybrid vehicles (PHEVs) [20], leading to the potential of using electric vehicle battery storage as a medium for excess energy produced by wind power [21]. Similarly, solar photovoltaic (PV) systems have received attention in tandem with electric vehicles (EVs). A study conducted in Germany [22] demonstrated the potential of CO<sub>2</sub> emissions reduction in the transportation sector when using EV's paired with solar PV's.

The method of integrating transportation energy with a building is referred to as vehicle-2-grid (V2G) [23,24]. Although most of the research is based on EVs, attention is required for fuel cell vehicles (FCV) as well. A FCV can generate power using its onboard stored hydrogen as compared to an EV that can be seen simply as a storage medium that cannot produce electricity. An advantage to a FCV over an EV is the potential of storing a greater amount of energy in compressed gas form and generating electricity using the onboard fuel cell. FCVs can also be refueled much faster than EVs.

There are several benefits when integrating transportation energy to achieve a net zero energy balance for a building. The integration using a FCV helps to eliminate the need for centralized large power generators, and provides a vector for the utilization of industrial waste hydrogen gas, synthesis gas and biogas from gasification and anaerobic digester processes converted to hydrogen during a steam reformation process.

#### *G. Fuel cell systems*

There are several types of fuel cells that can be used for stationary and vehicle applications. The proton exchange membrane fuel cell (PEMFC) capitalizes on the essential simplicity of the fuel cell. Most biogases have low heating values, due to the high levels of carbon oxides and nitrogen, which are not attractive for gas engines. The molten carbonate fuel cell (MCFC), solid oxide fuel cell (SOFC), and phosphoric acid fuel cell (PAFC) are able to handle very high concentrations of carbon oxides [25].

Although there are several fuel cell types that can be used for creating electrical power, the PEM fuel cell is considered

more advantageous than MCFC, SOFC and PAFC types. This is due to the limitations MCFC, SOFC and PAFC have over the PEMFC. The limitations are that MCFC, SOFC and PAFC operate at higher temperatures and are not ideal for stop and go applications. But a PEMFC is not limited to the high operating temperatures and has the capability of stop and go operation, making it an advantageous fuel cell for vehicle application [25].

### III. ANALYSIS AND METHODOLOGY

Modelling community and transportation energy use can present several challenges, such as acquiring and generating appropriate input data based on highly variable energy usage patterns. How and when occupants exercise their energy needs is a key consideration for all green building planning, design, operations and decision-making.

Fuel cell vehicles can be used as a new power generation source, supplying electricity to homes, and to the grid. The V2G mode helps implement this connection and uses the hydrogen fuel cell powertrain and the stored hydrogen on board the vehicle as a new power generation source supplying electricity.

#### *A. House electrical consumption*

A bungalow style house is chosen for this study, however the model can be applied to any size and type of house. It is assumed that all the appliances in the house are electrical including the domestic hot water tank. A list of common appliances and devices that use electricity are outlined in Table 1.

TABLE I. ELECTRICAL APPLIANCES IN THE HOUSE

Appliance and Device	Description		
	Spot measurement (W)	Model	COP
Electric furnace	4,600	NT14A018A	0.83
Air conditioner	10,000	21ECM10	1.00
Electric domestic hot water	3,500	RTEX-04	
Fridge	57.20	LG LTCS24223	
Clothes washer	13.70	LG WM9500H* A	
Clothes dryer	7,200	DLEX7600 VE	
LED television	70	LGUH6100	
Electric stove	3,800	YWEE510S 0FS	
Dishwasher	27.30	Samsung DW80K704 9	
Microwave	2.20 - 10		
Lighting (Candle light, A19, T8, MR16, PAR30)	5, 10, 18, 5, 14	LED	
Coffee maker	70 – 1,000		
PC and monitor	6.4 – 75		
Laptop	2 – 25		
Stereo	30		
DVD player	3.8 – 17		
Video game consoles	3.6 – 36		
Chargers	4 – 13		
All in one printer and scanner	4.40		
Router	8		
Phone	2.80		

a. Usage and quantity is dependent on the number of occupants in the house

The heating and cooling electrical consumption from the electric heater and air conditioner used for this house depends on the wall insulation and the assumption of steady state heat loss and heat gain in the house. The heat loss and heat gain for the house is calculated as follows:

$$Q = U \cdot A \cdot \Delta T \quad (1)$$

where Q is the heat loss during winter and heat gain during summer, U is the measure of the effectiveness of the total insulation, A is the area of the house, and  $\Delta T$  is the outside air and house internal temperature. The comfortable indoor air temperature for winter according to a study is between 20°C and 23°C [26], while the comfortable indoor air temperature for summer is between 23°C and 25°C [26].

The effectiveness of the insulation of the house is calculated using the R-value of the insulating materials. The R value is the capacity of an insulating material that resists heat flow, and the higher the R-value, the greater the insulation for the application.

The  $U_{\text{total}}$  the measure of the effectiveness of an insulator for the house, is calculated from the total U values of the windows, doors, walls, floors, ceiling, and roof that comprises of the components of a house. The lower the U value, the better the material for heat insulation. The  $U_{\text{total}}$  can be calculated as follows:

$$U_{\text{total}} = U_{\text{window}} + U_{\text{door}} + U_{\text{wall}} + U_{\text{floor}} + U_{\text{ceiling}} + U_{\text{roof}} \quad (2)$$

The electric consumption of the electric heater and air conditioner is calculated for each hour of the year. Similarly the electrical usage of appliances, lighting apparatuses and other appliances in the house are quantified as follows:

$$E_{\text{House\_total}} = E_{\text{Appliances}} + E_{\text{Lighting}} + E_{\text{Devices}} \quad (3)$$

where  $E_{\text{Appliances}}$  is the total electricity used by the appliances for the duration of an hour,  $E_{\text{Lighting}}$  is the total electricity used by the lights in the house for an hour, and  $E_{\text{Devices}}$  is the total electricity used by devices in the house that use electricity for an hour. The appliances, lighting and devices used for this study are listed in Table 1.

### B. Solar power generation

The number of solar panels that can be installed onto the rooftop of the house can be written as:

$$N_{\text{PV}} = (A_{\text{roof}} / 4) * (I / A_{\text{PV}}) \quad (4)$$

where  $N_{\text{PV}}$  is the number of solar panels,  $A_{\text{roof}}$  is the area of the roof and  $A_{\text{PV}}$  is the area of the solar panel. The solar array area can be calculated as:

$$A_{\text{array}} = A_{\text{PV}} * N_{\text{PV}} \quad (5)$$

The maximum power capacity of the total solar PVs installed on the rooftop can be calculated as follows:

$$P_{\text{V}_{\text{total}}} = A_{\text{array}} * \eta_{\text{module}} \quad (6)$$

where  $\eta_{\text{module}}$  is the solar module efficiency.

By varying the area of the roof and calculating the maximum power capacity, the total solar PVs can also vary and this can be used for various house sizes. Using the information calculated the electricity produced per hour (EPV) can be obtained from the NREL website [27].

### C. Fuel cell vehicle fuel usage

There are several examples of development of hydrogen vehicles in the past decade. The automotive sector is a good

candidate for using hydrogen to reduce CO<sub>2</sub> emissions, as the quantity of vehicles exceeds the numbers of other modes of transportation. On board hydrogen storage is in the range of approximately 5 to 13 kg, a requirement to enable a driving range of more than 480 km (300 miles) for the full platform of light-duty automotive vehicles using fuel cells [28].

The fuel cell hydrogen usage can be made comparable to the house electricity usage and the solar panel power generation by using (7) to convert 1 kg of hydrogen to kWh.

$$33.22 \text{ kWh/l kg}_{\text{hydrogen}} * \eta_{\text{PEM fuel cell}} = E_{\text{hydrogen}} \quad (7)$$

where the PEM fuel cell efficiency is assumed to be 60% and E<sub>hydrogen</sub> is the useable kWh per kg of hydrogen. Equation (8) can be used to determine the kWh of energy on board a fuel cell vehicle:

$$E_{\text{hydrogen}} * S_{\text{hydrogen storage}} = E_{\text{FCV}} \quad (8)$$

where S<sub>hydrogen storage</sub> is the fuel tank size in kg, and E<sub>FCV</sub> is the amount of energy on board measured in kWh.

The electricity usage rate per kilometer is based on an assumption of combined city and highway driving. In this study it is assumed that the driving distance is constant with no road traffic or diversions of the path traveled between the workplace and the house.

#### IV. RESULTS AND DISCUSSION

The data for the electrical consumption of the house, the power generated by the solar PV and the hydrogen usage by the FCV (and hence the amount potentially available for building operations) can be determined on an hourly basis for the duration of a year.

In this case with the current solar panel installation, the sum of the electricity produced and the electricity used by the house makes this house a net negative energy building. The calculations show that a total of 17,650 kWh of electricity is used from the grid annually as shown in Figure 1.

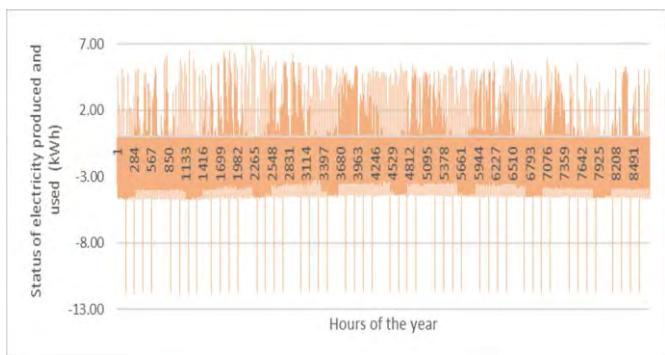

Figure 1. Total summed electricity produced by the solar PV and the electricity used by the house (kWh)

From this study it is observed that the electricity produced by the solar PV is not fully utilized during the day, while the occupants are away at work and most of the electricity

consumption is during peak times when they have arrived back at the house from the workplace. To demonstrate this, day 1 is extracted from Figure 1 and shown in Figure 2 below.

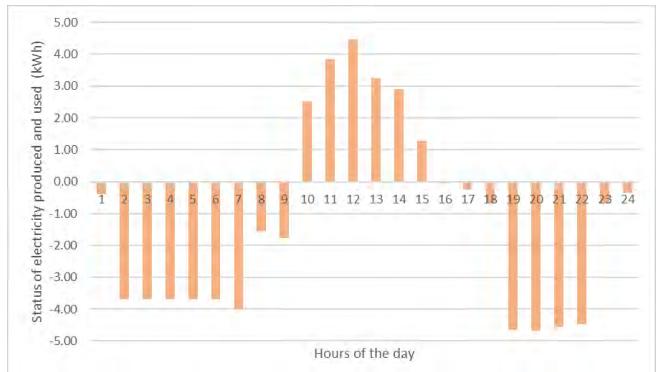

Figure 2. Sum of electricity produced and electricity used for Day 1 (kWh)

The FCV can be used to offset the net shortfall of the electricity produced by the solar PV throughout the day by using the hydrogen fuel cell on board the vehicle during high peak hours. The surplus electricity generated between 10am and 3pm is sent to the grid but is subsequently offset, during high peak times through the integration of FCV to the house. The integration of the FCV to the house for Day 1 can be observed in Figure 3, where the orange bar represents the sum of the electricity produced by the solar PV and the electricity used by the house compared to the green lines representing when electricity from the FCV was used. The house becomes a net positive energy building annually with 3,321 kWh provided by the integration of FCV. This indicates that approximately 21,000 kWh of solar PV energy that was not fully used by the house may be sent to the grid. The integration of the FCV powered by waste gas streams indicates that the house is fully powered from zero emission sources maintaining its net zero energy status.

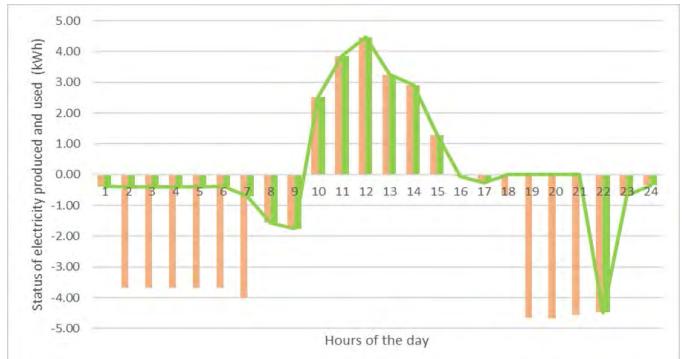

Figure 3. FCV integration to the zero energy building (kWh)

#### V. CONCLUSIONS

The integration of the FCV with a net zero energy building can be beneficial. This is due to the solar PV energy not being fully used by the unoccupied house during the day. The fuel recovered from the waste streams, such as hydrogen from electrochemical plants, synthesis gas converted to hydrogen

using steam reformation from bio gasification and anaerobic digestion processes, is used by the FCVs. The FCV's power generation capability allows the house to remain fully powered from zero emission sources and to utilize waste streams from the community.

**Abstract**—The stretched laminar flame model provides a convenient approach to embed realistic chemical kinetics when simulating turbulent premixed flames. When positive-only periodic strain rates are applied to a laminar flame there is a notable phase lag and diminished amplitude in heat release rate. Similar results have been observed with respect to the other component of stretch rate, namely the unsteady motion of a curved flame front when the stretch rates are periodic about zero. Both cases showed that the heat release rate or consumption speed of these laminar premixed flames can vary significantly from the quasi-steady flamelet model. Deviation from quasi-steady behaviour increases for conditions further from stoichiometric such that unsteady time scales of the flow are of the same magnitude as the chemistry. A challenge remains in how to use such results predictively for local and instantaneous consumption speed for small segments of turbulent flames where their stretch history is not periodic. This paper uses a frequency response analysis as a characterization tool to simplify the complex non-linear behaviour of premixed methane air flames for equivalence ratios from 1.0 down to 0.7, and frequencies from quasi-steady up to 2000 Hz using flame transfer functions. Various linear and nonlinear models were studied to identify appropriate flame transfer functions for low and higher frequency regimes, as well as to extend the predictive capabilities of these models. Linear models were only able to accurately predict the flame behaviour below a threshold of when the fluid and chemistry time scales are the same order of magnitude.

**Keywords:** Laminar Premixed Flames, Transient Response, Linear and Nonlinear Systems, Frequency Response Analysis

## I. INTRODUCTION

Understanding turbulent combustion is important due to industrial applications such as internal combustion engines and furnaces. The challenges related to predicting turbulent combustion behavior have been discussed extensively in terms of their time-dependent and multidimensional nature, as well as

having a large range of hydrodynamic time and length scales interacting with the time and length scales of the chemistry [1]. In this regard, the formulation of these problems is well-posed by a system of partial differential equations and algebraic constraints that represent the conservation of mass and energy, as well as considerations of momentum and individual species while being subjected to convection, diffusion, and chemical reaction. All these phenomena are captured in direct numerical simulations with appropriate boundary conditions, but their solutions, due to these equations being highly nonlinear and strongly coupled, come at a significant computational cost [2], and thereby creates the need for model-level understandings.

A conceptual modeling approach that allows for estimation of local burning rates with pre-calculated complex chemistry is based on flamelets, which can collectively represent a turbulent flame. In their classical premixed form, flamelets provide a local consumption speed of the flame (referenced to their reactant state), and are generally assumed to be local planar structures subjected to a specified steady strain rate and of fixed reactant composition. This consumption speed,  $S_L$ , is the rate mass is converted from reactants to equilibrium products per unit area of flame and divided by the density of the reactants, and can readily be converted to the local heat release rate per unit flame area knowing the enthalpy of reaction. The validity of these assumptions has been challenged in terms of the response of laminar flames to changing positive strain rates [3], or mixture composition fluctuations [4]. Key observations for these planar flames included the flame responding in a quasi-steady manner at low frequencies, but at high frequencies the burning rate response becoming significantly attenuated, as well as having a phase lag.

Sahafzadeh et al. [5] showed the same results occur when flame stretch was created through the motion of a curved flame where both positive and negative transient stretch rates were applied. As a result, within an unsteady flow, classical flamelet models would predict the wrong magnitude of local burning and any expected maxima or minima events would occur at the wrong time. Lastly, an alternate approach to reduce the

computational load of complex chemistry is to use reduced chemistry and simple transport properties. It has been found that the transient response of a stretched flame is not necessarily captured accurately due to the change in the internal flame structure [6].

In the current work, the approach is to keep the full chemistry and then estimate the instantaneous local consumption speed by a frequency response analysis in the form of a flame transfer function using the local stretch history as the input.

The focus of this paper is on premixed combustion in the Damköhler and Karlovitz regimes where reaction occurs in identifiable flame structures that are locally subjected to unsteadiness in the flow. The objective of this paper is to further develop a model of a flame for the practical purpose of capturing the impact of unsteadiness on the rates of conversion from reactants to products. To be explicit, no consideration is given here to spatial variations along a flame, which is another important characteristic of turbulent flames.

## II. FREQUENCY RESPONSE ANALYSIS

To create a useful transfer function from a frequency response analysis, consideration needs to be given to its input and output. Within the context of premixed turbulent flame modeling in the flamelet regime, a goal is often to represent the flame as an interface with burning rates that vary over the surface depending on local conditions. For example, basic flamelet libraries are used to assign a consumption speed to an element of the flame depending on its equivalence ratio and stretch rate. Since one of the goals of the current work is to better account for the unsteadiness in turbulent flames, which includes unsteadiness in stretch rate, the input to the transfer function was chosen to be the varying stretch rate and the output is the varying local consumption speed. By choosing stretch rate, the transfer function could be seen as independent of the geometry that creates it, and therefore applicable to flamelets of a turbulent flame.

The numerically modeled flame used to produce the results for this frequency response analysis has been previously reported in the combustion literature [5], and is therefore only briefly described here. Reactants of methane and air of a specifiable equivalence ratio flow radially outward from the inlet boundary ( $r = 5$  cm) and through the outlet boundary ( $r = 11$  cm). The mean and fluctuating components of the inlet mass flow rate were specified so that all the chemical reactions occur within the domain and are well removed from the boundaries. The model is based on a finite volume approach for solving the discretized equations for mass, momentum, energy, and species. The thermodynamic and transport properties come from CHEMKIN, and the reaction mechanism is based on GRI 3.0 [7] involving 36 species and 219 reactions.

For the simulations, the mass flow rate was changed sinusoidally with time (Eq. 1) at the inlet boundary.

$$\dot{m}(t) = \dot{m}_0 + B \sin(\omega t) \quad (1)$$

In Eq. 1,  $\dot{m}$  is the mass flow rate at the inlet boundary,  $\dot{m}_0$  the mean mass flow rate at steady state,  $B$  represents the amplitude of the oscillation, and  $\omega$  is the angular frequency. The frequency was varied between 20 Hz and 2000 Hz. The reason to consider frequencies up to 2000 Hz is for the relevance to turbulent flows. For example, in the middle of a premixed turbulent duct flame stabilized by a backward facing step, mean frequency of the flame motion across a fixed point was observed to be in this range [8]. In the present study, the equivalence ratio was varied from 1.0 to 0.7 in order to compare the stoichiometric condition to lean flames, which are usually of interest due to their applicability to low-emission combustion systems.

The geometry studied herein has unique features of flame dynamics relative to the counter-flow configuration, which is usually used to generate flamelet libraries. The steady flame is unstretched due to the balance of curvature and flow divergence (*i.e.*, strain). However, when the flame is exposed to a flow field fluctuation, the expanding flame is subjected to positive stretch, whereas the contracting flame generates negative stretch, which has generally been ignored in the literature. The magnitude of the stretch rate could be changed by varying mean flame curvature, amplitude and frequency of oscillations, equivalence ratio, and fuel type. The choice of the marker, usually associated with a scalar field, to convert a flame with internal structure spread over space to an interface affects the magnitude of the stretch rate. To reduce this sensitivity, it is common to choose a marker that is on the trailing edge of the flame structure [9]. The flame marker used in this work is an iso-therm based on the temperature field with a value of 90% of the maximum temperature. Once calculated, this changing stretch rate becomes the input for the response analysis to create the transfer function.

The output for the response analysis is related to the total heat release, which is the chemical energy source term integrated for all species and in all control volumes in the domain, and is defined by Eq. 2.

$$\dot{E}_b = \sum_{i=1}^{N_{cv}} \sum_{k=1}^{N_{sp}} h_k \dot{\omega}_k \mathbb{V}(i) \quad (2)$$

In Eq. 2,  $\dot{E}_b$  is referred to here as the rate of enthalpy conversion from chemical to sensible sources for the whole flame, otherwise known as the burning rate,  $\mathbb{V}(i)$  represents the volume of cell  $i$ ,  $h_k$  is the molar specific enthalpy of species  $k$ , and  $\dot{\omega}_k$  is the molar rate of creation of species  $k$  per unit volume.

Fig. 1 shows this instantaneous consumption speed as a phase plot with respect to the corresponding instantaneous stretch rate. The quasi-steady response is a point (not shown in the figure) located on  $\kappa = 0$  and  $S_L = 0.2$ , which is essentially the steady state value and would be referred to as  $S_L^0$ . At very low frequencies (20 Hz), the relationship between local flame speed and stretch rate is almost linear. By further increasing the frequency, the line becomes an ellipse. The slope of the ellipses are negative which has been shown in other works for

methane-air flames in the same range of equivalence ratio [1]. The sensitivity of the local flame speed to the stretch rate first increases (*i.e.*, the vertical amplitude of the ellipse) in low the frequency regime and then decreases in the high frequency regime. For the case of  $\varphi = 0.8$ , this changing behaviour is seen in the variation from 100 to 200 Hz where the consumption speed increases, and from 200 to 500 Hz where the consumption speed decreases. Hence, there seems to be separate low and high frequency responses.

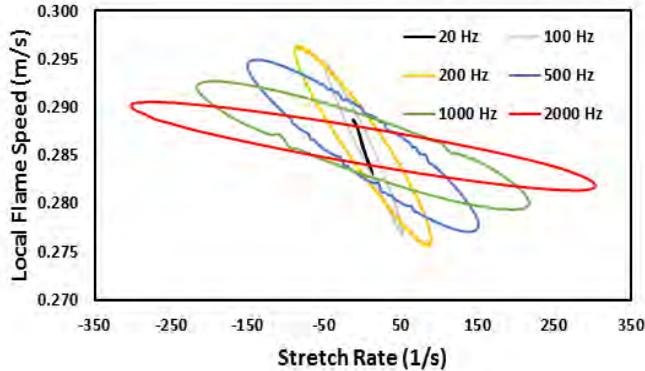

Figure 1. Local flame speed versus stretch rate for the equivalence ratio of  $\varphi=0.8$  and quasi-steady response for the frequencies between 20 Hz and 2000 Hz

From this analysis, it is obvious that the flame response to a changing stretch rate depends on parameters such as equivalence ratio and the frequency of oscillation. Therefore, it would seem desirable to find a describing function to replace the cumbersome complex chemistry computations of transient response of turbulent and laminar premixed flames.

### III. LINEAR HIGHER ORDER ANALYSIS

In this section of the paper, in order to include flame behavior to a flow change upstream of the flame front, one needs to simulate each case for a wide range of frequencies and various input functions such as step, ramp, pulse, etc. This time consuming process can be replaced by one or more transfer functions to define the overall behavior of the flame. With regard to the application of this study, the input to the transfer functions are converted to stretch rate. The calculation of stretch rate is adopted from [5]. Therefore, the relationship between the stretch rate and local flame speed, which has been ignored in the current approach to flamelet modeling, reveals how flamelets respond to the time-dependent motion of a curved flame front. In order to have a better prediction of the transfer functions, a Polynomial Discrete-Time ARX (Autoregressive Exogenous) Model [10], which is a generalized transfer function, has been used. Equation (5) shows the general form of linear (due to the linear relationship between input and output) higher order (more than one term) transfer functions.

$$C(z^{-1})y(t) = \sum_{i=1}^{nu} D_i(z^{-1})u_i(t - nk_i) \quad (3)$$

In this equation,  $u(t)$  is the input,  $y(t)$  is the output,  $C$  and  $D$  are polynomials expressed in the time-shift operator  $z^{-1}$ ,  $u_i$  is the  $i^{\text{th}}$  input,  $nu$ , the total number of inputs, and  $nk_i$ , the  $i^{\text{th}}$  input delay that characterizes the transport delay. In the present study, the system is SISO (single input/single output), therefore the transfer function takes a more familiar form wherein  $i=1$ . A Z-transform (Time-Discrete Fourier Transformation) can be used to convert the discrete-time form of the transfer function (Eq. 3) into a complex frequency domain representation.

This approach was first used to estimate the transfer function of the flame (with equivalence ratio of 0.8) response at 20 Hz fluctuations in mass flow rate. Then, the flame response to higher frequencies has been predicted using this transfer function. It has been observed that the accuracy of predictions decreases with increasing frequency. Increasing error in prediction of the transient response in the low frequency regime confirms that nonlinearity of the system increases with increasing frequency at each equivalence ratio. However, it could be considered insignificant until the oscillation reaches the high frequency regime, where the intrinsic structure of the flame may be changed locally. In the next step, the whole range of low frequencies (frequencies less than 200 Hz, which is the cut-off frequency for equivalence ratio of 0.8) has been used to generate the transfer function (Eq. 6). Figure 5 shows that the average accuracy of the predictions is  $\sim 88\%$  for frequencies up to 200 Hz; however, the flame response experiences a significant drop in accuracy after 200 Hz (not shown in the figure).

$$\begin{aligned} C(z) &= 1 + 0.9623z^{-1} + 0.636z^{-2} + 0.2826z^{-3} + \\ &\quad 0.122z^{-4} \\ D(z) &= -0.6376z^{-1} + 0.6915z^{-2} + 0.5377z^{-3} - \\ &\quad 0.5923z^{-4} \end{aligned} \quad (4)$$

$C(z)$  and  $D(z)$  are the expressions represented in Eq. 3. The fourth order transfer function results indicate that a minimum of the first four terms on each side of Eq. 3 is required to have the most accurate predictions. It should be noted that  $C(z)$  and  $D(z)$  are usually referred to as the *poles* and *zeros* of a transfer function in the literature.

Based on the higher order linear model, a transfer function (Eq. 5) is generated for predicting the high frequency regime transient response. Figure 3 illustrates the accuracy of this model for frequencies higher than 200 Hz.

$$\begin{aligned} C(z) &= 1 + 0.2641z^{-1} - 0.2513z^{-2} - 0.3054z^{-3} - \\ &\quad 0.2756z^{-4} \\ D(z) &= 0.0012z^{-1} - 0.0044z^{-2} + 0.0051z^{-3} - \\ &\quad 0.0019z^{-4} \end{aligned} \quad (5)$$

In order to study the effect of the amplitude on flame behavior and the transfer function, the ratio of the oscillations to the mean value was doubled. The results depict a fourth order transfer function similar to the previous cases, which

predicts the high frequency responses (70% for 500 Hz, 84% for 1000 Hz, and 91% for 2000 Hz), with different coefficients.

The fourth order equation is the effective transfer function for various equivalence ratios. For example, a stoichiometric flame was tested with different flame curvature and amplitude. The optimum transfer function has the same format as it does with the other cases. The accuracies for the high range of frequencies is 83% for 500 Hz, 93% for 1000 Hz, and 94% for 2000 Hz. The higher accuracy at the same frequencies was expected due to the faster burning rate at the stoichiometric condition compared to the lean flames.

As can be concluded from the recent results in this section, the whole range of frequencies is divided in two regimes based on the cut-off frequency obtained from numerical simulations of transient response of laminar premixed flames for each equivalence ratio, and a separate transfer function is defined for each section. Although the accuracies are in an acceptable range, there may be considerable improvement using nonlinear models to predict the output. Therefore, in order to study the capability of nonlinear models to predict the flame response more accurately, different nonlinear transfer functions were analyzed in the next section.

#### IV. NONLINEAR SYSTEM ANALYSIS

As shown in the previous section, although linear transfer functions can achieve accurate prediction in the low frequency range of flame response to changes in stretch rate, they are not able to predict the response at some high frequencies. As mentioned in the introduction, in analyzing flame instabilities, flow velocity perturbations (as the input to the system) change the heat release rate (as the output) by influencing the flame surface area. Therefore, flame transfer functions are studied using the flame response to velocity fluctuations. The heat release rate modulations result in acoustic pressure perturbations, and could be linked to inlet flow velocity oscillations. Therefore, in order to capture the nonlinearities in the thermos-acoustic coupling, the flame transfer function has been replaced by the flame-describing function [11]. It has been reported that in premixed combustion systems, the relationship between velocity and heat release makes the system nonlinear, whereas gas dynamic processes generally stay in the linear regime [12].

Among these predictive models, using NARX (Nonlinear Autoregressive Exogenous) led to better results in estimating the transient response of the flame for the whole range of frequencies, including both low and high frequency regimes. Figure 3 illustrates the NARX predictions in comparison to the complex chemistry numerical results for the flame with an equivalence ratio of 0.8 at different frequencies. NARX models (which are an extension of ARX in polynomial transfer functions) are flexible nonlinear functions that are able to capture the complex behavior in nonlinear systems such as the current data set. Eq. (6) illustrates the structure of a linear Single Input/Single Output ARX model:

$$y(t) + a_1y(t-1) + a_2y(t-2) + \dots + a_{na}y(t-na) = b_1u(t) + b_2u(t-1) + \dots + b_{nb}u(t-nb+1) + e(t) \quad (6)$$

Where  $u$ ,  $y$  and  $e$  are the input, output, and noise, respectively. This structure implies that the output  $y(t)$  is predicted as a weighted sum of past output values and current and past input values.  $na$  is the number of past output terms, and  $nb$  is the number of past input terms used to predict the current output. It has been shown that the surface wrinkling in turbulent flames at one location, in addition to the local velocity perturbation, also depends on the flame surface fluctuations at previous times upstream of the flame front [13]. Therefore, an ARX model could capture this memory effect occurring in turbulent flames by modifying the laminar flamelet response to a change in upstream flowrate.

After applying the nonlinear ARX model to predict the flame response, the results need to be validated by comparing the estimations with time series datasets obtained from complex chemistry numerical simulations. The nonlinear ARX model has been applied to three different datasets including, the low frequency regime (nonlinear ARX 2 in Fig. 2), the high frequency regime (nonlinear ARX 2 in Fig. 3), and the whole range of frequencies (nonlinear ARX 1 in Fig. 2 and 3). Therefore, three different nonlinear transfer functions were generated and tested against the numerical computations. As can be concluded from Figs. 2 and 3, nonlinear ARX model 2 based on two different frequency regimes, shows accurate predictions for each frequency compared to the linear higher order ARX model and nonlinear ARX model 1. It should be noted that these models are all capable of predicting the transient responses due to their storing of time histories in their structures. However, because of the nonlinear relationship between the input and output at high frequencies, nonlinear models are more accurate in general.

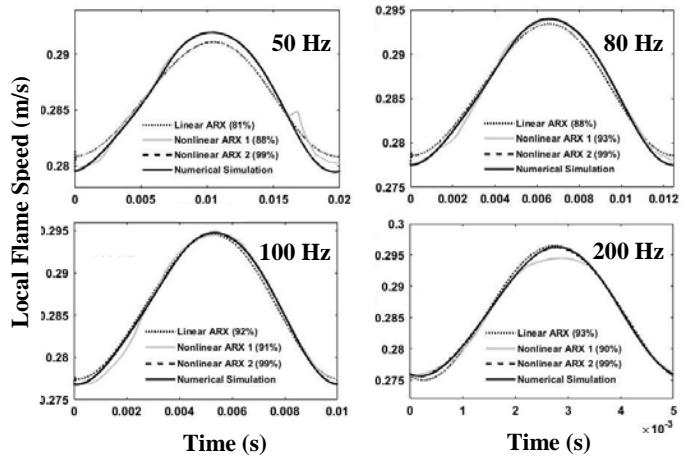

Figure 2. Estimation of transient response of a laminar premixed flame for  $\phi=0.8$  using a higher order linear ARX model and a nonlinear ARX model in the low frequency regime

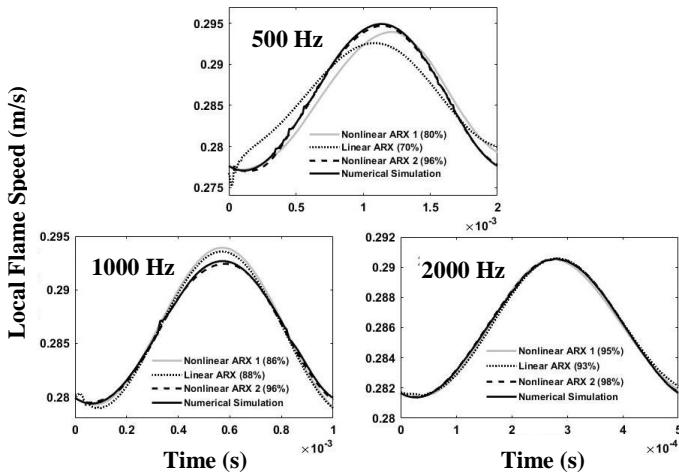

Figure 3. Estimation of transient response of a laminar premixed flame for  $\phi=0.8$  using the higher order linear ARX model and nonlinear ARX model in the high frequency regime

## V. CONCLUSIONS

In this paper, the transient response data on the rate of conversion of chemical to sensible enthalpy, and the local flame speed for a laminar premixed flame that was exposed to periodic flow conditions, was analyzed in order to estimate a transfer function between these inputs and outputs. The study of the transient response analysis of a curved flame could be a potential modification to the quasi-steady assumption used in laminar flamelet libraries in order to improve premixed turbulent combustion modeling. The transient response dataset was taken from a previous study, which was a complex chemistry simulation of an inwardly burning laminar premixed (lean methane/air) flame in a cylindrically-symmetric geometry for different equivalence ratios (0.7 – 1.0) with cyclic exposure to positive and negative stretch rates at different frequencies (0 – 2000 Hz). In this paper, the higher order linear and nonlinear analyses have been performed for equivalence ratio of 0.8 only, to show the capability of transfer functions to capture the flame behavior when exposed to a flow perturbation upstream of the flame front.

A linear first order model was applied to the data and it fit the low frequency results for each flame. However, the flame behavior deviates from that of a linear first order system as the frequency increased and approached conditions where the chemical and flow time scales were similar. Applying higher order linear transfer functions improved the predictions (except for in the high frequency regime) due to the capability of the transfer function to store the time histories in its structure.

Nonlinear models, such as the nonlinear ARX model, could correctly predict the transient local flame speed over the whole range of frequencies and changing flow conditions. This transfer function could also reconstruct the local flame speed response for any arbitrary flow input, which enables the model to capture the transient effects of a flame in any conditions.

Therefore, estimating a flame transfer function for laminar premixed flames could yield a better understanding of flame dynamics and could be used in order to modify the quasi-steady assumption in laminar flamelet models of turbulent combustion. Using the generated transfer functions based on the simulation datasets, the transient complex chemistry results were predicted with an accuracy over 70%.

# Wind Turbine Wake Effect Visualization and LiDAR Measurement Techniques

Michael McKinnon, David A. Johnson  
Mechanical and Mechatronics Engineering  
University of Waterloo  
Waterloo, Canada  
mmckinno@uwaterloo.ca

**Abstract**—The expansion of wind energy development has resulted in larger wind farms and closer placement of turbines to utilize the space available. Each turbine produces a wake that affects downstream turbines, which causes issues such as production loss, blade loading, and fluctuating electrical output. In order to minimize this impact, the wake produced by turbines must first be understood. Experimental methods were used in the exploration of the wake effects of wind turbines. Smoke visualization inside a controlled wind facility was used to determine the helical vortex wake distribution behind a 3.3 m diameter turbine as well as the tip vortex shedding on the blade. Wind Doppler Light Detection and Ranging (LiDAR) measurement devices are used to measure the velocity of aerosols to determine the wind velocity. This technique can be used to measure the airspeed in the wake of a wind turbine. The University of Waterloo Wind Energy Group has a ZephIR z150 LiDAR to use in this study. The LiDAR was verified for accuracy against a cup and vane anemometer. The results determined that the LiDAR was suitable to provide accurate measurements in further turbine wake experiments. The University of Waterloo's facilities provide the advantage to study wake effects under controlled wind conditions as well as under realistic open-air conditions.

**Keywords**-wind energy; wake effects; LiDAR; wind farm layout

## I. INTRODUCTION

Increasing energy demands and the need for cleaner electricity sources have fueled the development of renewable energy, especially wind energy [1]. More wind farms are being developed with increased density of turbine spacing to utilize areas with high wind conditions. Therefore, wind turbine interaction is becoming a greater concern when developing and operating wind farms.

Wakes are produced by the wind turbines which affect other downstream turbines. This can cause blade loading problems, affect rotor performance, cause fluctuating electrical output, and reduce production [2]. It is important to study the wake effects of wind turbines to be able to design wind farms to reduce the effects on downstream turbines.

Several methods have been explored to measure and simulate the behaviour of the wakes. Some key behaviour characteristics include wake recovery, meandering, and expansion [2]. Experimental methods include wind tunnel tests and field measurements. The University of Waterloo's Wind Energy Group has the capability to test small-scale wind turbines in both wind tunnel and field conditions. The issue with most wind tunnel experiments is obtaining accurate results while scaling wind turbines to fit the wind tunnel specifications. The University of Waterloo's Controlled Wind Facility is able to house a 3..3 m diameter wind turbine with the benefit of obtaining controlled wind conditions up to 13 m/s. Additionally, the University has a 10 m wind turbine located in the external environment to test actual field conditions that would be experienced by commercial wind turbines.

With these two wind turbines, the characteristics of wind turbine wakes can be studied and compared to get an understanding of the theoretical and actual behaviour of the wake. Experimental analysis using smoke visualization gives a visual of the wake profile, while a Light Detection and Ranging (LiDAR) measurement device measures the air speed in the wake. Both methods are used to determine the wake effects of the turbines in controlled and external conditions.

## II. EXPERIMENTAL FACILITIES

Experiments to determine the behaviour of wind turbine wakes were tested inside the University of Waterloo Controlled Wind Facility. The large-scale wind turbine testing facility uses six 75 kW variable speed fans to obtain consistent wind conditions up to 13 m/s in the test area [3]. Fig. 1 shows the

Figure 1. Controlled Wind Facility fans

fans on the outside of the facility.

A 3.3 m diameter wind turbine, shown in Fig. 2(a), was developed by the UW Wind Energy Group to operate inside the controlled wind facility. The wind turbine, called the UW WEG turbine, has an output of 3 kW under 11 m/s wind conditions.

A small-scale, grid connected wind turbine is located in the Region of Waterloo and is used by the Wind Energy Group for open-air testing. The turbine, manufactured by Wenvor Technologies, has two blades with passive variable pitching and a diameter of 10 m. The hub height is 30 m and has a power rating of 35 kW. The Wenvor turbine is shown in Fig. 2(b).

### III. FLOW VISUALIZATION

Smoke visualization was used inside the Controlled Wind Facility to gain a visual understanding of the wake behaviour as well as provide quantitative measurements. Two smoke visualization techniques exist to study the wake behaviour of turbines [4]. Each method was explored in the experiments. The first method attached smoke emitters to the tip of the one of the blades. This method was used to analyze the wake behind the turbine. The second method ignited smoke in front of the turbine directed at the tip of the blade sweep to analyze the tip vortices.

Both experiments were performed at a wind speed of 6 m/s and constant rotational speed of 100 RPM with the UW WEG turbine, resulting in a tip speed ratio of approximately 3.9. The behaviour of the smoke was captured at various views.

A view of the progression from the tip ejection experiment using method 1 can be seen in Fig. 3. As the smoke propagates downstream, a helical pattern can be seen. This shows a typical helical vortex wake distribution. As vortex cylinders are shed from the blades of the turbine, they follow a helical path due to the rotation of the blade. The wake expansion can also be

Figure 2. University of Waterloo's wind turbines: (a) UW WEG Turbine and (b) Wenvor Turbine

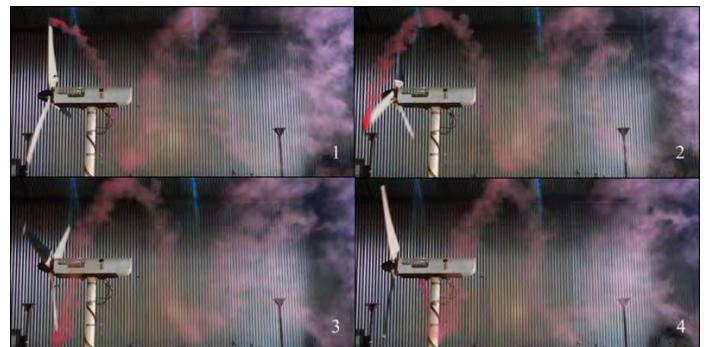

Figure 3. Tip smoke visualization progression of the UW WEG turbine for 6 m/s wind speed and a blade rotation of 100 RPM

determined from the smoke visualization experiment. As the smoke moves downstream, the diameter increases due to this expansion.

A close up of the tip of the blade in Fig. 4 shows the angle at which the smoke leaves the blade tip. This is known as the helix angle,  $\phi$ , or the flow angle at the blade tip [5]. This angle is used to determine the direction of the vortex cylinder parallel to the axis of rotation. As a result, the induced velocity at the rotor plane can be calculated using Biot-Savart law if the vorticity strength is known. The experiment resulted in a helix angle of 25° from the setup parameters.

The second smoke emission method released smoke upstream of the turbine to visualize the vortices being shed from the blade tips. A tip vortex forms as the blade passes through the smoke. The vortex moves downstream and another is formed as the next blade passes. This effect is seen in the results of the experiment in Fig. 5, which shows a tip vortex being formed and vortex that has moved downstream with the flow. The distance between these vortices is related to the helical path of the vortex cylinders that was seen in the previous experiment.

### IV. LiDAR MEASUREMENTS

Wind Doppler LiDARs have the capability to measure the velocity of particulates in the air, which are used as seeding material to determine the wind speed [6]. The LiDAR achieves

Figure 4. Helix Angle of the UW WEG turbine for 6 m/s wind speed and a blade rotation of 100 RPM

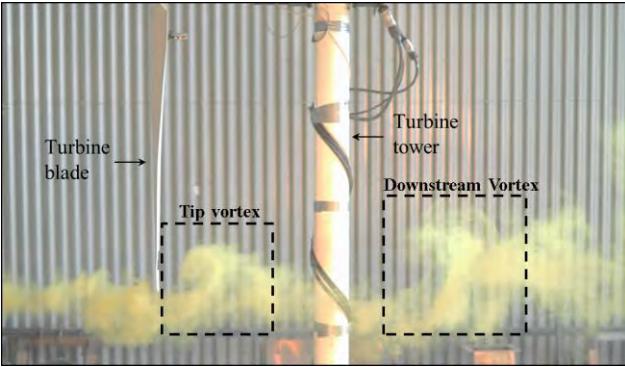

Figure 5. Upstream smoke visualization of the UW WEG turbine 6 m/s wind speed and a blade rotation of 100 RPM

this by the use of a laser, which uses the Doppler Effect from the scattered light reflected from the particulate to calculate the speed of that particle.

Therefore, to measure the velocity of the air in the wake of the turbine, a ZephIR z150 LiDAR, shown in Fig. 6, is used. The LiDAR has the ability to measure various heights and uses a conical sweeping pattern to calculate the direction of the wind. Therefore, it can be used to get a representation of the velocity profile in the wake as it progresses downstream.

Before using the LiDAR for wake measurements, it was first verified for accuracy [8]. A test was conducted to compare the LiDAR against a cup and vane anemometer, each at different heights in atmospheric conditions. The anemometers were attached to the Wenvor wind turbine tower and located at a vertical height of 10 m from ground level and a height of 20 m for the cup and vane anemometers respectively.

Due to constraints on the LiDAR, a minimum height of 12 m was achieved to compare against the cup anemometer. The vane anemometer was used to verify the wind direction. The LiDAR was located 18 m away from the Wenvor tower to avoid interference due to the conical sweeping of the laser. The LiDAR was placed at a similar distance away from a nearby tree line and ensured that the ground level was consistent with the tower. A view of the setup is shown in Fig. 7. Data was

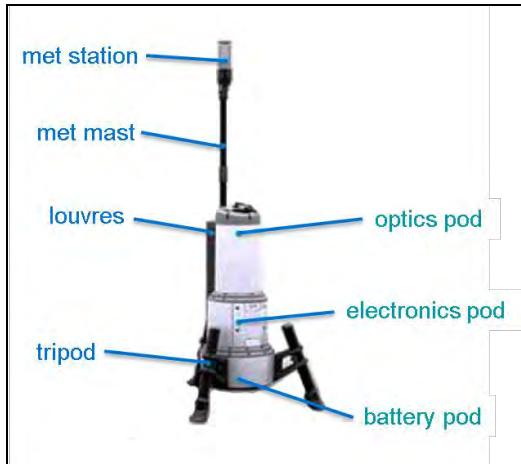

Figure 6. ZephIR z150 LiDAR [7]

collected in 10-minute averages over the span of one hour.

The result of the velocity comparison for the LiDAR and cup anemometer is shown in Fig. 8. Due to the limitations of the LiDAR minimum measurable height, the measurements were scaled based on the power law to get equivalent values at 10 m. Both measurements followed the same trend and were within the error of measurements. However, the data was skewed, which could be the result of the scaling or a bias in the cup anemometer measurements.

Similar to the velocity comparison, the direction measurements also showed similar trends as seen in Fig. 9. Again, the comparison shows the measurements were with error. Therefore, it was concluded that the LiDAR measurements were within reasonable accuracy to use for wake measurements.

In order to take measurements in the wake of a turbine, the LiDAR needs to be modified to convert the conical sweep of the laser to a single point line-of-sight laser [9]. This ensures that the measurement position can be placed at a single point and then traversed to gain a profile of the wake.

## V. CONCLUSION

Understanding wake behaviour of wind turbines is important for the development of new wind farms and design of wind turbines. Understanding can be achieved through experiments using flow visualization and LiDAR measurements.

The University of Waterloo Wind Energy Group uses two wind turbines to contribute to the study of wakes. The two turbines have the benefit to compare controlled wind versus open-air conditions. A controlled wind facility allows for the testing of a 3.3 m diameter wind turbine under steady wind conditions up to 13 m/s, while an external 10 m diameter turbine experiences realistic variable wind effects.

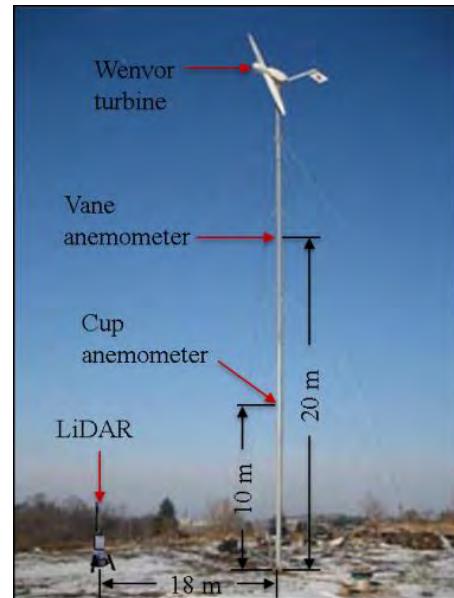

Figure 7. LiDAR verification test setup

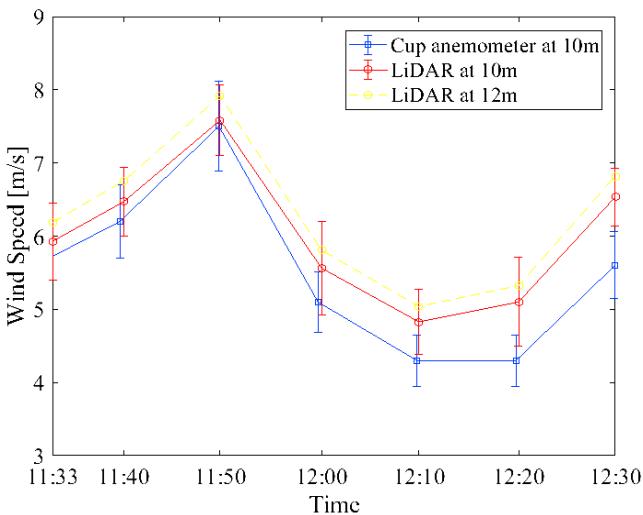

Figure 8. Cup anemometer and LiDAR velocity comparison

Smoke visualization was used to determine the wake characteristics such as a helical vortex distribution, tip vortex shedding, and wake expansion inside the Controlled Wind Facility. This was completed with two smoke visualization techniques that emit smoke from the tip of a turbine blade and another to emit smoke upstream of the turbine directed at the sweeping blade tips. In the first method, the helix angle was able to be measured with a value of  $25^\circ$ . The second method showed the formation and downstream propagation of the tip vortices.

Wind Doppler LiDAR measures the speed of aerosols in the wind to calculate the wind speed. A ZephIR z150 LiDAR was measured against a cup anemometer at a height of 10 m to verify the wind velocity measurements. The LiDAR was also measured against a vane anemometer with a 20 m height to verify wind direction measurements. The comparison between the LiDAR and both anemometers showed the same trend and were within error, resulting in the conclusion that the LiDAR had sufficient accuracy to use in the measurement of air speeds. Therefore, the LiDAR is able to be used to measure the

velocity profile in the wakes of the turbines.

The comparison between controlled and external conditions will allow for a better relation between the theoretical understanding of wake effects and the actual behaviour of a wind turbine. With this, better optimization of wind farms can lead to increased density while reducing production losses and turbine maintenance.

#### ACKNOWLEDGMENT

The authors acknowledge the help and support of the University of Waterloo Wind Energy Group and technicians in the aid of experiments and contribution to the research topic.

**Abstract**—Triboelectric nanogenerator (TENGs), based on the principles of triboelectrification and electrostatic induction, have recently been viewed as a promising approach to harvest mechanical energy, which would otherwise be wasted through dissipation to surrounding. Large contact area and large surface area have been identified as the basic design principles to promote the performances of TENGs. In this study, particulate leaching method was used to introduce and tailor the open-cell morphology of negative triboelectric layers in TENGs. The effects of material type, material geometry, open-cell morphology on the level of triboelectrification induced by mechanical motions were also investigated. Experimental results revealed that polyvinylidene fluoride (PVDF) performed better than high density polyethylene (HDPE) as the negative triboelectric layer of the TENG. Furthermore, increasing the contact area, reducing the thickness, and introducing fine pores would enhance the performances of TENGs.

**Keywords**-energy harvesting; geometry; open-cell morphology; polymer; triboelectrification

## I. INTRODUCTION

Triboelectrification, in conjunction with electrostatic induction, has been developed into an innovative energy harvesting technology – triboelectric nanogenerators (TENGs) [1]. Although different types of technologies based on electrostatic, electromagnetism, and piezoelectricity exist to convert mechanical energy into electrical energy [2], TENGs have recently been drawing attentions. It is considered as a promising solution to harvest mechanical energy, which will otherwise be wasted, into useful energy. In addition, TENGs are also capable of powering sensors, portable electrics, and biomedical microsystems [1,3].

There are several different modes of TENGs. Among them, the contact-separation mode is one of the simplest ones. In this mode, two friction materials with different triboelectric properties contact and separate periodically. Each of them is attached to an electrode. During contact, electrons transfer from one material to the other because of their abilities to attract electrons. As a result, the material loses electrons would become positively charged while the other gains electrons would be

negatively charged. Subsequently, the two oppositely charged materials separate and a potential difference will be generated between them. This will electrostatically induce a current flow along an external circuit connected to the two electrodes adhered by the two materials in order to compensate the potential difference. When the two materials are pressed again, the potential difference will decrease and a reverse current flow will be induced. This periodic action will in turn generate an alternating current [3].

Although triboelectrification is a well-known phenomenon, its fundamental is not fully understood yet. Various parameters can affect the degree of triboelectrification of materials, and thereby the performances of TENGs. These factors include humidity, external force applied to induce the periodic contact and separation of friction materials, chemical composition of the friction layers, geometrical parameters (e.g., thickness and contact area), and morphological parameters (e.g., shape and surface area).

Recently, researchers have conducted studies to investigate the effects of these governing factors on the degree of triboelectrification in order to optimize the performances of TENGs [1-3]. Wang revealed that microstructuring the surface of PDMS, which was used as the negative side of the friction materials, could influence the charge density accumulated on the material surfaces [4]. It is believed that the creation of pyramid-based micro-patterns is effective to enhance the contact area and potentially the triboelectrification. Lee *et al.* suggested that the introduction of a film-covered pillar structure on PDMS would enhance the conformable contact and adhesion energy, which would in turn increase triboelectrification [5]. Another recent work fabricated a hydrophobic polydimethylsiloxane (PDMS) sponge to study the effect of pore size and humidity on TENG parameters [2]. They observed that TENG voltage and current density greatly increased when PDMS pore size reduced from 10  $\mu\text{m}$  to 0.5  $\mu\text{m}$ . Furthermore, the developed voltage only slightly decreased when relative humidity increased from 20 to 80%, which showed reasonable stability of hydrophobic structure under different humidity conditions. Chen *et al.* posed that matrix of high dielectric nanoparticles like strontium titanate ( $\text{SrTiO}_3$ ) in PDMS can enhance charge density of TENG and improve the power output of the device by five times [6].

This paper studied the effects of material type and material geometry (e.g., thickness and contact area) on the electrification of polymer-based TENGs. After identifying the appropriate material type, particulate leaching was used to introduce and tailor the open-cell structures of negative triboelectric layers. Parametric studies were conducted to elucidate how the open-cell morphology of the triboelectric layer influenced the output performances of TENGs. This work enhanced the understanding of material design on their triboelectrification and provided new and effective strategy to enhance the performances of TENGs.

## II. EXPERIMENTAL

### A. Materials

Polyvinylidene fluoride (PVDF, Kynar 741, Arkema) and high density polyethylene (HDPE, Sclair® 2710, NOVA Chemicals) were used to fabricate the negative triboelectric layers of TENGs. Thermoplastic polyurethane (TPU, Estane® 2103-70A, Lubrizol) was used to fabricate the positive triboelectric layers of TENGs. Table I summarizes the physical properties of PVDF, HDPE, and TPU. Sodium chloride (NaCl) was used as the leaching agent to fabricate porous negative triboelectric PVDF layers. The electrodes of TENGs were made by copper tapes with conductive adhesive. All materials were used as received without any modification.

TABLE I. PHYSICAL PROPERTIES OF PVDF, HDPE, AND TPU

Polymer	Physical Properties	
	Density	Young's Modulus
HDPE	951 kg/m <sup>3</sup>	1000 MPa
PVDF	1780 kg/m <sup>3</sup>	1700 MPa
TPU	1060 kg/m <sup>3</sup>	2.1 – 5.2 MPa

### B. Sample Preparation

Solid triboelectric negative layers were fabricated by compression molding (Craver Press, 4386 CH) PVDF powders or HDPE pellets at 185°C and 140°C, respectively, into samples with various thicknesses and areas. In the first step, the heat platens of the compression molding machine were brought into contact with the mold, which loaded with polymer powders or pellets, for 5 minutes to ensure the complete melting of the materials. Subsequently, the molding pressure was ramped up to 27 MPa and was held at the set pressure for 5 minutes to fabricate the disc samples. Similar procedures were used to fabricate the solid TPU triboelectric positive layers, which were 0.5 mm thick.

Porous PVDF triboelectric negative layers were fabricated by compression molding and particulate leaching process using the procedures indicated below:

- STEP 1. NaCl powders were sieved into different sizes (i.e., <53 µm and 53 – 250 µm).
- STEP 2. PVDF powders were dry-blended with 80 wt.% sieved NaCl powders.
- STEP 3. PVDF-NaCl mixtures were molded by a compression molding machine at 185°C and 27 MPa into disc

samples of desired thicknesses and areas. All porous samples are 0.50 mm in their thicknesses and 3.14 cm<sup>2</sup> in their areas.

- STEP 4. Molded samples were submerged under water at room temperature (i.e., 23°C) for 72 hours to leach out the NaCl crystals. Water was changed regularly to avoid the saturation of NaCl.
- STEP 5. The open-cell PVDF samples were then dried in an oven at 50°C for 24 hours.

Table II summarizes the key parameters being studied in this work to elucidate the effects of material type, material geometry, and open-cell morphology of the negative triboelectric layer on the triboelectrification of the TENG.

TABLE II. PHYSICAL PROPERTIES OF PVDF, HDPE, AND TPU

Parameter	Value	Unit
Material Type	PVDF and HDPE	-
Thickness	0.15, 0.22, and 0.50	mm
Area	2.0, 4.0, 6.0, and 8.0	cm <sup>2</sup>
Pore Size	<53 and 53–250	µm

### C. Sample Characterization

The morphology and structure of the samples were characterized by a scanning electron microscope (SEM) (FEI Company Quanta 3D FEG. The cross-sections of porous PVDF samples were exposed by cryo-fracturing the samples under liquid nitrogen. The fractured surfaces were then sputter-coated with gold (Denton Vacuum, Desk V Sputter Coater).

Open-cell contents of porous PVDF samples were measured by a gas pycnometer (Quantachrome, Ultrapyc 1200e). Nitrogen was used to determine the total volume of the solid part and the closed-cell ( $V_t$ ) by employing Archimedes' principle of fluid displacement, and Boyle's Law of gas expansion. Then, the open-cell content ( $O_c$ ) can be determined by Equation (1).

$$O_c = \frac{V_g - V_t}{V_g} \times 100\% \quad (1)$$

where  $V_g$  is the geometric volume of the open-cell foam sample.

A simple contact-mode TENG, as illustrated in Figure 1, was constructed by using two pieces of cast acrylic plates as the substrates. Copper electrodes with conductive adhesive were adhered to the two plates. The positive and negative triboelectric layers were adhered to the two electrodes. Conducting wires were used to connect the two electrodes to an oscilloscope (Tektronix, TBS1052B-EDU) to measure the output voltage of the TENG during its operation. The measurement was obtained by averaging the output voltages generated by the mechanical vibration as a result of dropping the TENG's top plate, which was attached with a 195 g mass, onto its bottom plate for at least 25 times from a height of 3 cm. All data points were obtained from the characterization of three samples and the error bars present the standard deviations of the data values.

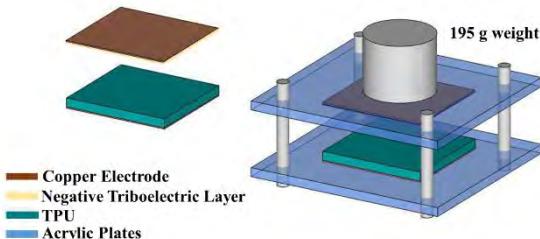

Figure 1. Schematic of Triboelectric Nanogenerator Setup

### III. RESULTS AND DISCUSSION

The performance of TENG was predominantly depending on the degrees of triboelectrification in both the positive and the negative triboelectric layer. In this context, parametric studies were conducted to study the effects of polymer type, triboelectric layer's geometry, as well as foam morphology on the degrees of triboelectrification of these friction layers.

#### A. Effect of Polymer Type on Triboelectricity

The tendencies of materials to gain, lose, or hold electrons when contacting other materials depend on their chemical compositions. Literatures have reported different triboelectric series to organize materials according their ability to gain electrons. These data tables indicated that both PVDF and HDPE have higher tendencies than TPU to gain electrons. Therefore, when they are pairing up with TPU in a TENG, PVDF and HDPE will serve as the negative triboelectric layers while TPU will serve as the positive triboelectric layer. To compare their abilities to draw electrons away from TPU upon periodic contact and separation, solid PVDF and HDPE samples with the same contact area (i.e.,  $4 \text{ cm}^2$ ) and varying thicknesses were used as the negative triboelectric layers of the TENG setup. Figure 2 illustrate the average peak voltages generated by TENG consisted of PVDF and HDPE as the negative triboelectric layers. It can be observed that, regardless of the layer's thickness, the peak voltages generated in the TENGs with PVDF negative triboelectric layers were ~2 times of those generated in the TENGs with HDPE negative triboelectric layers.

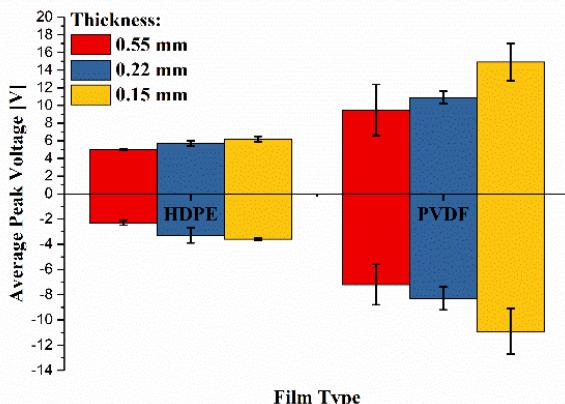

Figure 2. Comparison of PVDF and HDPE's Performances on Triboelectrification for Contact Area of  $4 \text{ cm}^2$

#### B. Effects of Sample Geometry on Triboelectricity

The effects of triboelectric layer's thicknesses and contact area on the degree of triboelectrification were investigated by measuring the changes in vibration-induced voltage generated as these two geometric factors of the negative triboelectric layer (i.e., PVDF and HDPE) were varied. Figures 3 and 4 illustrate the effects of the thickness and contact area of the PVDF layer and the HDPE layer, respectively, on the peak voltages generated during periodic contact and separation of the TENG. Likewise, regardless of the thickness and the contact area, the uses of PVDF as the negative triboelectric layer consistently resulted in higher degrees of triboelectrification than the uses of HDPE.

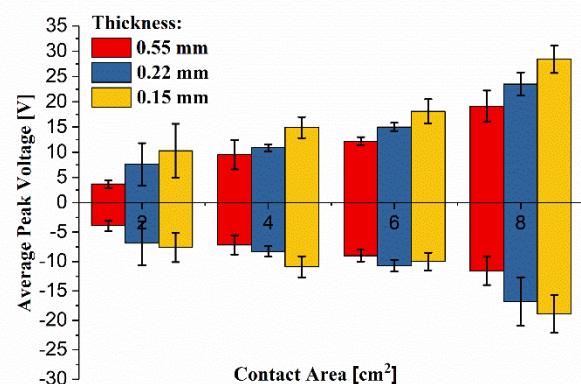

Figure 3. Effects of PVDF Layer's Geometry (i.e., Thickness and Contact Area) on Triboelectrification

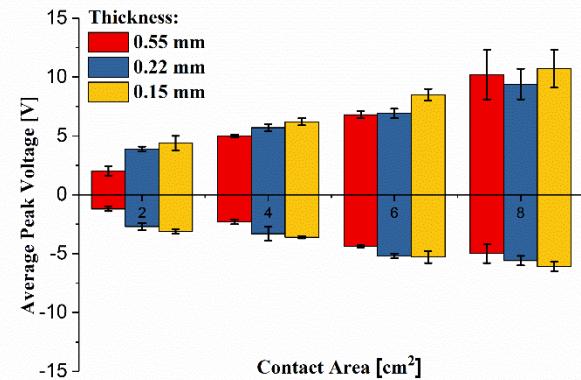

Figure 4. Effects of HDPE Layer's Geometry (i.e., Thickness and Contact Area) on Triboelectrification

For both PVDF and HDPE, it can also be observed that the peak output voltages of the TENG increased by increasing the triboelectric layer's contact area or decreasing the triboelectric layer's thickness. The effect of contact area on the degree of triboelectrification was intuitive. Increasing the contact area would result in the accumulation of more charges between the

opposite triboelectric layers, leading to a higher degree of electrification during the periodic contact and separation between the two layers. In contrast, decreasing the thickness of the PVDF or HDPE layer increased the peak output voltage. This could be attributed to the higher degree of electrostatic induction by the charged triboelectric layers and the electrodes. Experimental results confirmed the analytical model of the induced charge density (i.e., Equation (2)) derived by Wang *et al.* [7].

$$\sigma' = \frac{\sigma d_3 \epsilon_{r1} \epsilon_{r2}}{d_1 \epsilon_{r1} + d_3 \epsilon_{r1} \epsilon_{r2} + d_2 \epsilon_{r2}} \times 100\% \quad (2)$$

where  $\sigma'$  is the induced charge density;  $\sigma$  is the triboelectric charge density;  $\epsilon_{r1}$  and  $\epsilon_{r2}$  are the relative permittivity of the positive triboelectric layer and negative triboelectric layer, respectively;  $d_1$ ,  $d_2$ , and  $d_3$  are the thicknesses of the positive triboelectric layer, negative triboelectric layer, and the air gap, respectively.

### C. Effects of Open-Cell Morphology on Triboelectrification

Figure 5 illustrates an SEM micrograph of a representative open-cell PVDF sample prepared by using 80 wt% of NaCl with particle size of 53  $\mu\text{m}$  – 250  $\mu\text{m}$ . The individual cells resembled the cubic shape of NaCl crystals. It can be observed that the cubic pores were uniformly distributed and interconnected throughout the PVDF matrices. Figure 6 revealed the effect of NaCl particle size (i.e., pore size after the particulate leaching process) on the open-cell contents of porous PVDF foams fabricated by using 80 wt% NaCl.

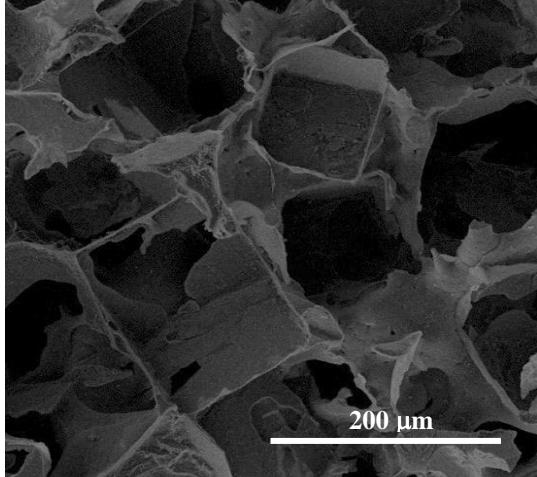

Figure 5. SEM Micrograph of Porous PVDF Negative Triboelectric Layer

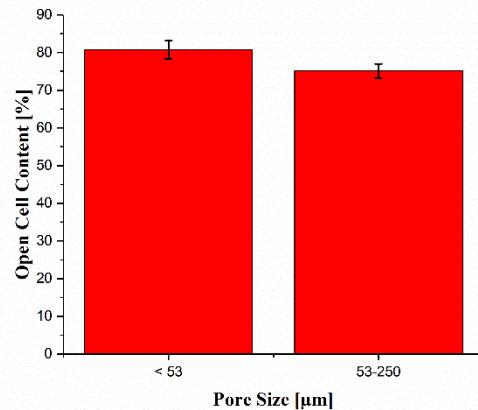

Figure 6. Effect of NaCl Particle Size on the Open-Cell Content of the Porous PVDF Layer

It can be observed that smaller NaCl particle sizes would yield porous PVDF foams with higher open-cell contents. The negative correlation between these two parameters could be attributed to the higher packing efficiency of smaller particles. Figure 6 shows that smaller NaCl particle size would increase the open-cell content of the fabricated PVDF foams after the complete leaching of NaCl. The higher packing efficiency of smaller NaCl particles would promote the interconnectivity among the particles, increasing the opening among adjacent pores after the leaching process.

Figure 7 revealed that open-cell PVDF layer led to a higher degree of triboelectrification than solid PVDF layer. Furthermore, the promoted performance became more significant as the pore size decreased. It is believed that the presence of pores in the PVDF layer would enhance the degree of triboelectrification in three-fold. On the one hand, the omnipresence of pores throughout the PVDF layer significantly increased the surface area of the triboelectric layer. This would increase the accumulation of charges during the periodic contact and separation of the opposite layers. On the other hand, this also reduced the local thickness of the triboelectric layer. It is speculated that this would enhance the electrostatic induction and thereby increased the peak voltage generated. Finally, the promoted conformability of the contact surfaces introduced by the PVDF foam structures would enhance adhesion energy, which would then promote the triboelectric output [5].

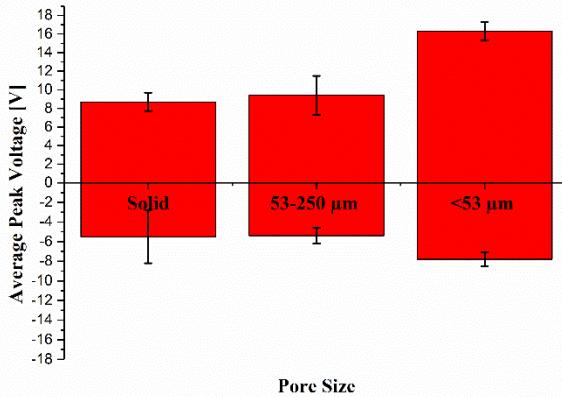

Figure 7. Effects of PVDF Layer's Morphology (Porosity) on Triboelectrification

#### IV. CONCLUSION

The study has investigated the importance of polymer type, contact area, triboelectric layer thickness, and porosity on the triboelectric output voltage of TENG. Experimental results revealed that PVDF was a more efficient negative triboelectric material than HDPE, which increased the peak voltage by ~2 times. Furthermore, increasing the contact area and decreasing the triboelectric layer thickness positively influenced the degree of triboelectrification and/or electrostatic induction. Finally,

particulate leaching, using NaCl as the leaching agent, could introduce open-cell structures within the PVDF layer. The presence of pores and the reduction in pore size were found to be effective strategies to promote the triboelectric output of TENG.

**Abstract**—In the present work, combined cycle power generation configuration studies with natural gas as a primary fuel. Steam is injected in main combustion chamber and reheat combustion chamber individually and simultaneously to understand the performance of combined cycle work output and greenhouse gas emissions. The effect of pressure ratio, gas turbine inlet temperature on combined cycle work output, thermal efficiency and exergy efficiency carried out with and without steam injection. It is observed that the steam injection increases gas cycle efficiency and decreases the steam cycle efficiency. Ideal pressure ratio found to be 25 in all different combined cycle power generation system configurations. Maximum CO<sub>2</sub> emission reduction (7.2%) occurs when steam injected in reheater combustion chamber.

**Keywords – combined cycle; steam; turbines; energy efficiency; exergy efficiency**

## I. INTRODUCTION

This Research investigations are conducted to study the combined cycle power generation systems with various options to increase efficiency and to reduce carbon dioxide emissions. Srinivas et. al. [1] conducted parametric simulation of steam injected gas turbine combined cycle. Waldyr [2] compared the humid air turbine (HAT) cycle with simple gas turbine cycle, steam injected gas turbine and also with the combined cycle. Nishida et. al. [3] investigated the performance characteristics of the regenerative steam injected gas turbine system. Shukla and Singh [4] conducted thermodynamic analysis of steam injected gas turbine cycle power plant with inlet air cooling. Bahrami et. al., [5] conducted performance comparison between steam injected gas turbine and combined cycle during frequency drops. Korakianitis et. al. [6] conducted performance investigations

for combine-cogeneration power plants with performance enhancements. In the present work the effect of steam injection in main and reheat gas turbine combustion chambers and the role of operating variables for different natural gas fired combined cycle power generation systems are investigated.

## II. CONFIGURATION AND METHODOLOGY

### A. Natural gas combined cycle configuration

Natural gas fired combined power generation systems are gaining popularity due to their higher combustion efficiency and reduced emission. Different combined cycle power generation configurations are considered in the present work and are listed in Table 1. Figure 1 shows the schematic diagram of these configurations.

The topping cycle consists of air compressor (*C*1) followed by an intercooler (*IC*). Air is further compressed in second air compressor (*C*2). Compressed air is burned with methane in combustion chamber (*CC*1). In case of configuration #2 and #3 from Table 1, a fraction of a steam ( $\zeta$ ) is injected in the first combustion chamber. Products of first combustion chamber enters main gas turbine (*GT*1) and produced work output. Exhaust gas from main gas turbine further burned with methane in second combustion chamber (*CC*2). In case of configuration #3, a fraction of steam ( $\omega$ ) is injected in reheater combustion chamber. Product of reheater combustion chamber enters the reheater gas turbine (*GT*2) to produce work output. Exhaust gas from gas turbine enters heat recovery steam generator (*HRSG*) which produces steam in the bottoming cycle. The Steam then enters the steam turbine (*ST*) and produces work output. Fraction of steam ( $\zeta$  and  $\omega$ ) is taken out at particular pressure and used in topping cycle for power augmentation. Water vapor from steam turbine is then condensed in condenser and recirculates in the

bottoming cycle through pump. It is assumed that system is operating at steam state steady flow conditions.

TABLE I. CONFIGURATIONS

Configuration	Description of Study
1	Combustion of air and methane without steam injection
2	Combustion of air and methane with steam injection in main combustion chamber
3	Combustion of air and methane with steam injection in main combustion chamber and reheat combustion chamber

Figure 1 shows the generalized schematic diagram for all configuration listed in Table 1. Air is compressed from ambient condition into air compressor ( $C1$ ) and ( $C2$ ). An intercooler ( $IC$ ) is used between  $C1$  and  $C2$  to bring the air temperature down and to reduce overall compressor work. Compressed air [ $\phi O_2 + (\theta \times 3.76)N_2$ ] enters combustion chamber 1 ( $CC1$ ) and burned with methane fuel ( $\alpha$ ) at constant pressure. Combusted gas has high thermal energy and expanded partially into Gas Turbine 1 ( $GT1$ ) to obtain shaft work ( $\dot{W}_{GT1}$ ). Partially expanded gas enters combustion chamber 2 ( $CC2$ ) and burned with methane fuel ( $\beta$ ) to elevate the thermal energy of the gas. Gas coming out of  $CC2$  is expanded in Gas Turbine 2 ( $GT2$ ) to obtain shaft work ( $\dot{W}_{GT2}$ ). Gas coming out of  $GT2$  is passed through Heat Recovery Steam Generator (HRSG) to generate more steam which passes through Steam Turbine ( $ST$ ) to obtain shaft work ( $\dot{W}_{ST}$ ). Saturated water flows through pump ( $P$ ) in order to increase pressure and then passed through HRSG, which then completes the Rankine cycle.

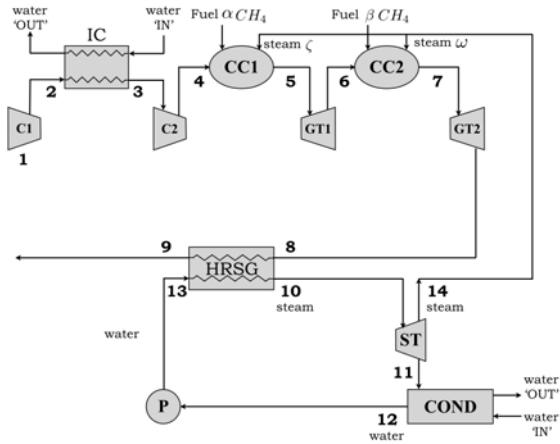

Figure 1. Schematic diagram of configuration 1, 2 and 3 (Listen in Table-1)

The configuration #2 has basic schematic same as configuration #1, except a fraction of steam ( $\zeta$ ) is extracted from  $ST$  and injected inside combustion chamber  $CC1$  with air and fuel. The fraction of steam  $\zeta$  is percentage of air mass flow which enters combustion chamber  $CC1$  at state 4. The steam  $\zeta$  is then taken out from steam turbine at the stage where steam pressure is 5% higher than pressure of combustion chamber 1 ( $CC1$ ). The configuration #3 is an extension from configuration

#2, where fraction of steam ( $\omega$ ) is injected inside of reheat combustion chamber ( $CC2$ ). Steam is taken out of steam turbine at 5% higher pressure present inside combustion chamber 2 ( $CC2$ ).

### B. Thermodynamic Analysis and Methodology

For the considered configurations energy and exergy analyses are conducted with steam injection in gas turbine combustion chambers. Equations are developed for the configurations and the role of steam injection and effect of operating variables are simulated on performance and carbon dioxide emissions..

All simulations have been conducted using Engineering Equation Solver (EES).

### III. RESULTS AND DISCUSSIONS

#### A. Effects of pressure ratio on combined performance with fraction of steam injection

The effects of pressure ratio on combined cycle for both thermal and exergy efficiency is shown in Fig 2. It can be seen from Fig. 2 that there is a sharp increase in thermal efficiency for initial pressure ratio range from 5 to 25. For configuration #1, there is a reduction in thermal efficiency corresponding to pressure ratio of 25 to 40 whereas for configurations #2 and #3, there is no such noticeable reduction in thermal efficiency after optimum pressure ratio has reached. Furthermore it can be seen from Fig. 2 that there is an increase of 1.57% exergy efficiency corresponding to 5% steam injection in CC1 and CC2.

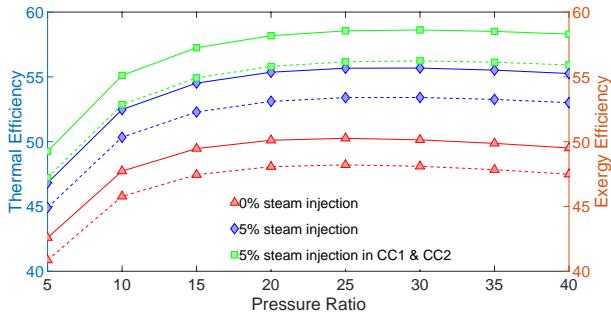

Figure 2. Effects of pressure ratio on combined cycle for both thermal (solid line) and exergy efficiency (broken line)

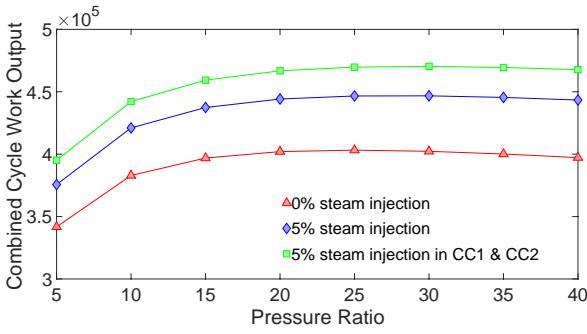

Figure 3. Effects of pressure ratio on the combined cycle work output

#### B. Effects on $CO_2$ emission with fraction of steam injection

Amount of fuel reduction with steam injection has direct impact on  $CO_2$  emissions. The operating parameters of the combined system are set as pressure ratio = 25, Ambient temperature =  $25^\circ C$ , Ambient pressure = 1 bar, Steam temperature =  $500^\circ C$  and Steam pressure = 100 bar. The effects of steam injection on  $CO_2$  emission is shown in Fig. 4. When steam  $\zeta$  is injected to CC1, a constant TIT1 is maintained through reduction on air mass flow, thus reduction in compressor work. At this flow rate, combined cycle net work output increase by 3.2%, because of increase in mass flow of the steam from 0%

to 10% in GT1. In order to maintain constant combined cycle work output, fuel ( $\alpha$ ) consumption reduces. And when steam  $\omega$  is injected in CC2 only, mass flow rate affects only GT2 and through reduction of fuel  $\beta$  in CC2, 7.2% of  $CO_2$  emission reduction observed. However, when steam  $\zeta$  and  $\omega$  were injected in CC1 and CC2 together, only 0.9% of  $CO_2$  emission was observed. The results indicates that injecting steam in CC2 alone has greater effects on reduction of  $CO_2$  emissions.

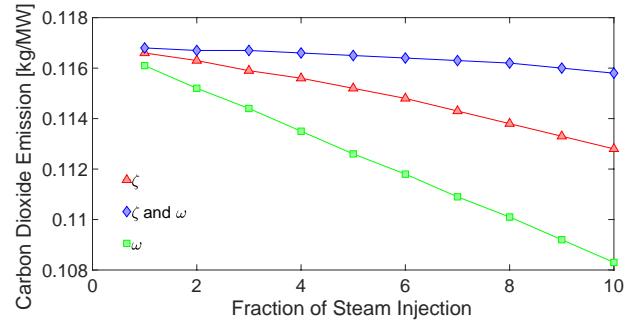

Figure 4. Effects of steam injection in CC1 and CC2 on Carbon Dioxide Emission.

#### C. Performance analysis on fuel ratio for combined cycle with fraction of steam injection

Table II shows fuel supply ratio between CC1 and CC2. At pressure ratio of 25 and Theo<sub>air</sub> of 200%, ideal fuel supply is  $\alpha = 54\%$  and  $\beta = 46\%$ . At this fuel supply TIT1 and TIT2 are very close to each other, which then becomes an important factor to gas turbine efficiency. Furthermore, Table III shows steam  $\zeta$  and  $\omega$  injected at CC1 and CC2 respectively. As steam  $\zeta$  injected in CC1, there is a reduction in TIT1 due to increased mass from the steam, which further resulting in reduction of flame temperature. There is a sharp reduction in TIT1 of  $88^\circ C$  with 10% steam injection in CC1. Further addition of steam  $\omega$  in CC2 resulting further reduction of TIT2. Work output of the gas turbines are increased about 5MW but sharp decline in the net work output (37MW) due to work output lost from the steam turbine. Furthermore Table III shows ideal theoretical air input at different steam injection to maintain the same net work output. Theoretical air is reduced by 32%. It is assumed that complete combustion takes place in both CC1 and CC2. Steam injection decreases the amount of excess air in the combustion chamber, which also supports in controlling the temperature. The amount of steam injection has a limit depending on the air quality on the compressor. As a result of decreased fuel mass, the flue gas from the combustion chamber decreases resulting reduction in  $CO_2$  and  $NO_x$  emission (Fig. 4).

#### D. Exergy destruction in combined cycle system

Figure 6 shows exergy destruction in each individual component in combined cycle compared to overall exergy destruction in the cycle. These results corresponds to fixed turbine inlet temperature of  $1200^\circ C$  and pressure ratio of 25. The main source of exergy destruction in the combined cycle unit are the main combustion chamber (CC1), reheat combustor

(CC2) and heat recovery steam generator (HRSG) which are responsible for 37%, 20% and 16% respectively of the total exergy destruction. It can be seen from the Fig. 6 that the combustors of topping cycle have the highest exergy destruction. Moreover, reducing the destruction in the combustors of topping cycle will lead to a significant improvement in the exergetic efficiency and also reduced destruction in the combined cycle.

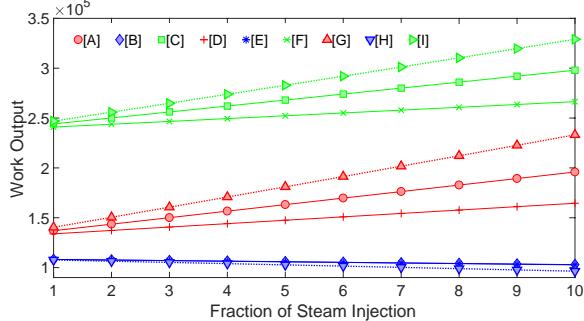

Figure 5. Effects of work output with steam injection for Configuration #1, #2 and #3.

TABLE IV. EFFECTS OF WORK OUTPUT WITH STEAM INJECTION FOR CONFIGURATION #1, #2 AND #3 (FIG. 5).

	Work Output	Steam injection in:
[A]	Gas Cycle Work Output	CC1
[B]	Steam Cycle Work Output	CC1
[C]	Combined Cycle Work Output	CC1
[D]	Gas Cycle Work Output	CC2
[E]	Steam Cycle Work Output	CC2
[F]	Combined Cycle Work Output	CC2
[G]	Gas Cycle Work Output	CC1 and CC2
[H]	Steam Cycle Work Output	CC1 and CC2
[I]	Combined Cycle Work Output	CC1 and CC2

The exergy destruction in the combustion chamber is related to chemical reaction that occurs in combustion process. The exergy destruction ratios that associated with both turbines are less than 10% of total exergy destruction of the power plant. Although the rejected heat in the condenser is considered as tremendous amount from first law of thermodynamics perspective, the exergy destruction ratio associated with the condenser unit is low because the steam at condenser condition does not have potential power to produce useful work. As the fraction of steam (5%) injected in CC1 and CC2, there is a drop of exergy destruction in CC1 and CC2 by 2.3% and 2% respectively. Steam injection adds more useful work and lowers the requirement of fuel amount in combustion chamber, that further reduces the destruction.

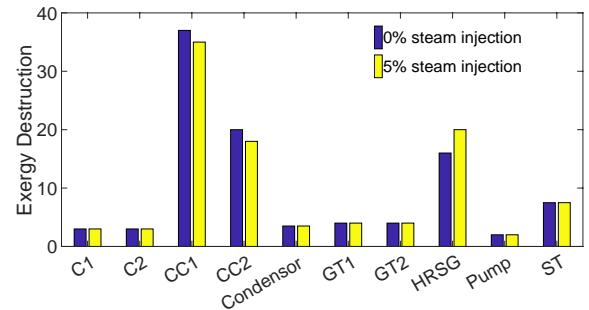

Figure 6. Percentage of exergy destruction in each component as compared to overall destruction on combined cycle with steam injection.

#### IV. CONCLUSIONS

It is observed that the steam injection increases gas cycle efficiency and decreases the steam cycle efficiency. Ideal pressure ratio found to be 25 for considered combined cycle power generation configurations. Steam injection in main combustion chamber and reheat combustion chamber individually has more benefit than steam injection in both combustion chambers together. Maximum CO<sub>2</sub> emission reduction (7.2%) occurs when steam injected in reheat combustion chamber. Thermal efficiency of combined cycle system increased by 8.2% when 10% steam injection in both combustion chambers. The present results and trends on steam injection effect on work output and efficiency are in agreement with results reported in the literature.

# Numerical Simulation of Gas-Liquid Phenomena in the Cathode of a Stirred Tank Reactor Proton Exchange Membrane Fuel Cell

Xichen Wang, Biao Zhou<sup>1</sup>, Mengcheng Jiang

Department of Mechanical, Automotive and Materials Engineering  
University of Windsor  
Windsor, ON, Canada, N9B 3P4

**Abstract**—Liquid water management is still a critical issue in the improvement of proton exchange membrane fuel cell (PEMFC) performance. In this work, for the first time, the liquid water behavior and transport inside the cathode of a PEMFC with a stirred tank reactor (STR) design, rather than the conventional PEMFC flow channel design, are numerically studied. The volume of fluid (VOF) method is employed in the simulation to track the gas-liquid interface. The capability of STR-PEMFC to reduce the liquid water flooding is also investigated and verified from the simulation, showing the potential of this channel-less type fuel cell in the further development.

**Keywords**-proton exchange membrane fuel cell; water management; volume of fluid; stirred tank reactor.

## I. INTRODUCTION

Generally, fuel cells can be classified into five major types according to the electrolyte used: the phosphoric acid fuel cell (PAFC), the solid-oxide fuel cell (SOFC), the alkaline fuel cell (AFC), the molten carbonate fuel cell (MCFC), and the proton exchange membrane fuel cell (PEMFC) [1]. Among these types of fuel cells, PEMFC has been considered as one of the best potential candidates for vehicle and distributed power applications, mainly because of their low operating temperature, high power density, and good start-stop cycling durability. However, PEMFCs suffer from a water management problem that may cause a decrease in power output. Because the operating temperature of a PEMFC is under 100°C (usually 50–100°C), water generated from the electrochemical reaction easily condenses into liquid water and accumulates in the cathode.

Channels in the bipolar plate of the PEMFC can distribute the gas flow and remove excess liquid water, which is an effective way to improve the water management [2]. Many different types of flow field channel designs have been developed so far and most of them can be classified into three categories: parallel, serpentine, and interdigitated. In 2004, an innovative PEMFC with a porous layer connected to a stirred tank reactor (STR) rather than conventional gas flow channels was developed by Benziger et al. [3]. This STR PEMFC provides ideally suitable approaches to examine the fuel cell

dynamics in the reaction and transport processes. The further experiments and analysis of the operating STR fuel cell were also reported by Hogarth and Benziger [4]. The results showed that compared to the conventional PEMFC with serpentine channels under humidified feeds or dry feeds, the STR fuel cell with dry feeds can provide higher power density and voltage at high current density. The features of this channel-less PEMFC include “dry-feeding, auto-humidification and self-draining” [4]. These research works by Benziger et al. [3, 4] not only revealed a simplified method for the PEMFC design, operation and control, but also indicated the remarkable advantages of auto-humidification in the commercialization of PEMFCs. However, no research to date has investigated the liquid water behavior and transport inside the STR PEMFC.

Comparing with other numerical models applied in the simulation of water management in PEMFCs such as the two-fluid model [5–7] and the mixture model [8–10], the volume of fluid (VOF) model [11] has the advantage of simulating the liquid water removal process by tracking the interface between the liquid and gaseous phases. In recent years, VOF method has been recognized as the most popular approach in the simulation of gas-liquid two-phase flow in PEMFCs [12] and a series of numerical studies have been reported in this area [13–19].

In this study, a three-dimensional, two-phase flow model is developed to study the gas-liquid dynamics in the cathode of a PEMFC with STR flow field design. The corresponding simulations are conducted by using the VOF method. The liquid water general transport and emerging process are presented and discussed.

## II. NUMERICAL MODEL DESCRIPTION

### A. Computational Domain and Boundary Conditions

The numerical simulation domain (Fig. 1) is an STR PEMFC cathode, having similar dimensions to Hogarth and Benziger’s model [4], consisting of a porous layer connected to a stirred tank reactor rather than conventional gas flow channels.

The porous layer is 0.019 m × 0.019 m × 0.0003 m (in the X, Y and Z direction respectively). The attached STR is 0.015 m × 0.015 m × 0.0017 m and has an open rectangular plenum

<sup>1</sup>Corresponding Author and Principal Investigator: Dr. Biao Zhou, [bzhou@uwindsor.ca](mailto:bzhou@uwindsor.ca), 1-519-253-3000 ext. 2630

as the gas flow field, minus four distributed pillars at intervals of 0.003 m in the X-Y plane. The dimension of these pillars is  $0.003 \text{ m} \times 0.003 \text{ m} \times 0.0017 \text{ m}$ . A gas inlet channel and an outlet channel with the same dimensions as the pillars are connected to the STR and distributed on the diagonal corners. Gravity acts along the diagonal of the plenum connecting the gas inlet and outlet channels and is directed toward the outlet. The porosity of the porous layer is 0.3.

The no-slip boundary condition is applied to the walls in STR model. The liquid mass flow rate is set as  $1.331 \times 10^{-4} \text{ kgs}^{-1}$  and the gas mass flow rate is set as  $6.615 \times 10^{-5} \text{ kgs}^{-1}$ . The pressure outlet boundary condition is applied at the outlet. The contact angle for the side walls of plenum, upper walls of plenum and walls of porous layer are  $53^\circ$ ,  $43^\circ$  and  $130^\circ$  respectively.

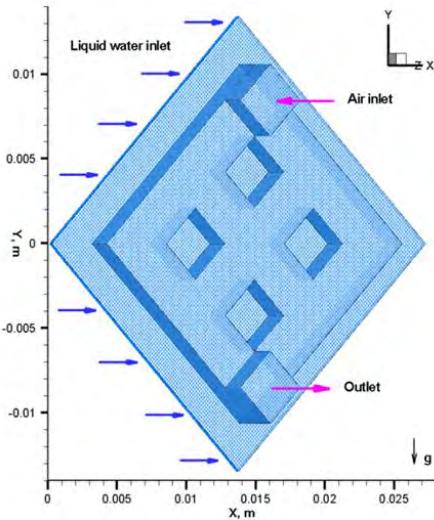

Figure 1. Computational domain of STR model.

### B. Computational Methodology

The VOF method is employed in the present study to track the gas-liquid flow interface. Air is considered as the gaseous phase and liquid water is considered as the liquid phase. The fluid flow is laminar because of the low flow velocity and the small size of the channels. Heat transfer and phase changes are not considered in this study to reduce the computation time. The simulations are conducted using the commercial software package ANSYS Fluent. The governing equations for VOF method are the same as those employed in our previous work by Wang and Zhou [15].

### C. Grid Independence

The computational domain of the STR model is meshed by 167,400 cells with a total volume of  $4.602 \times 10^{-7} \text{ m}^3$ . The cell size is approximately  $1.67 \times 10^{-4} \text{ m}$  in the X and Y directions, whereas the dimensions in the Z-direction are  $1.4 \times 10^{-4} \text{ m}$  in the plenum domain and  $5 \times 10^{-5} \text{ m}$  in the porous layer domain. This grid size has been validated for PEMFC-related simulations by Le et al. [14], and the grid independency check is achieved by increasing and decreasing certain percentages of grid cells.

## III. RESULTS AND DISCUSSION

### A. General Process of Liquid Water Transport in STR Model

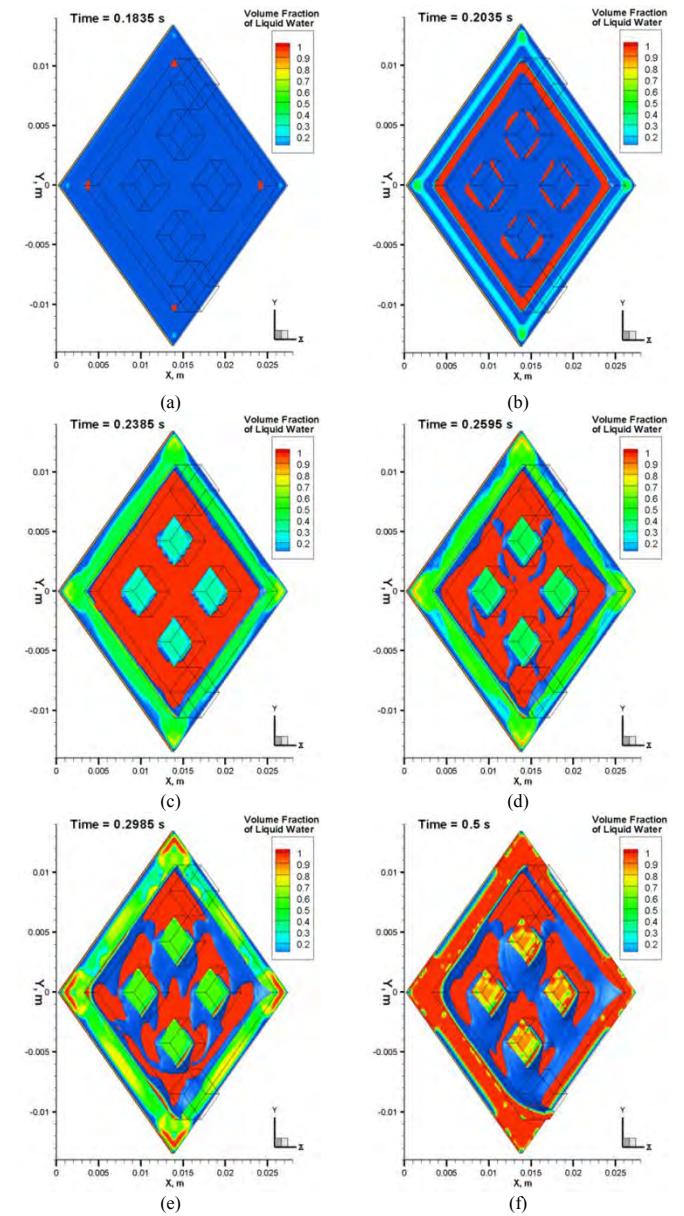

Figure 2. General liquid water transport in the STR model.

Fig. 2 shows the general process of liquid water transport over time at several selected time instants, which can be divided into the following sub-processes:

- 1) The liquid water generated from the electrochemical reaction is supplied continuously from the liquid inlet boundary, i.e., the back surface of the porous layer.
- 2) The liquid water migrating through the porous layer reaches the interface between the porous layer and the plenum, first at the four corners (Fig. 2(a)), then at the peripheral edges of the plenum domain and the edges of four pillars (Fig. 2(b)).

- 3) Liquid water passes through the interface and emerges along the sidewalls of the plenum domain and also at the sidewalls of each pillar (Fig. 2(c)). Some liquid water emerges from the circumjacent areas near the pillars as well (Fig. 2(d)).
- 4) The liquid water emerging from the peripheral edges of the plenum domain and from the edges of the pillars merge together with the liquid water from the circumjacent areas near the pillars, forming a “tooth shape” (Fig. 2(e)).
- 5) As more water enters the plenum, the areas below the pillars become flooded. With the force of gravity and the gas flow, the liquid water drains out of the computational domain through the outlet channel (Fig. 2(f)).

### B. Liquid Water Distribution in Plenum

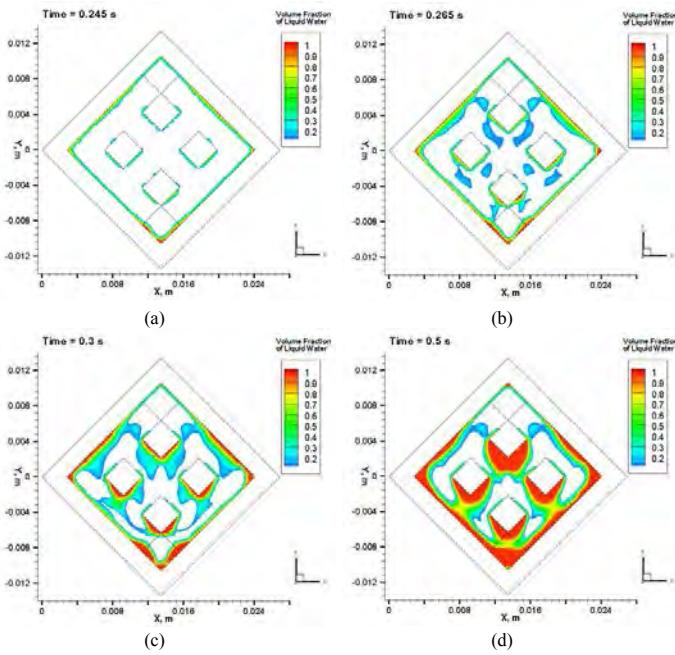

Figure 3. Liquid water distribution on plenum plane near interface ( $Z = 0.00031$  m) in the STR model.

Fig. 3 shows the liquid water distribution on the X-Y plane extracted from the plenum domain at  $Z = 0.00031$  m, which is very close to the interface of the porous layer. At first, liquid water emerges from the peripheral edges of the plenum domain and the edges of pillars (Fig. 3(a)), especially the lower edges. Subsequently, water emerges from the circumjacent areas near the lower sides of the four pillars and also the upper sides of the top pillar and gradually merges with the water from the edges of plenum (Fig. 3(b)), forming tooth-like shapes (Fig. 3(c)). Finally, the lower areas near the pillars become flooded, as well as the areas near the peripheral edges of the plenum (Fig. 4(d)). It can be observed that the liquid water appears mainly in the lower part of the plenum, which is caused by the direction of gravity and the locations of the inlet and outlet channels.

### IV. CONCLUSIONS

In this study, the gas-liquid behavior inside an STR PEMFC is numerically investigated through the VOF method. The liquid water general transport process and liquid water distribution in the Plenum are presented and discussed. It is found that a PEMFC cathode with the STR design has a promising capability for water drainage, so that the fluid flow field in the STR model rarely becomes blocked or fully flooded, which weakens the reduction of the power density of fuel cell. These numerical results verify that self-draining liquid water is one of the merits of the STR PEMFC, which has been noted by Hogarth and Benziger [4].

Windsor, ON, Canada, N9B 3P4

**Abstract**—Among the numerical studies on liquid water transport in Proton Exchange Membrane Fuel Cells (PEMFCs), the static contact angle (SCA) model is generally used, while the dynamic contact angle (DCA) model is only applied on the simulation of droplet behaviors with simple geometries like a single microchannel. In this study, the DCA model is employed to study the gas-liquid phenomena inside the cathode of PEMFC with parallel flow field design, i.e., Parallel-DCA model. The water emerging and transport processes are simulated based on this Parallel-DCA model using the volume of fluid (VOF) method. The numerical results are also compared to those from the Parallel-SCA model with the same computational domain and operating conditions.

**Keywords**-proton exchange membrane fuel cell; volume of fluid; dynamic contact angle; parallel.

## I. INTRODUCTION

As the main product in the cathode, water plays an important role in the performance of a proton exchange membrane fuel cell (PEMFC). Too much or too little liquid water will result in an increase of voltage loss, which is considered to be a key point affecting the performance of PEMFCs. Therefore, water management, particularly liquid water management, is a significant technical issue in the optimization of the PEMFC performance, which has received further attention in this research area.

Comparing with existing numerical models employed in the simulation of gas-liquid dynamics in PEMFCs, the volume of fluid (VOF) model, which was proposed by Quan et al. [1], has the advantage of tracking the interface between the liquid and the gas so that the liquid water distribution and transport can be described in detail. Recently, for the numerical studies on two-phase flow in PEMFCs, the VOF method has been widely used and recognized as an effective tool in this area and a series of research works have been reported [2-9].

However, all the aforementioned numerical studies only considered static contact angle (SCA) as wall boundary condition. It is known that the geometric dimensions of PEMFCs are quite small, namely from a microscopic view, wall adhesion and surface tension significantly affect the

gas/liquid distribution and transport, thus the contact angle is unlikely to stay at equilibrium. Djilali et al. [10, 11] noted that liquid water behavior on the GDL surface is affected by the contact angle when water emerges from a pore. Consequently, in the numerical models of PEMFCs (unsteady, two-phase flow model), it is not reliable to use static contact angle (SCA) as the wall boundary condition. Sikalo et al. [12] conducted experimental and numerical studies for droplet impact on horizontal surface, and it is revealed that there are obvious limitations using SCA as one of the boundary conditions and the DCA should be considered. The Hoffman function [13], an empirical correlation for DCA (also known as Kistler's Law), was employed in [12] to predict the contact angle values:

$$\theta_d = f_{\text{Hoff}}[Ca + f_{\text{Hoff}}^{-1}(\theta_s)] \quad (1)$$

$$f_{\text{Hoff}}(x) = \arccos \left\{ 1 - 2 \tanh \left[ 5.16 \left( \frac{x}{1 + 1.31x^{0.99}} \right)^{0.706} \right] \right\} \quad (2)$$

In (1),  $Ca$  is the capillary number and  $f_{\text{Hoff}}^{-1}(\theta_s)$  is the shift factor obtained from the inverse of the Hoffman function under SCA [14]. Hoffman function is considered as one of the promising formulae in DCA simulations [15]. However, so far, nearly all the numerical models with DCAs are for simple geometries and use the DCA only for a single wall boundary [16-18]. Recently, Jiang et al. [15] found that the AR-DCA model, which is implemented with Hoffman function and considers both advancing and receding dynamic contact angles, can well simulate droplet behaviors and dynamic wetting behaviors. This AR-DCA model is validated against a series of experiments for droplet impact on horizontal and inclined surfaces from Sikalo et al. [19, 20], showing its potential to be applied in the simulation of gas-liquid phenomena in PEMFCs.

In this study, we extend our previous work [4] by applying DCAs at multiple wall boundaries to investigate the gas-liquid phenomena inside the cathode of a parallel PEMFC, i.e., Parallel-DCA model. The general liquid water transport processes are presented and discussed, and also compared to those from Parallel-SCA model.

## II. NUMERICAL MODEL DESCRIPTION

### A. Numerical Simulation Domain

The numerical simulation domain for the parallel model represents the geometry of a full-scale cathode side of a single PEMFC, as shown in Fig. 1. The detailed dimensions and descriptions of this domain can be found in [4].

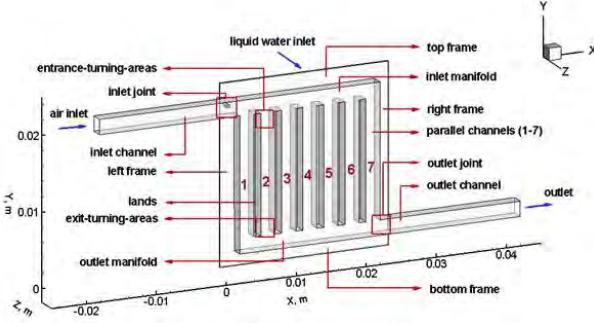

Figure 1. Computational domain of Parallel model.

### B. Computational Methodology

A three-dimensional PEMFC cathode model is developed in this study to investigate gas-liquid phenomena and water transport processes. Air is modeled in the gaseous phase and liquid water is modeled in the liquid phase; these two-phases are assumed to be immiscible. The VOF method is applied to track the liquid-gas flow interface. The governing equations and corresponding computational methodology were reported in our previous work by Wang and Zhou [4]. The method to implement DCA model was reported by Jiang and Zhou [15]. More details and descriptions can be found in [4] and [15].

### C. Boundary Conditions and Grid Independence

The accelerated model [3] is employed in this study by adjusting the mass flow rate of air and liquid water, which can significantly save the computation time. The mass flow rate for the liquid water inlet and gas inlet is set as  $1.7 \times 10^{-4}$  kg s<sup>-1</sup> and  $2.0 \times 10^{-5}$  kg s<sup>-1</sup> respectively. The initial contact angle for the side walls of channels, upper walls of channels and walls of porous layer are 40°, 43° and 140° respectively. In Parallel-SCA model, the contact angles are constant for the wall boundaries, whereas in the Parallel-DCA model, the contact angles vary with the change of the flow field and can be expressed as parameters associated with time and location.

The Parallel-DCA model and Parallel-SCA model [4] share the same computational domain and the mesh set up and independency has also been reported in [4].

## III. RESULTS AND DISCUSSION

### A. General Process of Liquid Water Transport in Parallel-DCA Model

The general process of liquid water transport in the Parallel-DCA model, as shown in Fig. 2, can be summarized into several sub-processes:

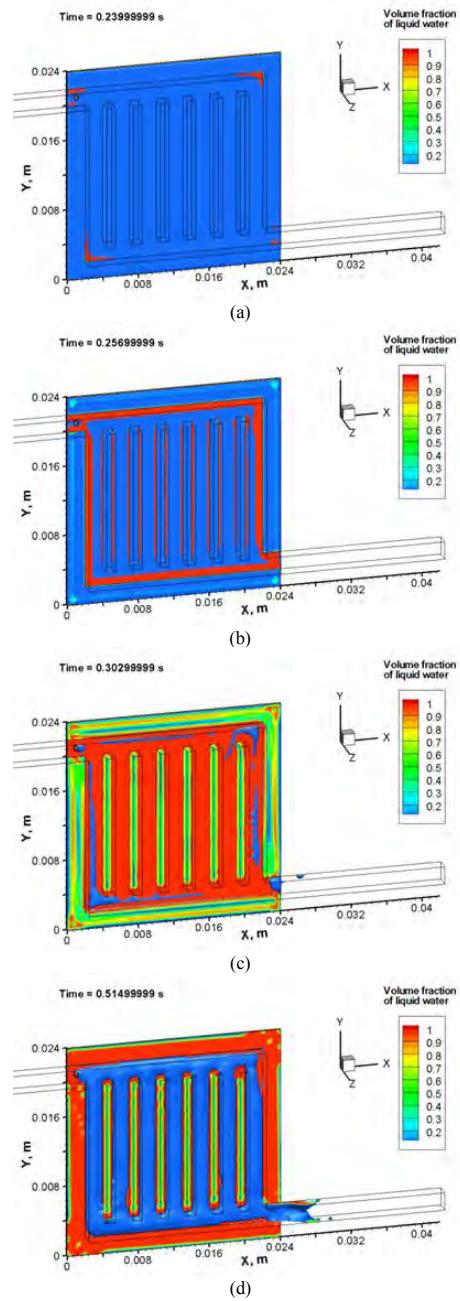

Figure 2. General liquid water transport in the Parallel-DCA model.

- 1) Liquid water is supplied from the back surface of the porous layer with a constant mass flow rate to simulate the liquid water generation through the electrochemical reaction.
- 2) The liquid water reaches the top surface of the porous layer, first accumulates at the four corners of the interface under the channels domain (Fig. 2(a)), and then the frame and the edges of each parallel channel (Fig. 2(b)).
- 3) Liquid water from the porous layer emerges into the gas flow channels first from the interface under the frame of the channels domain, in the middle area of the channels (Fig. 3(c)).

- 4) More liquid water emerges into the channels. With time, channels become flooded and liquid water starts to drain out through the outlet channel, as shown in Fig. 2(d).

In summary, the general process of water transport and removal in the Parallel-DCA model are similar to those of the Parallel-SCA model [4] in the early stage (Fig. 2(a) and (b)). However, some different phenomena can be observed: for the Parallel-DCA model, the liquid water emerges into the gas channels first from the middle area of the interface under the channels, whereas for the Parallel-SCA model, the liquid water emerges into the gas channels from the peripheral edges of the lands and the peripheral edges of the channels domain. The detailed comparisons are provided and illustrated in the following sections.

### B. Comparison of Emerging Process

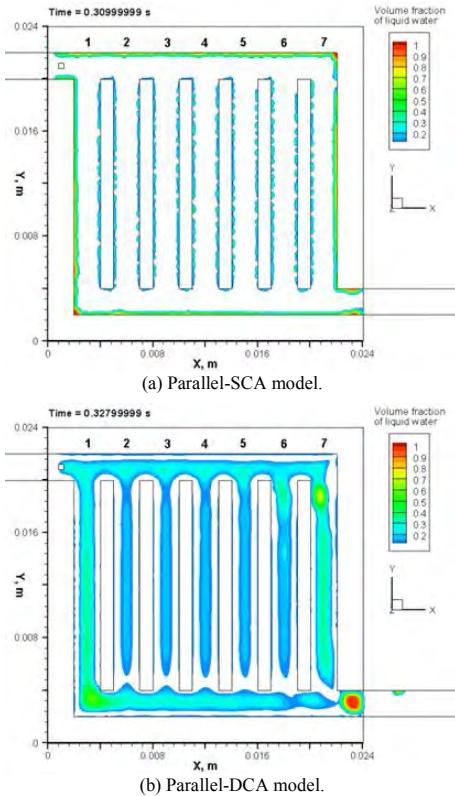

Figure 3. Comparison of the liquid water distribution near interface at  $Z = 0.00031$  m.

Fig. 3 (a) and (b) show the liquid water emerging pattern in the gas flow channels from Parallel-SCA and Parallel-DCA models respectively, located at the plane extracted near the interface ( $Z = 0.00031$ m) from the channel domain. It can be further observed that for Parallel-SCA model, the liquid water enters into the gas flow channels from the peripheral edges of the channel domain and emerges from the land edges (Fig. 3(a)); whereas for Parallel-DCA model, the liquid water mainly passes through the interface under the middle area, with only a small amount of water emerging from the edges of the lands and moving along the sidewalls (Fig. 3(b)).

The detailed emergence and growth of liquid water from the porous layer into the channels is presented by Fig. 4, which shows the liquid water volume fraction with different reference velocity vectors located at the No. 7 parallel channel on the plane (extracted from the computational domain at  $Y = 0.012$  m as illustrated in Fig. 4(a)). For Parallel-SCA model, due to the uniform water generation rate on the back surface of the porous layer, the liquid water from the porous layer enters into the channels from the land edges; it can also be observed that there is a pair of vortices – an upper vortex and a lower one – in the cross-section of the parallel channels, referred to as Dean vortices, which normally occur in curved channels or pipes [21]. For Parallel-DCA model, the liquid water emerges from the porous layer enters into the channel at the middle area, and the pair of vortices has a left-right distribution.

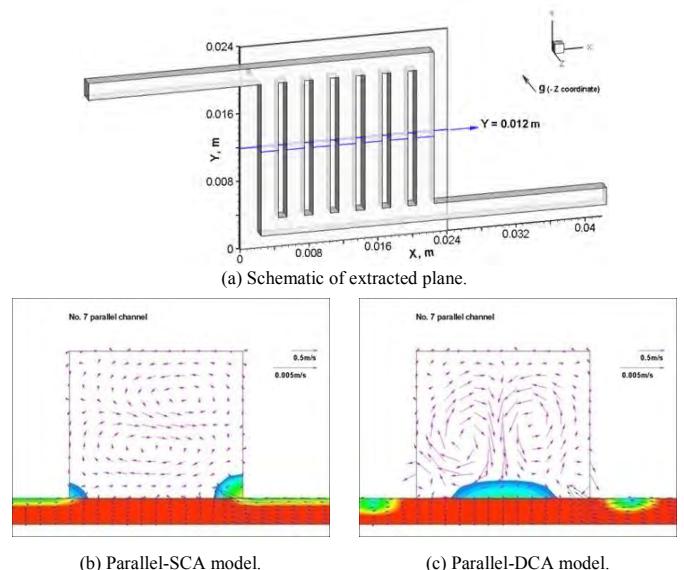

Figure 4. Comparison of liquid water emerging on plane at  $Y = 0.012$  m (enlarged plane with velocity vectors).

### C. Comparison of Flow Pattern in the Draining Process

The draining process in the Parallel-SCA and Parallel-DCA models can be explained by Fig. 5, which shows the deformation of the draining liquid water in the outlet channel. For the Parallel-SCA model, valley-shaped water near the outlet joint will deform into a top-bottom stratified flow pattern while moving along the outlet channel to drain out, as shown in Fig. 5(a); whereas for the Parallel-DCA model, the deformation of the liquid water in the outlet channel is in a stratified-slug pattern, as shown in Fig. 5(b). Also, it can be observed that there are several splashed, small droplets in the outlet channel adhered to the sidewalls of the outlet channel, because their inertial force is not strong enough to overcome the friction or wall adhesion.

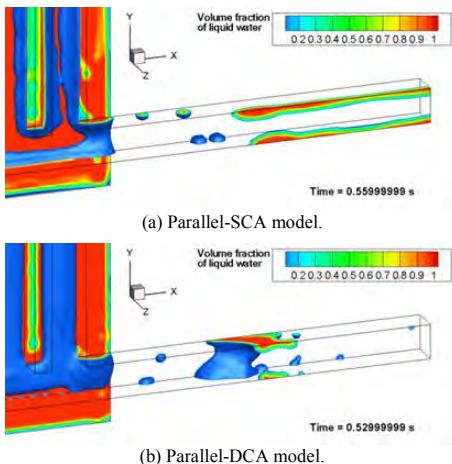

Figure 5. Comparison of the flow pattern in the draining process.

#### IV. CONCLUSIONS

In this study, the Parallel-DCA model is proposed by applying DCA at multiple wall boundaries in a PEMFC cathode. The gas-liquid phenomena and water transport processes are simulated and investigated using the Parallel-DCA model and VOF method. The numerical results are compared to those from the Parallel-SCA model [4]. It is indicated that although the general water transport processes from these two models are similar, there are several differences observed from the phenomena that can be summarized as follows:

- (1) Emerging pattern (SCA model: liquid water first emerges from the edges of the interface under the channels; DCA model: liquid water first emerges from the middle of the interface under the channels).
- (2) Dean vortices evolution (SCA model: upper-lower distribution; DCA model: left-right distribution).
- (3) Draining deformation (SCA model: top-bottom stratified flow; DCA model: stratified-slug flow).

In the future, we will further investigate the potential of the DCA model to be applied in the simulation of gas-liquid phenomena in PEMFCs with other complex flow field designs.

**Abstract**— Lower cost, lighter weight, and higher electrical conductivity are among many advantages of using metallic bipolar plates (BPs) over the conventional graphitic materials in PEM fuel cell applications. In this study, diamond-like carbon (DLC) coatings are deposited on top surfaces of stainless steel (SS316) and Aluminum (Al5052) substrates via Plasma Enhanced Carbon Vapor Deposition (PECVD) in order to increase the durability. Further, the effect of different plasma power intensities and type of precursor gases, including methane ( $\text{CH}_4$ ) and acetylene ( $\text{C}_2\text{H}_2$ ), on the growth of DLC films is studied. Various ex-situ characterization techniques have been used to examine the strength of adhesion, morphologies, structures/compositions, and wettability of the DLC coatings. It is found that coatings produced from  $\text{CH}_4$  gas show superior adhesion in comparison to those obtained from the  $\text{C}_2\text{H}_2$  gas. Results indicate that higher deposition power intensity can produce more  $\text{sp}^3$  bonds than  $\text{sp}^2$  bonds. It is also determined that the type of the metallic substrates has predominant roles on the morphology of the DLC coatings. In addition, a moderate power intensity of 250 W results in desirable properties in DLC, including adhesion and wettability, compared to higher and lower plasma power intensities.

**Keywords-** Proton exchange membrane fuel cell; Bipolar plates; Diamond-like carbon.

## I. INTRODUCTION

Bipolar plates (BPs) are one of the crucial components in polymer electrolyte membrane (PEM) fuel cells. They conduct electrons between adjoining cells, distribute reactants, facilitate water and heat management, and provide mechanical support. To accomplish these functions, bipolar plates must exhibit a number of desirable mechanical and surface properties. However, most commercial bipolar plates are made of heavy-

graphite and are considered to be the bulkiest and the second most-expensive component in the manufacture of PEM fuel cell stacks [1]. Due to the technical and cost requirements of BPs [1-3], metallic bipolar plates have received considerable attention to replace conventional graphite materials, but their durability inside the acidic PEM fuel cell environment is a challenging issue. Various surface modifications and protective coatings have been investigated, including [4]: noble metals such as gold [5], metal nitrides, and metal carbides. In the last decade, diamond-like carbon (DLC) has been considered an innovative candidate as a coating material for metallic BPs in PEM Fuel Cells [6]. In general, DLC can be formed as a thin film at relatively low deposition temperatures on metallic substrates. One of the most suitable DLC deposition techniques is Plasma Enhanced Chemical Vapor Deposition (PECVD) [7-9]. Carbon-based layer is deposited on stainless steel (SS304) via PECVD, and the coating sample presents the lower interfacial contact resistance in comparison to the SS304 without coating [10]. In other work, a 1 $\mu\text{m}$ -thin layer of nickel is applied between the SS304 and carbon-base coating to improve adhesion [11]. The electrical conductivity of DLC film under different voltages is also reported [12]. Due to the potential advantages of using aluminum, different carbon-composite coatings for aluminum-base bipolar plates have also been investigated [13] [14]. However, information about DLC coating on the aluminum surfaces is limited. Therefore, the objective of this work is to investigate the effect of deposition parameters on the DLC properties for metallic-base substrates (stainless steel SS316 and aluminum Al5052).

## II. EXPERIMENTAL AND CHARACTERIZATIONS

The DLC coating is deposited on Al5052 and SS316 substrates by using the fully automated INTLVAC's AUTOSYS control system.  $\text{CH}_4$  and  $\text{C}_2\text{H}_2$  are separately used as a precursor gas, and the carrier gas is argon. Different plasma power intensities of 70, 250, and 1000 W are applied in

order to investigate its impact of plasma power on the various characteristics of DLC coatings, whereas the argon gas percentage is fixed at 30% and the deposition time is a constant of 74 min. Various ex-situ characterization methods are employed to investigate the properties of the deposited films. Scanning electron microscopy is used to study the morphology of the prepared samples. Since the adhesion of the coating DLC films is one of the most challenging tasks of surface engineering, tape pull-off tests are used to check the coatings' adhesion to the metallic substrates. The morphology of the coated film is investigated by field emission-scanning electron microscopy (FE-SEM). Further, X-ray photoelectron spectroscopy (XPS) spectroscopy is commonly used for quantitative comparison between the molecule compositions existing on the coated surface. The DLC surface wettability indicates the hydrophobicity behavior of the BP coatings in order to determine whether they are suitable for PEM Fuel cell applications. The surface wettabilities of the DLC coatings on different Al5052 and SS316 samples are evaluated by measuring the static contact angle ( $\theta$ ), a characterization technique that uses a Ramé-Hart contact angle apparatus.

### III. RESULTS

#### A. Adhesion

Table 1 summarizes the results of the adhesion tests between the DLC coatings on SS316 and Al5052 substrates, under the classifications as passed, failed, and partially failed. It shows the impact of varying the precursor gas between acetylene ( $C_2H_2$ ) and methane ( $CH_4$ ), and the power intensities between 70 W and 250 W, then 1000 W on the adhesion of the DLC coatings with the constant carrier gas (argon) percentage of 30 % and deposition time of 74 min.

TABLE 1. ADHESION TESTS OF DLC COATINGS ON SS316 AND AL5052 SUBSTRATES:

Deposition Parameters				Substrate Materials SS316	Substrate Materials Al5052
Power (W)	H/C gas	Ar (%)	Time (min)	Pass/Failed	Pass/Failed
70	$C_2H_2$	30	74	Failed	Failed
250	$CH_4$	30	74	Passed	Passed
1000	$CH_4$	30	74	Failed	Passed

It is observed that employing  $CH_4$  gas can result in higher adhesion than  $C_2H_2$  gas, especially with a moderate plasma power intensity of 250 for both Al5052 and SS316 substrates. This adhesion enhancement can be attributed to the different growth mechanisms of carbon composites between  $CH_4$  gas and those produced from  $C_2H_2$ . This difference occurs because DLC generated by using  $CH_4$  produces more hydrogen in reaction, hence the etching reaction is developed during the deposition processes [15]. It is also noticed that increasing the plasma power intensity has a negative effect on the adhesion between the SS316 substrate and the coating. That is, a higher power intensity of 1000 W can result in poor DLC adhesion in comparison to 250 W. The poor adhesion at higher plasma power intensity is associated with a fast deposition rate as well as the growth of thicker DLC films. Consequently, the residual stress is higher inside the films due to the noticeable increase

in  $sp^3$  bonding fraction, as will be discussed by the XPS analysis. On the other hand, varying the plasma power intensity has a negligible impact on the adhesion of the DLC coating on Al 5052 substrates. These results signify the roles of the metallic substrate on the adhesion property.

#### B. Morphology

Figure 1 (a-d) shows the surface morphologies of two different DLC coatings deposited on SS316 and Al5052 substrates at two different power intensities of 250 W and 1000 W. These images are taken from the top surface without using any gold coating. Figure 1 (a and b) are obtained using SS316, while 30 % of carrier gas is applied. These images show homogenous coverage, with the presence of big island-shaped regions (see the images with high magnification on top of the SEM images). Both surfaces are covered with dark and light particles, and this contrast can be attributed to the accumulation of particles with different electrical-conductivity properties. The DLC structure is basically amorphous carbon coordinated with  $sp^2$  and  $sp^3$  structures with different conductivity. It is expected that the  $sp^3$  bond is responsible for the mechanical properties, while  $sp^2$  bond presents the electronic properties. It can be seen that Figure 1 (a) is covered with a higher amount of darker particles, in comparison to Figure 1 (b). These results may suggest that using higher power in the PECVD process leads to a higher  $sp^3$  structure. Further, Figure 1 (c and d) demonstrates the top surface of the coating on the Al5052 substrate under identical deposition conditions as those for Figure 1 (a and b). It can be observed that the two images have uniform and homogenous coverages with a stripe-like structure, which is considerably different than island-shaped structure in the SS316 substrate. These images clearly suggest that the types of substrate are a predominant factor in the morphology of the DLC coating. However, the deposition conditions also play important roles. For instance, Figure 1 (a) and (c) are prepared under identical conditions using different substrates, but the morphology of the samples is completely different (island versus stripe).

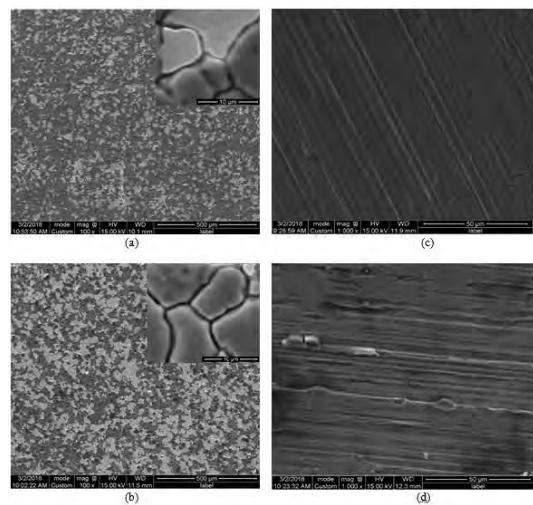

Figure 1. SEM images of coated films of DLC deposited SS316 substrates with plasma power intensity of (a) 250 W and (b) 1000 W, whereas (c) and (d) for coated films of DLC deposited on Al5052 substrates with plasma intensities of 250 and 1000 W, respectively

### C. X-ray Analysis

Figures 1 (a) and (b) show the XPS spectra of DLC films deposited on SS316 substrates for plasma power intensities of 250 W and 1000 W, respectively, with a fixed carrier gas (argon) ratio of 30 %. The coating films are obtained under a deposition time of 74 min. Since the surface properties of the DLC films are strongly influenced by the ratios between the  $sp^3$  and  $sp^2$  of the carbon bonds, it can be expected that DLC with higher  $sp^2$  carbon bonds will show graphene-like properties. It can be observed from Figure 1 (a-d) that the curve peak of DLC film deposited is deconvoluted into two components, which indicate the existences of different carbon bonds including  $sp^2$  and  $sp^3$ . It can be observed from Figure 1 (a) that about 81 % of the DLC coated film deposited on the SS316 is  $sp^2$  carbon bonds. However, increasing the deposition power intensity to 1000 W lowered the amount of graphene-like bonds in the coating films by 15%. Further, figure 1 (c) shows curve peaks at 284 corresponds to the  $sp^2$  binding energy on its spectrums, while the peak of DLC deposited with 1000 W has been shifted to the higher binding energy of 285 eV. It can be seen that the percentage of  $sp^2$  is 70.9 % in the coated samples produced with 250 W, while the DLC coatings obtained with 1000 W contain 58.7 %  $sp^3$  bonds. On the other hand, the second peak components occur at 286 eV, indicating the C=O bond in the coating film due to contamination. This suggests that a higher power intensity of 1000 W can result in incensing of the  $sp^3$  bond in the DLC films. Further, these results may suggest that the metallic-substrate material and the deposition-power intensity can impact the deposited-film properties.

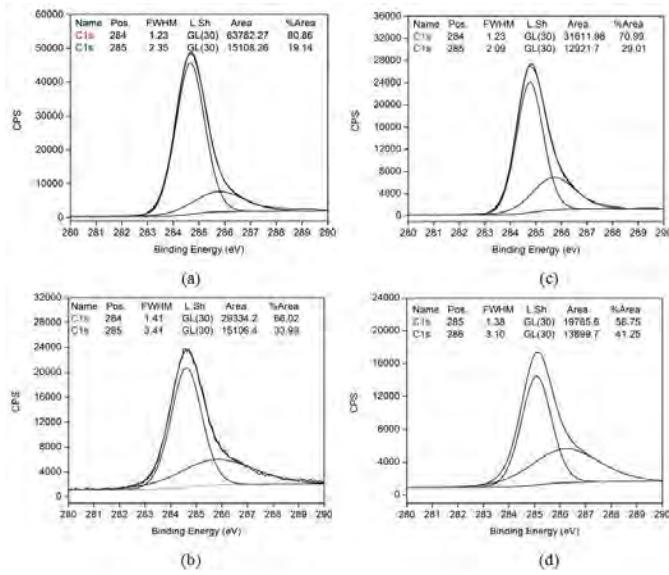

Figure 2. XPS analysis spectra of coating films of DLC with different power intensities (a) 250 W and (b) 1000 W deposited on SS316 substrates. Whereas coatings deposited on Al5052 substrates with power intensity of (c) 250 W and (d) 1000 W. Deposition conditions: CH<sub>4</sub> is a precursor gas, argon gas percentage of 30 %, time of 74 min, and voltage 120 V.

### D. Wettability

Water management is a crucial issue inside operating PEM Fuel cells. The wettability and water repellency of the bipolar plates are important surface properties for water removal [16].

Therefore, the DLC coatings of the bipolar plate coatings surface must exhibit hydrophobicity behavior and water repellency. The surface wettabilities of the DLC coatings on different Al5052 and SS316 substrates are evaluated as in Table 2, showing the average values of the water contact angles ( $\theta^\circ$ ) for the coated surface of SS316 and Al5052 substrates. The angles vary from 80° to 82° for the SS316 substrate, and from 76° to 91° for Al5052 under different plasma power intensities. Table 2 may suggest that the substrate material has a strong impact on the surface wettability characteristics. It demonstrates that increasing the deposition power intensity results in lowering the contact-angle values due to the diamond-like carbon structure [17]. This observation is found to be in good agreement with the XPS analysis discussed above, which showed that a higher percentage of  $sp^3$  bonds in the coating with a higher power intensity of 1000 W in comparison to 250 W. Further, it is seen that coated films deposited with a lower power intensity of 250 W results in a higher contact angle of 91°.

TABLE 2: STATIC CONTACT ANGLE ( $\theta$ ) OF DLC DEPOSITED ON AL5052 AND SS316 SUBSTRATES

Deposition Parameters				Substrate Materials SS316	Substrate Materials Al5052
Power (W)	H/C gas	Ar (%)	Time (min)	Contact angle (°)	Contact angle (°)
250	CH <sub>4</sub>	30	74	82	91
1000	CH <sub>4</sub>	30	74	80	76

### IV. CONCLUSIONS

The effect of power intensity on the carbon composite coatings deposited on aluminum (Al5052) and stainless steel (SS316) substrates has been investigated. Adhesion, SEM, XPS, and wettability measurements have been conducted to understand the characteristics and the compositions of the deposited coatings. It has been observed that coatings generated from CH<sub>4</sub> provide better adhesion than those coatings produced from C<sub>2</sub>H<sub>2</sub> gas. Results suggest that the ratio between  $sp^2$  and  $sp^3$  bonds in the DLC coatings is strongly affected by the plasma power intensity. It has been found that a large percentage  $sp^3$  (diamond-like) in the coating is produced at a high power density at the cost of the  $sp^2$  bond (graphene-like). Therefore, the surface morphology and composition of the DLC coatings are strongly influenced by the deposition parameters and material of the metallic substrates. The coatings generated under power intensity of 250 W shows stronger adhesion with the metallic Al5052 and SS316 substrates than those produced higher power of 1000 W. Further, the DLC coatings deposited on metallic substrates demonstration hydrophobicity properties with a contact angle of between 80° of 90°.

**Abstract**—In the present work, natural gas combined cycle power generation configurations are investigated with oxyfuel combustion. Steam is also injected in main combustion chamber and reheat combustion chamber to understand the performance of combined cycle work output and greenhouse gas emission. It is observed that the steam injection increases gas cycle efficiency and decreases the steam cycle efficiency. CO<sub>2</sub> emission reduction of 3.2% when steam injection in both combustion chambers for oxyfuel cycle. In oxyfuel combustion, higher ratio of recycle flue gas brings higher thermal efficiency and highest thermal efficiency is achieved when steam is injected in gas turbine main combustion chamber only.

**Keywords** – *combined cycle; oxyfuel; turbines; energy efficiency; exergy efficiency*

## I. INTRODUCTION

There is growing research investigations conducted on natural gas combined cycle power generation system with oxyfuel combustion approach due to the ability to capture carbon dioxide emissions and for carbon capture and storage. Mietzko et. al. [1] reported comparison of natural gas combined cycle power plants with post combustion and oxyfuel technology at different CO<sub>2</sub> capture rates. Stanger et. al. [2] presented details on oxyfuel combustion for CO<sub>2</sub> capture in power plants. They reported an overview of the current state of the art technology on the development of oxyfuel combustion systems for CO<sub>2</sub> capture. Sammak et. al., [3] reported conceptual mean-line design of single and two-shaft oxyfuel gas turbine in a semi closed oxyfuel combustion combined cycle. Thorbergsson and Gronstedt [4] conducted thermodynamic analysis of two competing mid-sized oxyfuel combustion combined cycles.

Jericha et. al., [5] presented gas turbine with CO<sub>2</sub> retention for 400MW oxyfuel system Graz Cycle. Woollatt and Franco [6] reported details on conceptual aerodynamic design of turbomachinery components for natural gas oxyfuel cycles. Mathieu and Bolland [7] presented results on comparison of costs for natural gas power generation with CO<sub>2</sub> capture. In the present work, natural gas combined cycle power generation configurations are investigated with oxy fuel combustion. Steam is also injected in main combustion chamber and reheat combustion chambers to understand the performance of combined cycle work output and greenhouse gas emissions.

## II. CONFIGURATION AND METHODOLOGY

### A. Natural gas combined cycle configuration

Natural gas fired oxyfuel combustion combined power generation systems gaining popularity for carbon capture and storage. In the present work different oxyfuel combined cycle power generation configurations as listed in Table 1 are considered. Figure 1 shows the schematic diagram of these configurations.

The topping cycle consists of air compressor (C1) followed by an intercooler (IC). Air is further compressed in second air compressor (C2). Compressed air is burned with methane in combustion chamber (CC1). In case of configuration #2 and #3 from Table 1, a fraction of a steam ( $\zeta$ ) is injected in the first combustion chamber. Products of first combustion chamber enters main gas turbine (GT1) and produced work output. Exhaust gas from main gas turbine further burned with methane in second combustion chamber (CC2). In case of configuration #3, a fraction of steam ( $\omega$ ) is injected in reheat combustion chamber. Product of reheat combustion chamber enters the

reheater gas turbine (*GT*2) to produce work output. Exhaust gas from gas turbine enters heat recovery steam generator (*HRSG*) which produces steam in the bottoming cycle. The Steam then enters the steam turbine (*ST*) and produces work output. Fraction of steam ( $\zeta$  and  $\omega$ ) is taken out at particular pressure and used in topping cycle for power augmentation. Water vapor from steam turbine is then condensed in condenser and recirculates in the bottoming cycle through pump. It is assumed that system is operating at steam state steady flow conditions.

In configuration #1, pure oxygen ( $\phi$ ) obtained from air separator unit (ASU) is used as oxidizing agent and burned in  $CC1$  with main combustion chamber fuel  $\alpha$  and in  $CC2$  with fuel supply  $\beta$ . Expanded gas after  $GT2$  is passed through  $HRSG$  and steam is generated to operate bottoming Rankin cycle. Exhaust gas after  $HRSG$  contains only  $CO_2$  and water vapor. Water vapor is condensed through water separator (WS) and removed from exhaust gas.

Combustion of methane and pure oxygen produces very high flame temperature, which is not suitable for turbine operation at this stage. A fraction of  $CO_2$ , defined as  $\lambda$  is compressed in three compressors ( $C3, C4, C5$ ) coupled with intercooler between each compression. Highly compressed  $\lambda CO_2$  is removed from the cycle for sequestration. Remaining part of  $CO_2$  defined as  $(1 - \lambda)$  is compressed in  $C1$  and  $C2$  and recycled back to  $CC1$  to bring the flame temperature down to suitable operative condition.

TABLE I. CONFIGURATIONS

Configuration	Description of Study
# 1	Combustion of oxygen and methane without stream injection
# 2	Combustion of oxygen and methane with steam injection in main combustion chamber
# 3	Combustion of oxygen and methane with steam injection in main combustion chamber and re-heater combustion chamber

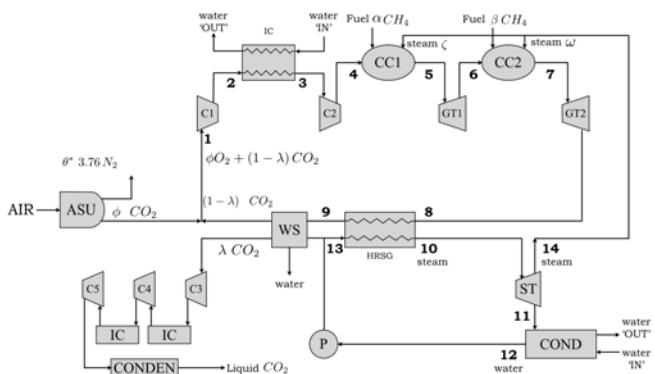

Figure 1. Schematic diagram of configuration 1, 2 and 3 (Listen in Table-1)

Similar to configuration #1, in configuration #2, a fraction of steam  $\zeta$  is extracted from  $ST$  and injected inside  $CC1$  with pure

oxygen  $\phi$  and fuel  $\alpha$ . The  $CC2$  is not injected with steam, where steam is taken from steam turbine at 5% higher pressure than pressure present inside the  $CC1$ . As an extension of configuration #2, in configuration #3, additional steam  $\omega$  is taken from steam turbine and injected inside of  $CC2$ . Pressure at which  $\omega$  is extracted from steam turbine is 5% higher than pressure present at  $CC2$ .

TABLE II. EFFECTS OF FLUE GAS RECYCLE ON TURBINE INLET TEMPERATURE IN COMBINED CYCLE STEAM – CONFIGURATION #1.

$\lambda$ [%]	90	80	60	40	20	0
TIT1 [°C]	1552	1643	1871	2194	2687	3545
TIT2 [°C]	1619	1697	1880	2105	2383	2710

### B. Thermodynamic Analysis and Methodology

For the considered natural gas oxyfuel combined cycle power generation systems energy and exergy analyses are conducted. Equations are developed and simulations are conducted to investigate the role of flue gas recycle ratio and steam injection on thermal efficiency and CO<sub>2</sub> reduction.

All simulations have been conducted using Engineering Equation Solver (EES).

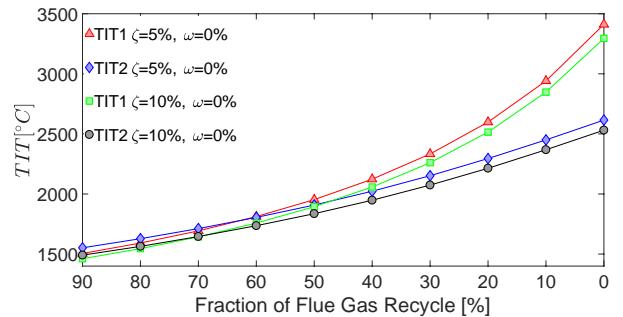

Figure 2. Effects of steam injection on TIT with fraction of flue gas recycle (Configuration #2)

### III. RESULTS AND DISCUSSIONS

#### A. Effects of flue gas recycle on turbine inlet temperatures

When fuel is burned with pure oxygen, it produces very high *TIT* (Turbine Inlet Temperature) which is not desirable for current operational turbine blades.

To bring *TIT* to operable level, the flue gas  $\lambda$  is recycled to the combustion chamber once all water vapor is isolated. Table 2 shows the effects of  $\lambda$  on *TIT1* and *TIT2* when fuel supply is maintained at  $\alpha = 54\%$  and  $\beta = 46\%$ .

### B. Effects of steam injection on TIT with fraction of flue gas recycle

Figure 2 shows the effects of steam injection (with 5% and 10% respectively) only in the *CC1*. Steam addition helps to lower the *TIT* as it adds mass of steam in combustion chamber. As more steam is injected in *CC1*, additional mass flow from steam reduces the *TIT* to the operational level of  $1000^{\circ}\text{C}$  –  $1400^{\circ}\text{C}$  (i.e. configuration #3, figure not shown here). Furthermore fig. 3 shows combined cycle efficiency if maximum when steam injected only in *CC1* and minimum when steam is injected in *CC1* and *CC2* together. Higher efficiency can be obtained from configuration #2 and #3.

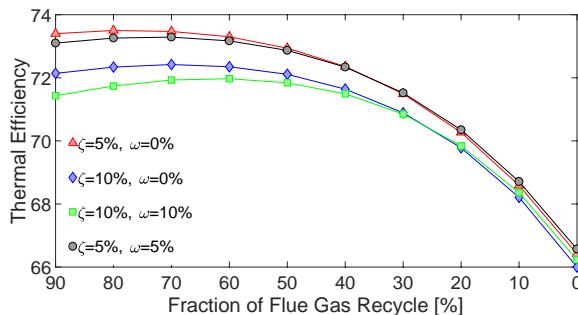

Figure 3. Effects of steam injection on combined cycle thermal efficiency with fraction of flue gas recycle (Configuration #2 and #3)

### C. Effects of pressure ratio on combined cycle work output, efficiencies and $\text{CO}_2$ emission

Various pressure ratio applied to the oxyfuel combustion system at fixed *TIT1* and *TIT2* of  $1200^{\circ}\text{C}$ . Figure 4 shows the effects of pressure ratio on both the topping cycle work output and combined cycle work output for all configuration listed in Table 1.

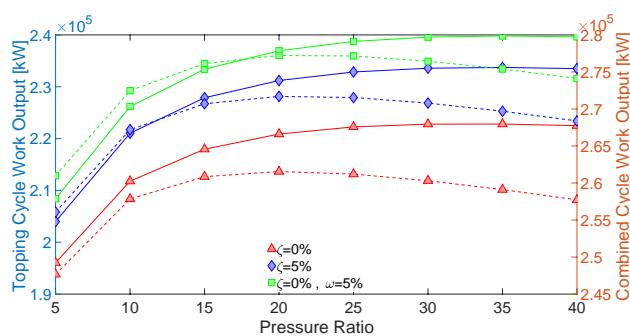

Figure 4. Effects of pressure ratio on topping cycle work output (left axis) and on combined cycle work output (right axis dotted line) for Configuration #1, #2 and #3.

It can be seen from Fig 4 that topping cycle increases work output up to pressure ratio of 25 and then remains constant at higher pressure ratio. Adding 5% steam injection at *CC1* further increases the topping work output and 5% steam injection at

*CC1* and *CC2* brings topping cycle work slightly higher. There is an increase of 2.3% work output when steam injected in *CC1* only and 0.3% further increase when steam is injected in both combustion chambers.

Figure 5 shows the  $\text{CO}_2$  emission for all configuration considered here. It can be observed from Fig 5 that, the lowest emission accounts in configuration #3 with corresponding pressure ratio of 25 and steam injection of 5%.

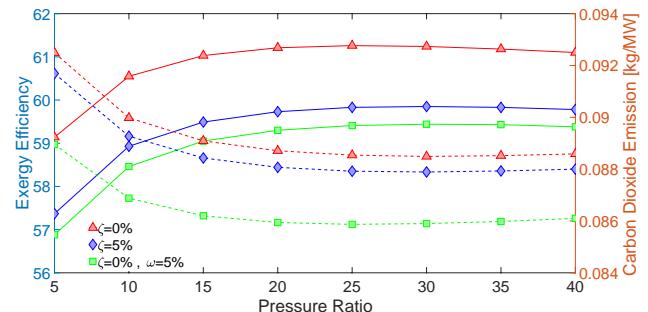

Figure 5. Effects of pressure ratio on exergy efficiency (left axis) and on  $\text{CO}_2$  emission (right axis dotted line) for Configuration #1, #2 and #3

## IV. CONCLUSIONS

$\text{CO}_2$  emission reduction of 3.2% when steam injection in both combustion chambers for oxyfuel cycle. In oxyfuel combustion, higher ratio of recycle flue gas brings higher thermal efficiency and highest thermal efficiency is achieved when steam is injected in main combustion chamber only. More than 10% steam in combustion chamber brings combined cycle thermal efficiency down. The present results and trends on oxyfuel combustion work are in agreement with results reported in the literature.

**Abstract**—Increasing energy demand for air conditioning due to climate change is posing a continuous threat to the environment. Absorption air-conditioning systems driven by solar thermal or waste heat energy are an alternative for providing cooling comfort in a sustainable manner. The crystallization problem of high performance LiBr-H<sub>2</sub>O absorption cooling system hinders its small-scale applications. In this study, the potential of a 10 kW LiCl-H<sub>2</sub>O absorption refrigeration system is discussed and analyzed. The new concept of advanced exergy analysis is coupled with conventional thermodynamic analyses, which provides the available potential of each component for overall system performance improvement. The analyses uncovered that only 45% of the total exergy loss is due to each component's own internal irreversibilities, whereas the remaining is through the interaction of the irreversibilities of other components in the system. The analyses also reveal that 43% of the total exergy loss is unavoidable and 57% can be reduced by improving the overall system efficiency.

**Keywords-** *LiCl-H<sub>2</sub>O; vapor absorption refrigeration; exergy analysis; advanced exergy analysis*

## I. INTRODUCTION

Global warming poses a continuous threat to the environment. At the same time, air-conditioning demand is increasing significantly on a global scale as a result of climate change, population growth, standard of living conditions and industrialization. Presently, air conditioning alone accounts for 40% to 55% of the total building energy consumption [1], which is a major sector of the total world energy consumption and carbon emissions [2]. The traditional vapor compression air-conditioning system is usually used for providing this cooling comfort, but consumes a huge amount of electricity, triggering the construction of new fossil fuel power plants worldwide. Therefore, it is imperative to employ renewable energy technologies in order to minimize climate change while

meeting the increased energy demand. A vapor absorption air conditioning system, driven by solar thermal energy, can replace the traditional vapor compressor by a thermally-driven one by using an environmentally friendly refrigerant, without utilizing grid electricity.

The most common absorbent-refrigerant working pairs for this cooling system are LiBr-H<sub>2</sub>O and NH<sub>3</sub>-H<sub>2</sub>O. The higher efficiency LiBr-H<sub>2</sub>O absorption system dominates in large scale air-conditioning applications. However, due to the crystallization problem, the LiBr-H<sub>2</sub>O absorption system cannot be scaled down for small residential applications. Meanwhile, the thermophysical properties of LiCl-H<sub>2</sub>O shows promise for small residential-scale applications. Many researchers have shown that LiCl-H<sub>2</sub>O has advantages over a LiBr-H<sub>2</sub>O system in terms of cycle performance as well as low energy consumption [3, 4-8]. Hence, it is important to perform a detailed thermodynamic analysis of a LiCl-H<sub>2</sub>O vapor absorption refrigeration system (VARS) in order to improve the cycle performance.

To quantify the potential of useful energy in any system, exergy analysis identifies the irreversibilities of the system components through the exergy destruction and losses. This process determines the true inefficiencies in the system and where the losses are taking place. Exergy analysis measures the actual improvement potential of the system. Exergy signifies the maximum work potential of a system that can be produced when the system proceeds from initial state to final state in relation to the surrounding environment. In this study, the exergy analysis was performed for each component and the total exergy destruction of each component was divided into endogenous, exogenous, unavoidable, and avoidable exergies. This relatively new exergy analysis is known as advanced exergy analysis. Finally, a comparison of conventional and advanced exergy analyses was performed on the component(s) that need to be improved via reducing the exergy losses.

## II. SYSTEM DESCRIPTION

The schematic of a single-effect LiCl-H<sub>2</sub>O absorption cooling system is shown in Fig. 1. The core components of this cooling system are the absorber, generator, condenser and evaporator. Two expansion (throttle) valves are used for reducing the pressure. A solution heat exchanger is considered to preheat the weak solution of LiCl-H<sub>2</sub>O leaving the absorber with the heat of the high temperature strong solution that flows back from the generator to the absorber.

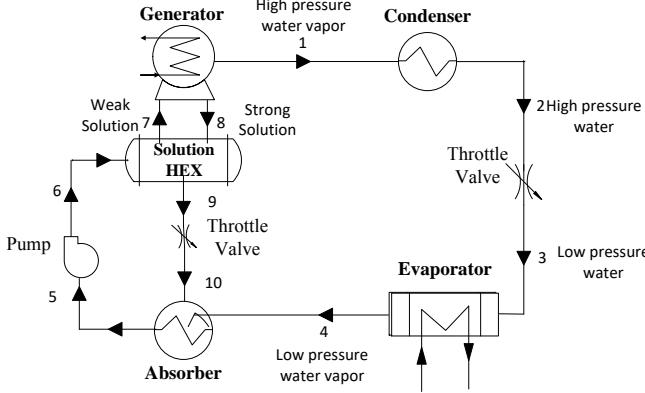

Figure 1: LiCl-H<sub>2</sub>O Vapor Absorption Refrigeration System (VARS)

## III. THERMODYNAMIC ANALYSIS

For a thermodynamic model of a vapor absorption refrigeration cycle, the principles of mass and energy conservation, and exergy balances was applied for each component of the system. The main components: generator, condenser, evaporator, absorber, and solution heat exchanger have been considered. To analyze the thermodynamic cycle, a control volume was applied to each component. All analyses were performed by considering the system under steady-state conditions.

### A. Conventional Exergy Analysis

The mass and the energy balance of each component of the LiCl-H<sub>2</sub>O refrigeration cycle in a control volume can be written as

Mass Conservation:

$$\sum \dot{m}_{in} - \sum \dot{m}_{out} = 0 \quad (1)$$

Energy Conservation:

$$\sum \dot{Q} = \sum \dot{m}_{out} h_{out} - \sum \dot{m}_{in} h_{in} + \dot{W} \quad (2)$$

where  $\dot{m}$  is the mass flow rate (kg/s),  $\dot{Q}$  is the heat transfer rate (kW),  $h$  is the specific enthalpy (kJ/kg) and  $\dot{W}$  is the rate of work leaving the control volume (kW).

The exergy balance in a control volume can be determined by [9]

$$\dot{E}_D = \sum (\dot{me})_{in} - \sum (\dot{me})_{out} + \sum \dot{E}_{Q,in} - \sum \dot{E}_{Q,out} + \sum \dot{W} \quad (3)$$

where  $\dot{E}_D$  represents the rate of exergy destruction (loss) in the system,  $(\dot{me})_{in}$  is the rate of exergy entering the control volume,  $(\dot{me})_{out}$  is the rate of exergy leaving the control volume,  $\dot{E}_Q$  represents the rate of exergy destruction in terms of heat transfer, to/from the component, and  $\dot{W}$  is the mechanical work done by or on the control volume.

At any constant temperature (T),

$$\dot{E}_Q = \dot{Q} \left( 1 - \frac{T_{ref}}{T} \right) \quad (4)$$

The overall exergy per unit mass of a fluid can be calculated by [10]

$$e = (h - h_o) - T_{ref}(s - s_o) \quad (5)$$

where  $e$  is the specific exergy,  $h$  is the specific enthalpy and  $s$  is the entropy at a given temperature  $T$ , and  $h_o$  is the enthalpy, and  $s_o$  is the entropy at the environmental temperature  $T_{ref}$ . The reference temperature and pressure are  $T_{ref} = 273.15$  K and  $P_{ref} = 101.325$  kPa, respectively. The specific exergy, specific enthalpy and entropy of a LiCl-H<sub>2</sub>O solution at a given temperature and pressure were calculated by using EES software [11]. In conventional exergy analysis, the exergy destruction [12] and the exergy destruction ratio [13] can be written as

$$\dot{E}_{D,k} = (\dot{E}_k)_{in} - (\dot{E}_k)_{out} \quad (6)$$

$$y_k = \frac{\dot{E}_{D,k}}{\dot{E}_{D,\text{total}}} \quad (7)$$

In Equations (6) & (7),  $\dot{E}_{D,k}$  is the exergy destruction rate of  $k^{\text{th}}$  component,  $(\dot{E}_k)_{in}$  and  $(\dot{E}_k)_{out}$  are the exergy entering/leaving to/from the  $k^{\text{th}}$  component,  $y_k$  is the exergy destruction ratio of the  $k^{\text{th}}$  component over the total exergy destruction of the system. The exergy destruction provides the thermodynamic inefficiency of each component of the system [14]. The energy and the exergy equations of each component of the LiCl-H<sub>2</sub>O absorption refrigeration system are shown in Table 1.

### B. Advanced Exergy Analysis

The exergy destruction of each component can be split into endogenous/exogenous and unavoidable/avoidable exergy destruction parts [15]. Dividing exergy destruction of a component into endogenous and exogenous parts provides the actual exergy destruction caused by the component itself and the exergy destruction of that component caused by the remaining components of the system. As a result, it will provide information as to whether the focus to improve the system performance should be in the component itself or on the remaining components of the system. Alternatively, when the component operates at actual (real) and theoretical conditions, dividing the exergy destruction into unavoidable and avoidable parts determines the exergy destruction that cannot be eliminated. Table 2 shows the different operating conditions that were applied for this advanced exergy analysis.

TABLE 1: ENERGY AND EXERGY BALANCE EQUATIONS

Cycle Components	Energy balance equation	Exergy balance equation
Generator	$\dot{Q}_{gen} = \dot{m}_1 h_1 + \dot{m}_7 h_7 - \dot{m}_6 h_6$ $X_6 \dot{m}_6 = X_7 \dot{m}_7$	$\dot{E}_{D,gen} = \dot{m}_6 e_6 - \dot{m}_1 e_1 - \dot{m}_7 e_7 + \dot{Q}_{gen}(1 - \frac{T_o}{T_{gen}})$
Condenser	$\dot{Q}_{con} = \dot{m}_1 (h_1 - h_2)$	$\dot{E}_{D,con} = \dot{m}_1 (e_1 - e_2) - \dot{Q}_{con}(1 - \frac{T_o}{T_{con}})$
Evaporator	$\dot{Q}_{eva} = \dot{m}_4 h_4 - \dot{m}_3 h_3$	$\dot{E}_{D,eva} = \dot{m}_3 (e_3 - e_4) + \dot{Q}_{eva}(1 - \frac{T_o}{T_{eva}})$
Absorber	$\dot{Q}_{abs} = \dot{m}_8 h_8 + \dot{m}_4 h_4 - \dot{m}_5 h_5$	$\dot{E}_{D,abs} = \dot{m}_4 e_4 + \dot{m}_8 e_8 - \dot{m}_5 e_5 - \dot{Q}_{abs}(1 - \frac{T_o}{T_{abs}})$
Solution HEX	$T_6 = \frac{\dot{m}_7}{\dot{m}_5} \eta_{HEX} T_7 + \left(1 - \frac{\dot{m}_7}{\dot{m}_5} \eta_{HEX}\right) T_5$ $h_8 = h_7 - \frac{\dot{m}_5}{\dot{m}_7} (h_6 - h_5)$	$\dot{E}_{D,HEX} = \dot{m}_7 e_7 + \dot{m}_5 e_5 - \dot{m}_8 e_8 - \dot{m}_6 e_6$ $\dot{E}_{D,total} = \dot{E}_{D,gen} + \dot{E}_{D,con} + \dot{E}_{D,eva} + \dot{E}_{D,abs}$

X is the LiCl mass fraction in solution;  $\eta_{HEX}$  is the heat exchanger efficiency

TABLE 2: ALGORITHM AND ASSUMPTION OF PARAMETERS FOR DIFFERENT OPERATING CONDITIONS

Cycle Components	Algorithm*	Ideal cycle	Real cycle**	Unavoidable cycle**
Generator	$P_{gen} = P_{cond}(1 - \Delta P_{gen})$ $T_{gen} = (T_{cond} + \Delta T_{gen})$	$\Delta P_{gen} = 0$ $\Delta T_{gen} = 0$	$\Delta P_{gen} = 2\%$ $\Delta T_{gen} = 5^\circ\text{C}$	$\Delta P_{gen} = 0.2\%$ $\Delta T_{gen} = 0.5^\circ\text{C}$
Condenser	$T_{cond} = (T_{cond} + \Delta T_{cond})$ $T_{cond} \rightarrow P_{cond}$	$\Delta T_{cond} = 0$	$\Delta T_{cond} = 5^\circ\text{C}$	$\Delta T_{cond} = 0.5^\circ\text{C}$
Evaporator	$T_{eva} = T_{eva} + \Delta T_{eva}$ $T_{eva} \rightarrow P_{eva}$	$\Delta T_{eva} = 0$	$\Delta T_{eva} = 2^\circ\text{C}$	$\Delta T_{eva} = 0.2^\circ\text{C}$
Absorber	$T_{abs} = T_{abs} + \Delta T_{abs}$ $P_{abs} = P_{eva}(1 - \Delta P_{abs})$	$\Delta T_{abs} = 0$ $\Delta P_{abs} = 0$	$\Delta T_{abs} = 5^\circ\text{C}$ $\Delta P_{abs} = 2\%$	$\Delta T_{abs} = 0.5^\circ\text{C}$ $\Delta P_{abs} = 0.2\%$

\*[12]

### Endogenous/Exogenous Exergy Destruction

The total exergy destruction ( $\dot{E}_{D,k}^{real}$ ) of a component (k) can be divided into endogenous ( $\dot{E}_{D,k}^{EN}$ ) and exogenous ( $\dot{E}_{D,k}^{EX}$ ) parts and can be written as [9]

$$\dot{E}_{D,k}^{real} = \dot{E}_{D,k}^{EN} + \dot{E}_{D,k}^{EX} \quad (8)$$

The endogenous exergy destruction of a component is associated with the internal irreversibilities of that component only when the other components are without irreversibilities. This can be determined by considering the case where this component will work on real operating conditions while the other components of the system will work in ideal (theoretical) operating conditions. Therefore, the endogenous exergy destruction is only due to the inefficiency of the k component. The remaining exergy destruction is the exogenous exergy destruction in that component. This exergy destruction represents the inefficiency of the k component and the inefficiencies of the remaining components of the system.

### Unavoidable/Avoidable Exergy Destruction

In real operating conditions, every component of a system works with some limitations such as technical and design limitations including material availability or cost of the materials etc. Therefore, some part of the total exergy destruction of a component cannot be reduced. This is called the unavoidable exergy destruction ( $\dot{E}_{D,k}^{UN}$ ). The rest of the total

exergy destruction of the component is avoidable ( $\dot{E}_{D,k}^{AV}$ ), which is represented by Equation (9). The unavoidable exergy destruction of a component is calculated assuming that the component is isolated from the system. The most reasonable operating conditions for calculating the unavoidable exergy destruction are the lowest temperature difference and pressure losses [15-17]. The unavoidable conditions are determined based on the maximum improvement that can be achieved for the component.

$$\dot{E}_{D,k}^{real} = \dot{E}_{D,k}^{UN} + \dot{E}_{D,k}^{AV} \quad (9)$$

### Combination of Two Dimensions of Exergy Destruction

The unavoidable exergy destruction of a component can be split again into endogenous unavoidable exergy destruction and exogenous unavoidable exergy destruction of that component. The exogenous unavoidable parts of a component cannot be reduced any more due to the technical limitations of the other components of the system for a given design and structure [17]. For a component, it can be determined by subtracting the endogenous unavoidable exergy destruction from the total unavoidable exergy destruction of that component and is defined by

$$\dot{E}_{D,k}^{UN} = \dot{E}_{D,k}^{EN-UN} + \dot{E}_{D,k}^{EX-UN} \quad (10)$$

The endogenous avoidable part of the exergy destruction of a component can be reduced by improving the efficiency of that component. It can be can be determined by

$$\dot{E}_{D,k}^{EN} = \dot{E}_{D,k}^{EN-UN} + \dot{E}_{D,k}^{EN-AV} \quad (11)$$

Likewise, the exogenous avoidable exergy destruction of a component can be reduced by the improving the design and structure of the overall system and also by improving the efficiency of the remaining components of the system. It is defined by

$$\dot{E}_{D,k}^{EX} = \dot{E}_{D,k}^{EX-UN} + \dot{E}_{D,k}^{EX-AV} \quad (12)$$

Therefore, the effect of the exergy destruction of each component on the overall system performance can be determined through this advanced exergy analysis. The total exergy destruction of a component is

$$\dot{E}_{D,k}^{real} = \dot{E}_{D,k}^{EN-UN} + \dot{E}_{D,k}^{EN-AV} + \dot{E}_{D,k}^{EX-UN} + \dot{E}_{D,k}^{EX-AV} \quad (13)$$

### C. Theoretical Considerations

The following assumptions have been used for analyzing the thermodynamic cycle in this study:

1. The system is operating under steady state conditions.
2. LiCl-H<sub>2</sub>O solutions are assumed to be in equilibrium in the generator and in the absorber at their corresponding pressures and temperatures.
3. The throttle valve is a constant enthalpy adiabatic process.
4. The vapor leaving the generator is 100% water vapor.
5. The refrigerant leaving the condenser is saturated water, and leaves the evaporator as water vapor.

6. The air cooling is considered for cooling of the condenser and the absorber at an atmospheric temperature of 25°C.

#### IV. RESULTS AND ANALYSIS

The thermodynamic values of different states of a 10 kW LiCl-H<sub>2</sub>O refrigeration cycle obtained from conventional exergy analysis under ideal (theoretical) and real operating conditions are summarized in Table 3. The exergy destruction ( $E_{D,k}$ ) and exergy destruction ratio ( $y_{D,k}$ ) of each component under ideal, real, and unavoidable operating conditions are shown in Table 4. Table 4 shows that the highest exergy destruction is in the absorber followed by the condenser, the generator and the evaporator for ideal and unavoidable operating conditions. However, the solution heat exchanger has the second highest exergy destruction after the absorber in real operating condition because of the heat exchanger effectiveness. These losses are due to high irreversibilities occurring in the absorber and the generator. This is because of the high temperature difference across the heat exchanger in the absorber, mass transfer between the two differently concentrated solutions and the mixing losses in the absorber and the generator [18]. Furthermore, the refrigerant (water) vapor is superheated when it leaves the generator/separators. As a result, a higher temperature is required under the same operating conditions, and this leads to higher thermodynamic losses in the generator. In addition, the condenser requires more cooling in order to cool the superheated water vapor that comes from the generator and this generates more exergy destruction in the condenser. This conventional exergy analysis suggests that the exergy loss in the absorber needs to be reduced first to improve the overall system efficiency. However, the irreversibilities of the other components in the system are partly responsible for the generator and condenser

exergy destructions, and the extent of responsibility can be determined by advanced exergy analysis.

In advanced exergy analysis, the exergy destruction of each component is split into four parts. The analyses have been performed based on the operating conditions in Table 2. The results of this analysis are shown in Table 5.

TABLE 4: RESULTS OF CONVENTIONAL EXERGY ANALYSIS OF A 10 kW LiCl-H<sub>2</sub>O ABSORPTION REFRIGERATION CYCLE UNDER DIFFERENT OPERATING CONDITIONS

Cycle Components	Ideal		Real		Unavoidable	
	$E_{D,k}$ (kW)	$y_{D,k}$ (%)	$E_{D,k}$ (kW)	$y_{D,k}$ (%)	$E_{D,k}$ (kW)	$y_{D,k}$ (%)
Generator	6.13	18.8	10.31	13.6	6.18	18.8
Condenser	7.54	23.1	7.70	10.1	7.51	22.9
Evaporator	6.13	18.8	7.53	9.7	6.11	18.6
Absorber	10.3	31.6	33.04	42.7	10.47	31.9
Solution HEX	2.53	7.8	18.76	24.3	2.60	7.9

It can be found from Table 5 that in a 10 kW LiCl-H<sub>2</sub>O absorption air conditioning system, the exogenous exergy destruction ( $\dot{E}_{D,k}^{EX}$ ) of the absorber and the solution heat exchanger is higher than the endogenous exergy destruction ( $\dot{E}_{D,k}^{EN}$ ). This is opposite for generator, condenser and evaporator. This demonstrates that the other components' irreversibilities have high impact on the absorber and the solution HEX performance. Whereas, the internal irreversibility of the generator, the condenser and the evaporator itself needs to be reduced. Therefore, to improve the overall system efficiency, the components themselves should be examined for design and performance improvement.

TABLE 3: THERMODYNAMIC PROPERTIES AT DIFFERENT STATES IN LiCl-H<sub>2</sub>O ABSORPTION CYCLES UNDER IDEAL & REAL OPERATING CONDITIONS

State	Temperature (°C) Ideal/Real	Pressure (kPa) Ideal/Real	Mass flow (g/s) Ideal/Real	% Concentration Ideal/Real	Enthalpy (kJ/kg) Ideal/Real	Entropy (kJ/kgK) Ideal/Real	Exergy, e (kJ/kg) Ideal/Real

		45%	55%	43%	57%	42%	0.5%	3%	54.5%

% are determined according to Equations (8), (9), & (13).

It is also noted from Table 5 that the total unavoidable exergy destruction ( $E_{D,total}^{UN}$ ) of the system is 33 kW which is 43% of the total exergy destruction rate. While  $E_{D,total}^{EN-UN} = 32$  kW (42%) is due to the components themselves. Therefore, the minimum exergy destruction rate of the system is 33 kW and this cannot be reduced further. In practice, only the avoidable part of the total exergy destruction can be reduced. It is noticed that the avoidable part of the exergy destruction is 57% (44 kW) of the total exergy destruction rate ( $E_{D,total}^{real} = 77$  kW). However, only 3% (2.2 kW) of the total exergy destruction can be eliminated by improving the components' own efficiencies, and 54.55% (42 kW) will be lowered by improving overall system efficiency. The value of  $E_{D,abs}^{EN-AV}$  in Table 5 indicates only 6% of the exergy destruction of the absorber can be reduced by technological improvement. It is also noticed that the exogenous avoidable is much higher than the endogenous avoidable exergy destruction ( $E_n^{EX-AV} \gg E_n^{EN-AV}$ ) for all components. Therefore, the improvement of the efficiencies of other components plays a significant role in enhancing the overall system efficiency.

To evaluate the overall system performance in advanced exergy analysis, the avoidable exergy destruction is the focus as this has the potential for improvement. However, it is shown in Fig. 2 that the endogenous exergy destruction of the overall system is 45%, out of which, 42% is unavoidable. Whereas, almost all of 55% of the exogenous exergy destruction is avoidable as shown in Fig 2. These results show the interaction between the components and how the internal irreversibilities of each component influence the overall system efficiencies. In this analysis, the higher unavoidable exergy destruction rate indicates that the system efficiency can be optimized by optimizing the operating conditions. The technological improvement of the system component, the size of the component, and the high heat and mass transfer mechanism can also have the positive impact to reduce the unavoidable exergy destruction rate.

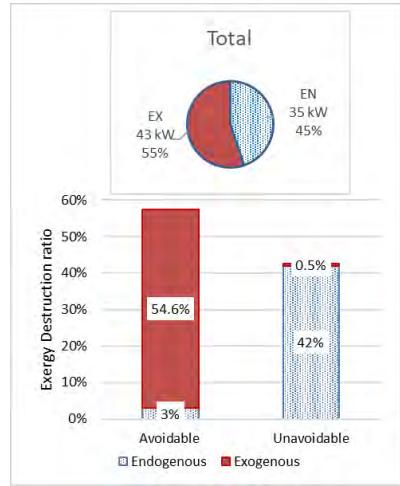

Figure 2: Exergy destruction ratio of the overall VAR system based on advanced exergy analysis.

Furthermore, based on the conventional and advanced exergy analyses, the influence of each component on the overall exergy destruction is shown in Fig. 3. Conventional exergy analysis concludes that the highest potential for improvement is the absorber, followed by the solution HEX and the generator, in order to improve the overall system performance. However, the advanced exergy analysis suggests that 32% (10.47 kW) of the total exergy destruction in the absorber is unavoidable, and 6% is available by improving the absorber itself. Whereas, all avoidable exergy destruction of the generator (40%), the solution HEX (86%), and the evaporator (17%) are exogenous avoidable. This clearly indicates that the irreversibilities of the overall system should be reduced for the system performance improvement. Furthermore, it is also noticed that 98% of the condenser exergy destruction is due to its internal irreversibilities, of which, 97% are unavoidable and 1% can be improved by improving other components efficiency.

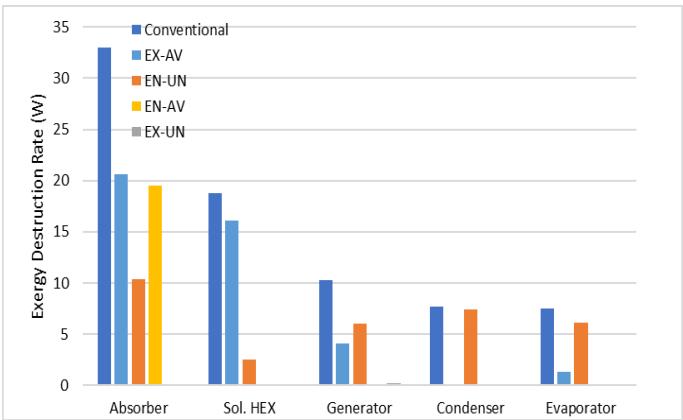

Figure 3: Exergy destruction rate of each component of a LiCl-H<sub>2</sub>O absorption refrigeration cycle based on conventional exergy and advanced exergy analyses.

## I. CONCLUSIONS

The advanced exergy analysis of a 10 kW LiCl-H<sub>2</sub>O absorption air-conditioning system offers useful information in identifying the component that has the most potential for the overall system improvement. This information cannot be provided by a conventional exergy analysis. The avoidable exergy destruction identifies the potential of each component that can be improved by technological improvement. The endogenous avoidable and exogenous avoidable exergy destruction relate the interactions between the components' irreversibilities and quantify the importance of the relative improvement of each component and the overall system.

Finally, the analysis in this study is a very effective tool for the exergoeconomic optimization of energy conversion systems. It can provide useful information to the designer for investment in order to reduce the endogenous avoidable and exogenous avoidable parts of exergy destruction and to measure the potential improvement of the overall system structure.

**Abstract**—Due to rising global environmental issues, electric vehicles (EV) are growing in popularity and will eventually replace vehicles that use internal combustion engines (ICE). EVs draw their power from batteries. Batteries are highly nonlinear storage elements used in a constantly changing environment making them highly dynamic and mathematically complex. In order to approximate the driving range of an EV, the state of charge (SOC) of the battery, which cannot be directly measured, has to be estimated accurately. SOC is highly dependent on the following parameters: internal resistance, temperature, and open circuit voltage. In this paper, two battery equivalent circuit models (ECM) are analyzed in conjunction with a thermal model to track the inner temperature of the battery. The states of the battery are estimated using the popular Kalman filter (KF) and unscented Kalman filter (UKF), and the results are discussed.

**Keywords**—electric vehicles; equivalent circuit models; Kalman filter; interacting multiple model; state of charge.

## I. INTRODUCTION

The effects of technology, and in particular automobiles, on the environment are a growing concern in society. Automobile technology is rapidly moving towards a relatively eco-friendlier solution in an attempt to minimize the output of harmful greenhouse gasses: electric vehicles (EV) [1]. When compared to petroleum-based vehicles using the internal combustion engine (ICE), EVs have a smaller footprint, of course depending on the energy source [2].

In an EV, batteries store the electrical energy in an electrochemical reaction for later use. There are several types of batteries in the industry. The most popular are lead-acid, nickel, alkaline and lithium-ion [1]. Lithium has become very popular because it is the lightest of all metals, has the greatest electrochemical potential and provides the largest specific energy per weight [1]. Current lithium-ion battery technology allows EV to cover about 180-350 km per battery charge [1, 2]. Unfortunately, batteries' full load capacity degrades over time as they are subject to charging cycles, resulting in a lower driving range throughout its lifetime [3]. In addition, the state of charge (SOC) and voltage measurement from the cell's terminal is crucial information to determine the available energy in the battery, which can be used to determine the

available driving range of the EV. It is not possible to have direct measurements of the SOC [2]. The main difficulties are as follows:

- The battery packs of EVs have hundreds of cells connected in series; the different accumulated potential of each cell voltage is different to each other making it hard to have unified compensation or elimination methods.
- Voltage measurements require high precision. Other parameters are estimated according to voltage measurements. Required voltage precision is around 1 mV to have low carried % errors [3].

The SOC of a battery can help estimate current driving range and prevent the battery pack from over charge and over discharge [3]. SOC is not easy to calculate for, as it would demand extensive computing times, expensive instrumentation or have the vehicle stopped preventing its application in real time [1, 4]. A solution is to generate estimates of the parameters, which requires a quality model, and good estimation strategy for the various scenarios: temperature, power demands, and state of function [3, 5].

In this paper, two battery electrical equivalent circuit models (ECM) are analyzed in conjunction with a thermal model. The states of the battery are estimated using the Kalman filter (KF) and unscented Kalman filter (UKF) [6, 7]. In addition, an interacting multiple model (IMM) is implemented for fault detection. Section II presents different filter techniques for the state of charge estimation process. Section III shows equivalent model of thermal, Rint, and Thevenin model. A numerical study and the simulated results are illustrated in Section IV. The paper is concluded in Section V.

## II. STATE OF CHARGE ESTIMATION

Three different estimation strategies, the Kalman filter (KF), unscented Kalman filter (UKF) and the interacting multiple model (IMM) method, are used to estimate the SOC, terminal voltage, and temperature behaviour of the battery. The following section briefly summarizes the filters and their algorithms.

### A. Kalman Filter (KF)

The Kalman filter (KF) was first introduced by R.E. Kalman in 1960 [8]. The KF provides the optimal solution, in terms of state estimation error, for known linear systems in the presence of white, Gaussian noise [8]. The system dynamic model and measurement model is described by the following two equations, respectively [6-8]:

$$\dot{x}_{k+1} = A_k x_k + B_k u_k + w_k \quad (1)$$

$$z_{k+1} = C_{k+1} x_{k+1} + v_{k+1} \quad (2)$$

where  $A$  is the system matrix,  $B$  is the input matrix,  $C$  is the output matrix,  $x$  is the system states,  $z$  is the measurement output,  $u$  is the input,  $w$  is the system noise, and  $v$  is the measurement noise. The following equations represent the KF estimation process [6].

Prediction stage:

$$\hat{x}_{k+1|k} = \hat{A}_k \hat{x}_{k|k} + \hat{B}_k u_k \quad (3)$$

$$P_{k+1|k} = A_k P_{k|k} A_k^T + Q_k \quad (4)$$

Update stage:

$$K_{k+1} = P_{k+1|k} C_{k+1}^T \left[ C_{k+1} P_{k+1|k} C_{k+1}^T + R_{k+1} \right]^{-1} \quad (5)$$

$$\hat{x}_{k+1|k+1} = \hat{x}_{k+1|k} + K_{k+1} \left[ z_{k+1} - C_{k+1} \hat{x}_{k+1|k} \right] \quad (6)$$

$$P_{k+1|k+1} = [1 - K_{k+1} C_{k+1}] P_{k+1|k} \quad (7)$$

### B. Unscented Kalman Filter (UKF)

The UKF is a form of sigma point Kalman filter (SPKF) which is based on a statistical linear regression strategy which linearizes the nonlinear model statistically [7]. In simple steps, SPKF techniques generate a certain number of points referred as ‘sigma points’ from the projected probability distribution of the states. These points are then projected using the nonlinear system model, to obtain the ‘a posteriori’ estimate for probability distribution. The main difference characteristic of the SPKF is that it does not calculate the Jacobian matrices of the system in an attempt to linearize the system often yielding better results than other forms of the KF such as the Extended Kalman Filter (EKF). In the literature, one of the most popular type of SPKF is the UKF.

The following is a summary of the UKF algorithm [8]:

*Initialization:*

$$X_{0,k|k} = \hat{x}_{k|k} \quad (1)$$

$$W_0 = \frac{k}{(n+k)} \quad (2)$$

$$\hat{x}_{k|k} + \left( \sqrt{(n+k)P_{k|k}} \right)_i \quad (3)$$

$$W_i = \frac{1}{[2(n+k)]} \quad (4)$$

$$X_{i+n,k|k} = \hat{x}_{k|k} - \left( \sqrt{(n+k)P_{k|k}} \right)_i \quad (5)$$

$$W_i = \frac{1}{[2(n+k)]} \quad (6)$$

*Prediction:*

$$\hat{X}_{i,k+1|k} = f(X_i, u_k, w_k) \quad (7)$$

$$\hat{x}_{k+1|k} = \sum_{i=0}^{2n} W_{i,k|k} u_k \quad (8)$$

$$P_{k+1|k} = \sum_{i=0}^{2n} W_i (\hat{X}_{i,k+1|k} - \hat{x}_{k+1|k}) (\hat{X}_{i,k+1|k} - \hat{x}_{k+1|k})^T \quad (9)$$

$$\hat{Z}_{i,k+1|k} = h(\hat{X}_{i,k+1|k}, u_k) \quad (10)$$

$$\hat{Z}_{k+1|k} = \sum_{i=0}^{2n} W_i Z_{i,k+1|k} \quad (11)$$

*Update:*

$$P_{zz,k+1|k} = \sum_{i=0}^{2n} W_i (\hat{Z}_{i,k+1|k} - \hat{Z}_{k+1|k}) (\hat{Z}_{i,k+1|k} - \hat{Z}_{k+1|k})^T \quad (12)$$

$$P_{xz,k+1|k} = \sum_{i=0}^{2n} W_i (\hat{X}_{i,k+1|k} - \hat{x}_{k+1|k}) (\hat{Z}_{i,k+1|k} - \hat{Z}_{k+1|k})^T \quad (13)$$

$$K_{k+1} = P_{xz,k+1|k} P_{zz,k+1|k}^{-1} \quad (14)$$

$$\hat{x}_{k+1|k+1} = \hat{x}_{k+1|k} + K_{k+1} (z_{k+1} - \hat{Z}_{k+1|k}) \quad (15)$$

$$P_{k+1|k+1} = P_{k+1|k} - K_{k+1} P_{zz,k+1|k} K_{k+1}^T \quad (16)$$

### C. Interacting Multiple Mode (IMM)

The interacting multiple model (IMM) strategy is useful when a system behaves according to more than one mode of operation or regime. Most engineering systems perform according to a number of different models. The IMM utilizes a finite number of models that calculates likelihood values based on the state estimates and state error covariance. These likelihood values are used to determine operating mode probabilities, and can be used for fault detection [6, 9].

A summary of the IMM algorithm broken down into 5 steps is shown below [8]:

*Calculation of the mixing probabilities:*

$$\mu_{i|j,k|k} = \frac{1}{\bar{c}_j} p_{ij} \mu_{i,k} \quad (1)$$

$$\bar{c}_j = \sum_{i=1}^r p_{ij} \mu_{i,k} \quad (2)$$

*Mixing stage:*

$$\hat{x}_{0,j|k} = \sum_{i=1}^r \hat{x}_{i,k|k} \mu_{i|j,k|k} \quad (3)$$

$$P_{0,j,k|k} = \sum_{i=1}^r \mu_{i|j,k|k} \left\{ P_{i,k|k} + (\hat{x}_{i,k|k} - \hat{x}_{0,j,k|k}) (\hat{x}_{i,k|k} - \hat{x}_{0,j,k|k})^T \right\} \quad (4)$$

*Mode – matched filtering:*

$$\Lambda_{j,k+1} = \mathcal{N}(z_{k+1}; \hat{z}_{j,k+1|k}, S_{j,k+1}) \quad (5)$$

$$\Lambda_{j,k+1} = \frac{1}{\sqrt{|2\pi S_{j,k+1}|_{Abs}}} \exp \left( -\frac{\frac{1}{2} e_{j,z,k+1}^T e_{j,z,k+1|k}}{S_{j,k+1}} \right) \quad (6)$$

*Mode probability update:*

$$\mu_{j,k} = \frac{1}{c} \Lambda_{j,k+1} \sum_{i=1}^r p_{ij} \mu_{i,k} \quad (7)$$

$$c = \sum_{j=1}^r \Lambda_{j,k+1} \sum_{i=1}^r p_{ij} \mu_{i,k} \quad (8)$$

*State estimate and covariance combination:*

$$\hat{x}_{k+1|k+1} = \sum_{j=1}^r \mu_{j,k+1} \hat{x}_{j,k+1|k+1} \quad (9)$$

$$P_{k+1|k+1} = \sum_{j=1}^r \mu_{j,k+1} \left\{ P_{j,k+1|k+1} + (\hat{x}_{j,k+1|k+1} - \hat{x}_{k+1|k+1}) (\hat{x}_{j,k+1|k+1} - \hat{x}_{k+1|k+1})^T \right\} \quad (10)$$

### III. ELECTRICAL EQUIVALENT CIRCUIT MODELS

ECM are models based on electrical components such as ideal voltage sources, resistors, and capacitors to simulate the behaviour of the battery. The vast majority of ECM models are semi-empirical models where the process of calculating your final outputs is based on two distinctive activities. First, the OCV with respect to SOC must be known beforehand by performing laboratory experiments where the battery is put through discharge and resting cycles. Second, the ECM parameters such as resistors and capacitors must be calibrated through I/O data using parameter identification techniques such as least square methods. ECM model design may be easily achieved, but depending on the output and accuracy, they can vary greatly [1]. Moreover, computational power and the simulation time needed to simulate the battery is low. These characteristics make ECM models more suitable for use and implementation in a battery management system (BMS) [12].

#### A. Thermal Model

Battery thermal management is critical for tracking and estimating parameters, as well as avoiding severe consequences. The thermal model used for determining the core temperature,  $T_c$ , and the surface temperature of the cell,  $T_s$ , is shown in Figure 1, where the core and the surface of the cell are modeled as RC branches [13]. The core's resistance,  $R_c$ , models the amount of heat flux leaving or entering the core and the capacitor,  $C_c$ , models the core's ability to store heat. The surface of the battery was modeled similarly, yielding four parameters. The two inputs to the model are demanded/supplied current,  $I_s$ , and forced convection to the skin of the cell,  $T_f$ .

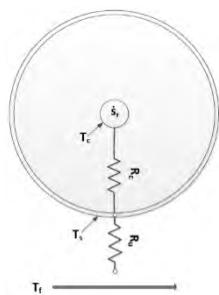

Figure 1. Schematic diagram of the battery thermal model [13].

The two differential equations for a cylinder cell were previously analyzed by [14] and [4]:

$$\dot{T}_c = \frac{1}{C_c} \left( s_c + \frac{T_s - T_c}{R_c} \right) \quad (8)$$

$$\dot{T}_s = \frac{1}{C_s} \left( \frac{T_f - T_s}{R_u} - \frac{T_s - T_c}{R_c} \right) \quad (9)$$

where  $s_r = (OCV - V_T)I_s$ , OCV is the open circuit voltage,  $V_T$  is the terminal voltage. The following is the state space representation of the two differential equations:

$$A = \begin{pmatrix} -\frac{1}{R_c C_c} & \frac{1}{R_c C_c} \\ -\frac{1}{R_c C_s} & -\frac{1}{C_s} \left( \frac{1}{R_c} + \frac{1}{R_u} \right) \end{pmatrix} \quad (10)$$

$$B = \begin{pmatrix} \frac{OCV - V_t}{C_c} & 0 \\ 0 & -\frac{1}{C_s R_u} \end{pmatrix} \quad (11)$$

$$u = [I_s \quad T_f]^T \quad (12)$$

This thermal model was used across all simulated ECMS. Furthermore, a value of 25 °C was used for  $T_f$  to simulate the battery inside a laboratory with the air conditioner on. The values for the model's parameters were taken from [13] and used to generate the simulation results.

#### B. Rint Model

The most basic and commonly used battery model is the Rint model. It consists of an ideal battery with an open-circuit voltage  $U_{OC}$  and a constant equivalent internal series resistance  $R_O$ .  $U_L$  is the terminal voltage of the battery and  $I_L$  is the load current with a negative value at charging and a positive value at discharging:

$$U_L = U_{OC} - R_O \quad (13)$$

The equations for the state space representation of the Rint model are as follows:

$$x = [SOC, T_{core}, T_{surface}]^T \quad (14)$$

$$A = \begin{pmatrix} 1 & 0 \\ 0 & A_{thermal} \end{pmatrix} \quad (15)$$

$$B = \begin{pmatrix} \frac{1}{C_{battery}} & 0 \\ 0 & B_{thermal} \end{pmatrix} \quad (16)$$

$$u = [I_s \quad T_f]^T \quad (17)$$

The state space representation of the system was discretized for implementation purposes. Once the SOC was derived based on the state space, the algorithm would update the parameter values for that SOC level and calculate the corresponding  $V_{OC}$ . The terminal voltage ( $V_T$ ) was derived using equation (13). The following section describes the corresponding output of the model based on Normal Conditions.

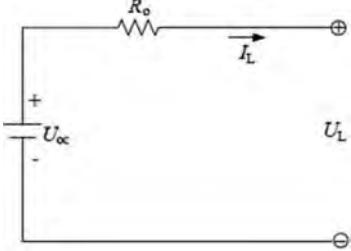

Figure 2. Schematic circuit diagram of Rint Model [7].

### C. Thevenin Model

The Thevenin model is often referred to as a first order battery model. It consists of a parallel RC circuit in series with a resistance. As shown in Figure 3, it is mainly composed of three parts: open-circuit voltage source ( $U_{OC}$ ), internal resistance, and equivalent capacitances. The internal resistances include the ohmic resistance ( $R_O$ ) connected in series and the polarization resistance ( $R_{Th}$ ) connected in parallel. Polarization resistance is used so that the battery does not provide energy (or ‘drain’) right away to the system. The equivalent capacitance ( $C_{Th}$ ) is used to describe the transient response during charging and discharging. ( $U_{Th}$ ) is the Thevenin voltage across the ( $C_{Th}$ ), ( $I_{Th}$ ) is the outflow current of ( $C_{Th}$ ) and ( $U_L$ ) is the terminal voltage. The electrical behavior (dynamics) of the Thevenin model can be expressed by Eq. 18 [11].

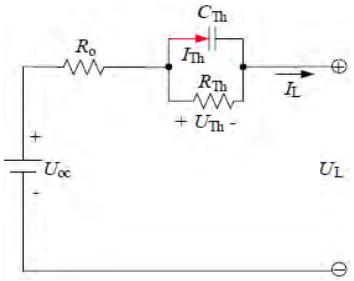

Figure 3. Schematic circuit diagram of Thevenin Model [11].

$$U_{Th} = -\frac{U_{Th}}{R_{Th}C_{Th}} + \frac{I_L}{C_{Th}} \quad (18)$$

$$U_L = U_{OC} - U_{Th} - I_L R_O \quad (19)$$

## IV. NUMERICAL SIMULATION AND RESULTS

Figure 4 depicts the supplied current used across the different models in this numerical study. Positive current was assumed to demand from the battery, thus discharging the battery. The algorithm to simulate the battery was developed in MATLAB®. The SOC was estimated based on the following equation:

$$SOC = SOC_o + \frac{1}{C_{battery}} \int_0^t I_s dt \quad (11)$$

where the  $C_{battery}$  refers to the nominal cell or battery capacity.

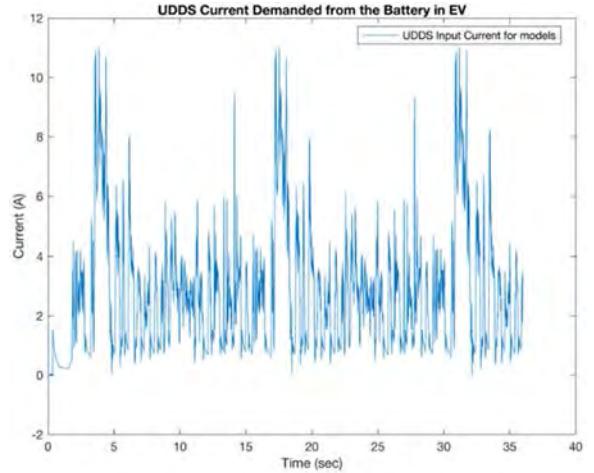

Figure 4. UDDS current profile.

As mentioned earlier, due to their dependence on SOC levels, model parameters curves are often derived offline experimentally using constant current (CC), and constant voltage (CV) charge and discharge cycles under constant temperature by using a thermal chamber. Similar experiments are performed at different temperatures and lookup tables are created for the models. Afterwards, the data is processed using software such as MATLAB to match parameters to a desired transfer function [15]. Other parameter identification techniques use genetic algorithms (GA) [14].

In this paper, the MATLAB® Simulink model was obtained from [17] and modified for the corresponding models to optimize the values of the model parameters:  $U_{OC}$ ,  $R_O$ ,  $R_{Th}$ , and  $C_{Th}$ . Furthermore, the input current and output voltage shown on Figure 5 were used for optimizing the parameter values.

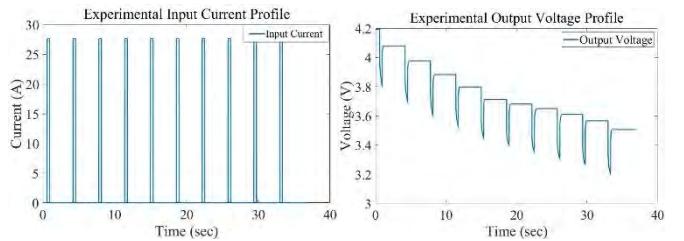

Figure 5. Input current Profile used across all models.

Figure 6 illustrates the resulting VOC-SOC curve from the optimization process. The VOC gradually increases with increasing SOC and reaches maximum at 4.2 V. This VOC-SOC curve was used for both models. Figure 7 shows the resulting capacitance values for the Thevenin capacitance,  $C_{th}$  for all levels of SOC. The nonlinearity of  $C_{th}$  is inherited by the model; making it nonlinear and thus, resulting in the implementation of the UKF method. Figure 8 depicts the calibration results of the Simulink model using the input-output data shown in Figure 5.

Lastly, the system and measurement noise covariance matrices were set to  $Q = 10^{-9}eye(4)$  and  $R = diag([10^{-4} \ 0.00172 \ 10^{-4}])$ . The initial state error covariance was set to  $P = 10Q$  and the  $C_{battery}$  was 27.625 Ah.

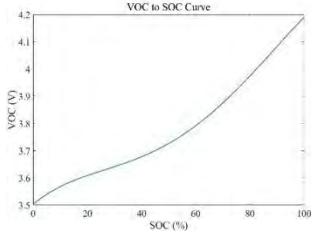

Figure 6. Open circuit voltage with respect to percentage of SOC for Rint model.

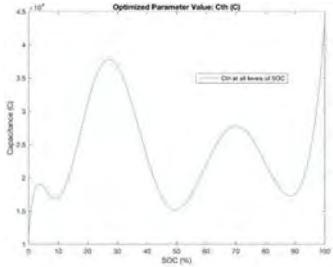

Figure 7.  $C_{th}$  profile with respect to percentage of SOC for Thevenin model.

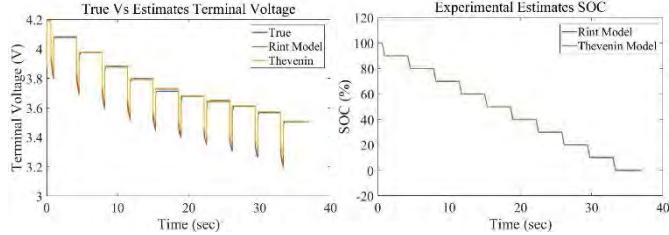

Figure 8. Calibrated Results of (a) terminal volatge and (b) SOC between Rint and Thevenin model.

#### A. Rint Model

The terminal voltage and the percentage of SOC for KF and IMM-KF of Rint model is presented in Fig. 10(a) and 10(b), respectively. Both terminal voltage and percentage of SOC decrease as time passes and KF almost follows the true value. However, as before, the IMM-KF tries to follow the trajectory but is slightly off from the true value. From Fig. 10(b), the KF follows the true SOC value and the IMM-KF is relatively close.

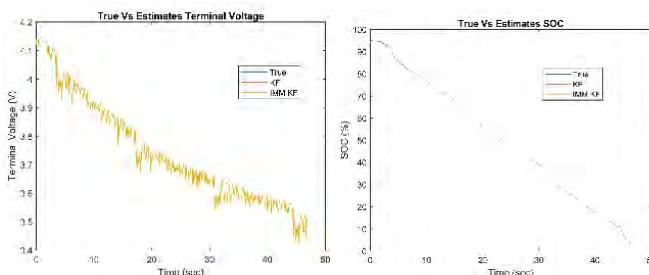

Figure 9. Simulated results of Rint model. (a) Terminal volatge and (b) SOC along with time for KF and IMM KF.

Using Thermal model, the temperature effect for Rint model is also analyzed. Figure 11(a) and 11(b) show the core and surface temperature behavior with respect to time of Rint model, respectively. Both temperatures decrease with time. Moreover, the surface temperature exponentially deceases and approaches 6 °C whereas the core temperature goes to nearly 23 °C. This is due to the thermal resistance between the core and surface, which is higher than the resistance between the surface and the air (e.g., natural cooling effect).

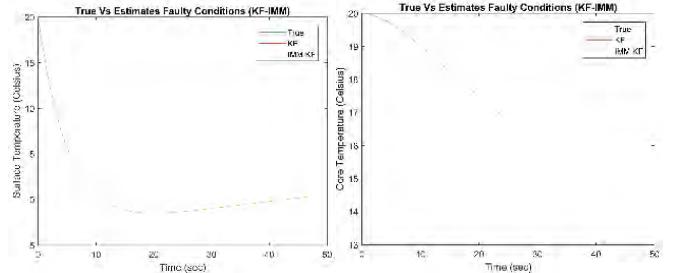

Figure 10. Simulated results of (a) core and (b) surface temperature for the KF and IMM-KF (Rint model).

#### B. Thevenin Model

The terminal voltage and SOC as a function of time are illustrated in Fig. 9(a) and 9(b), respectively. Terminal voltage shows the comparison between true values, UKF and IMM-UKF. It can be clearly seen from Fig. 9(a) that with time, the terminal voltage decreases and UKF follows the true value. Whereas the IMM-UKF is a slightly off from the true value. In this scenario, the UKF obtains the best result. A similar trend can be identified from the SOC curve in Fig. 9(b).

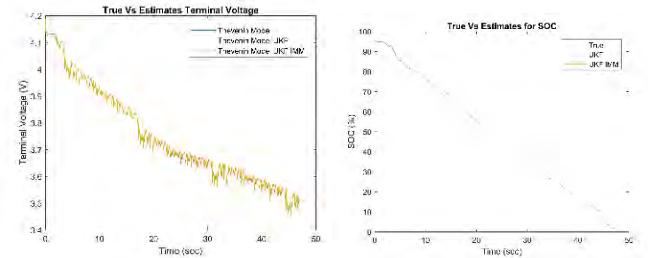

Figure 11. Simulated results of Thevenin model. (a) Terminal volatge and (b) SOC for the KF and IMM-KF.

## V. CONCLUSIONS

An analysis on two ECM battery models, as well as a popular thermal model, was presented in this paper. Moreover, states such as  $SOC$ ,  $V_T$ ,  $T_c$ , and  $T_s$  of the battery were estimated using the KF, UKF and IMM-KF estimation strategies. Parameter identification was performed using a modified MATLAB® Simulink model to calibrate battery models to a corresponding set of input-output data. Finally, the IMM was implemented for successful fault detection were the battery was aged and the thermal core resistance parameter was increased. Future work involves the development of an experimental testbed and implementation and comparison of other nonlinear battery models.

**Abstract**—Lithium ion batteries play important roles as energy storage solutions in electric vehicle, portable devices, and renewable energy systems. There are many issues facing lithium ion batteries. One of them is the long charging time due to the slow electrochemical dynamics. Fast charging is one of the most difficult techniques that affect the acceptance of the electric vehicles. This paper presents a single particle battery model for charging optimization. The single particle model is enhanced with electrolyte dynamics. An optimal charging problem is formulated based on the electrolyte enhanced single particle model. Safety constraints are identified and imposed on the optimal charging problem. Multiple techniques have been developed to reduce the computational load. The fast charging strategy is developed. The results show that the fast charging strategy includes multiple phases and is able to reduce the charge time significantly.

**Keywords**-fast charging; single particle model; Li-ion battery

## I. INTRODUCTION

Limited fossil fuel reserve and global warming provide a strong driving force for transportation electrification and clean energy technology. Lithium ion batteries play an important role as the most widely used energy storage system, and therefore are essential to the sustainable development of our society. There are still many issues facing lithium ion batteries. One of them is the long charging time due to the slow electrochemical dynamics. Compared with conventional vehicle which refuels in couple minutes, electric vehicle takes several hours to recharge. Battery recharge also requires meticulous control due to complex electrochemical reactions, immeasurable internal states, and serious safety concerns. It is thus important and also the focus of this article to develop a systematic approach solving for the optimal charging strategy while ensuring the safety during the charging process.

There are many charging protocols in the literature, such as constant-current / constant-voltage (CC/CV), pulse current charging, multi-stage charging [4], constant power charging, pulse voltage charging [1], [2], [3], neural networks[5], and fuzzy logic[6, 7]. The most widely used charging protocol is the constant-current / constant-voltage (CC/CV). These approaches use predefined charging profiles with fixed current, voltage, or power constraints. Therefore, they are simple to implement. Most of them are based on the basic knowledge or experience of battery dynamics. These charging methods don't provide the best achievable performance determined by the electrochemistry.

This paper aims to develop a systematical approach for solving the optimal charging strategy based on a single particle model with electrolyte dynamics. An optimal control problem is mathematically formulated. The fast charging strategy is investigated. Multiple techniques, including time to SOC domain conversion and electrolyte dynamics approximation, have been developed in this paper to reduce the computational burden while maintaining the accuracy.

The rest of the paper is structured as follows. In section II, the physics-based single particle model is presented, and the electrolyte dynamics is simplified and added to the single particle model. The model is validated against experimental data. In section III, the optimal charging problem is formulated, and the fast charging strategy is then derived and investigated. In section IV, the optimized fast charging strategy is discussed in details. Section V concludes the presented work.

## II. ELECTROLYTE ENHANCED SINGLE PARTICLE MODEL

In the following we describe in detail the single particle model with electrolyte dynamics.

A graphite/LiFePO<sub>4</sub> cell with 400mAh is considered in this study. The single particle approach is used here. In the SP model, electrodes are assumed to consist of spherical intercalation particles with identical size. The surface of the spherical particle is scaled to that of the porous electrode. The key assumption in the single particle model is that the current

distribution is taken to be uniform along the thickness of the electrode. Figure 1 provides a schematic of the SP model with electrolyte dynamics.

The mass balance of lithium ions in an intercalation particle of electrode active material is described by Fick's second law in a spherical coordinate system. Here the diffusion equation is simplified by using two-term polynomial approximation [8-10] as follows:

Cathode:

$$\frac{dx_{p,avg}}{dt} = \frac{-3J_p}{FR_p c_{p,max}}, J_p = \frac{I_{app}}{S_p} \quad (1)$$

$$x_{p,surf} - x_{p,avg} = \frac{-J_p R_p}{5FD_{s,p} c_{p,max}} \quad (2)$$

Anode:

$$\frac{dx_{n,avg}}{dt} = \frac{-3J_n}{FR_n c_{n,max}}, J_n = \frac{I_{app}}{S_n} \quad (3)$$

$$x_{n,surf} - x_{n,avg} = \frac{-J_n R_n}{5FD_{s,n} c_{n,max}} \quad (4)$$

where  $x_{i,avg}$ , electrode's SOC, is the ratio of the solid average concentration to the maximum solid concentration  $c_{i,max}$  for each electrode.  $J_i$  is the current density for each electrode.  $S_i$  is the electroactive surface area for each electrode.  $I_{app}$  is the applied current.  $R_i$  is the particle radius.  $x_{i,surf}$  is the ratio of the solid surface concentration to the maximum solid concentration.  $D_{s,i}$  is the solid phase diffusion coefficient.  $F$  is the Faraday constant.

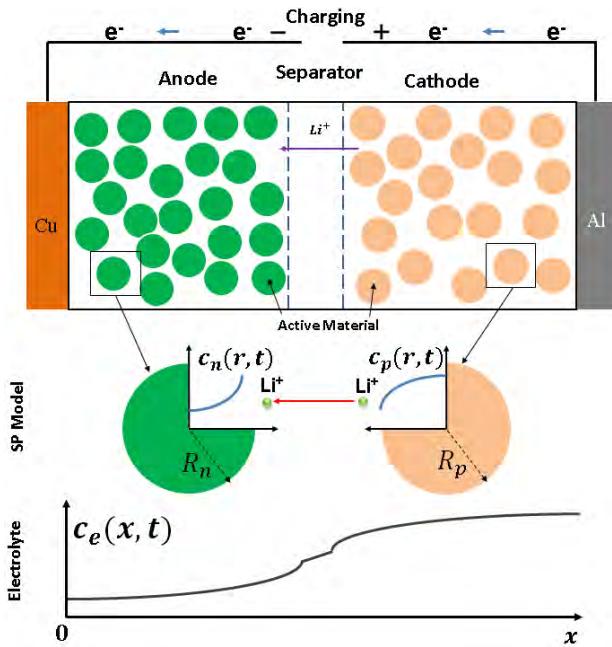

Figure 1. Electrolyte enhanced single particle model

The rate of lithium intercalation and deintercalation reactions is related to the surface SOC and over potential, and is expressed through the Butler-Volmer equation as follows.

$$J_i = k_i \left[ \exp\left(\frac{\alpha_{a,i}F}{RT}\eta_i\right) - \exp\left(\frac{-\alpha_{c,i}F}{RT}\eta_i\right) \right] \quad (5)$$

where  $\eta_i$  is the over-potential for lithium ion deintercalation/intercalation reactions.  $\alpha_{a,i}$  and  $\alpha_{c,i}$  are the anodic transfer coefficient and cathodic transfer coefficient respectively.  $R$  is the gas constant.  $T$  is the temperature.  $k_i$  is the reaction rate coefficient.

$\eta_p$  and  $\eta_n$  can be estimated as [11]

$$\eta_i = \frac{RT}{\alpha_a} \ln\left(\xi_i + \sqrt{\xi_i^2 + 1}\right) \quad (6)$$

where

$$\xi_i = \frac{J_i}{2k_i} \quad (7)$$

The over-potentials are calculated by the following equations

$$\eta_p = \phi_p - U_p^\theta \quad (8)$$

$$\eta_n = \phi_n - U_n^\theta \quad (9)$$

where  $\phi_i$  is the electrode's potential.  $U_i^\theta$  is the open circuit potential in the appendix.

The cell voltage equals to the difference of solid phase potential between the positive and negative electrodes plus the voltage loss due to the internal resistance.

$$V_{cell} = \phi_p - \phi_n + I_{app}R_{cell} \quad (10)$$

where  $R_{cell}$  is the internal resistance.

The material balance for the binary electrolyte in the liquid phase is given by [12]

$$\frac{\partial(\varepsilon_2 c_e)}{\partial t} = \frac{\partial}{\partial x} \left( D_e^{eff} \frac{\partial c_e}{\partial x} \right) + \frac{1-t_+^0}{F} J_i \quad (11)$$

$$\left. \frac{\partial c_e}{\partial x} \right|_{x=0} = \left. \frac{\partial c_e}{\partial x} \right|_{x=L} = 0 \quad (12)$$

where  $c_e$  is the lithium ion concentration,  $\varepsilon_2$  is the electrolyte phase volume fraction,  $D_e^{eff}$  is the effective electrolyte phase Li diffusion coefficient.  $t_+^0$  is the transference number.

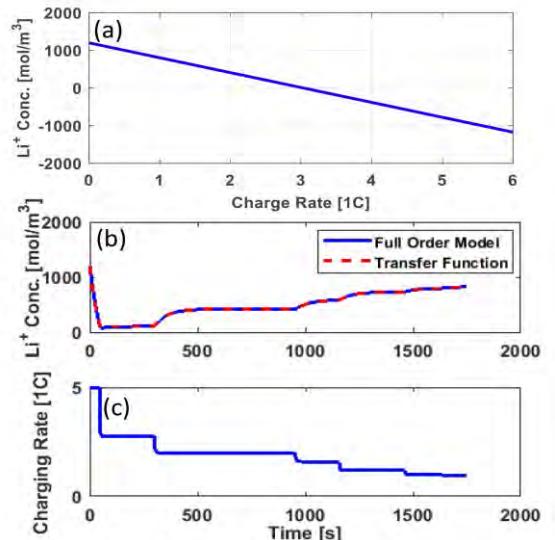

Figure 2. (a) Equilibrium  $\text{Li}^+$  concentration at different charge rates. (b) Comparison of  $\text{Li}^+$  concentration responses between full order model and transfer function. (c) Input current profile to both full order model and transfer function.

During charging, the longer the diffusion distance of the Li<sup>+</sup> ions, the greater the decrease of the Li<sup>+</sup> concentration in the electrolyte. The lowest electrolyte phase lithium ion concentration occurs near the anode current collector (the diffusion distance is longest from the cathode). Therefore, the lithium depletion could occur near the anode current collector. Based on the full-order model in our previous work [12], a static map is generated to predict the equilibrium Li<sup>+</sup> concentration at the anode current collector surface (here the diffusion distance is longest) at different charging rates as shown in Figure 2. The Li<sup>+</sup> concentration decreases at the anode current collector as the charge rate increases. It reaches 0 mol/m when charge rate reaches about 2.9C as shown in Figure 2. When the charge current continues to increase beyond 2.9C, the equilibrium Li<sup>+</sup> concentration decreases to negative values. This is impossible and meaningless in reality. However, it's possible in the simulation, because the concentration is just a continuous variable. Although the negative equilibrium Li<sup>+</sup> concentration beyond 2.9C is meaningless in reality, it is actually very useful for predicting concentration decreasing rate at high charge rates. The lower the negative equilibrium lithium concentration at a charging rate, the greater the decreasing rate of the current lithium concentration at that charging rate.

TABLE I. BATTERY MODEL PARAMTERS

Parameter	Negative electrode	Separator	Positive electrode
Electrode thickness (m)	$70 \times 10^{-6}$	$20 \times 10^{-6}$	$90 \times 10^{-6}$
Particle radius $R_s$ (m)	$3 \times 10^{-6}$		$0.2 \times 10^{-6}$
Electroactive surface area $S_i$ (m <sup>2</sup> )	0.8458		12.6641
Active material volume fraction $\varepsilon_1$	0.5384		0.4179
Filler volume fraction $\varepsilon$	0.172		0.172
electrolyte phase volume fraction $\varepsilon_2$	0.2896	1	0.4101
Max. concentration $c_{i,max}$ (mol m <sup>-3</sup> )	26390		22806
Initial electrode's SOC, $x_{i,avg}$	0.017		0.7862
Li diffusion coefficient $D_{s,i}$ (m <sup>2</sup> s <sup>-1</sup> )	$3.9 \times 10^{-14}$		$2 \times 10^{-17}$ ad
Initial electrolyte concentration (mol m <sup>-3</sup> )	1200	1200	1200
Charge transfers coefficient $\alpha_a, \alpha_c$	0.5		0.5
Reaction rate coefficient $k_i$ (Am <sup>-2</sup> )	$9.77 \times 10^{-2}$		$1.19 \times 10^{-2}$
Time constant for diffusion dynamics $\Delta T$ (s)	60	60	60

ad: adjusted

The nonlinear electrolyte diffusion equation has high fidelity. However, it's very computationally costly due to its PDE nature. Therefore, a first-order transfer function is used to approximate the Li concentration dynamics at anode current collector. The first-transfer function is given as follows.

$$G(s) = \frac{c_e(s)}{c_{e,eq}(s)} = \frac{1}{\Delta T s + 1} \quad (13)$$

where  $c_e(s)$  is the instantaneous lithium concentration (in Laplace domain) at anode current collector.  $c_{e,eq}(s)$  is the

equilibrium lithium concentration at a given charge rate.  $\Delta T$  is the time constant for the diffusion dynamics.

The transfer function in Laplace domain can be converted into time domain as follows

$$\frac{dc_e}{dt} = \frac{1}{\Delta T} (c_{e,eq} - c_e) \quad (14)$$

The above first-order equation is able to accurately predict the lithium concentration evolution at the anode current collector. In this equation, lower negative  $c_{e,eq}$  will lead to lower negative value of  $\frac{dc_e}{dt}$ , which means greater lithium ion decreasing rate. Therefore, a negative value beyond 2.9C in Figure 2 indicates a high decreasing rate of  $c_e$ . A comparison between transfer function prediction and the full-order model[12] prediction is shown in Figure 2. A charging current profile is input into both transfer function and full-order model. And the resultant Li<sup>+</sup> concentration profiles at anode current collector are compared. As shown in Figure 2, the transfer function has a very high accuracy (almost 100%) of predicting the Li<sup>+</sup> concentration compared with full-order model. Therefore the diffusion dynamics of electrolyte can be simplified by using a static map of equilibrium lithium concentration at different charge rates and a first-order transfer function. This technique developed in this paper significantly reduces the computational cost, and also the states needed in the optimal charging problem.

The battery model parameters are summarized in Table I and more details can be found in [12-14].

The single particle model with electrolyte dynamics is validated against experiment data. The battery cells used are graphite/LiFePO<sub>4</sub> cells with 400mAh nominal capacity. As shown in Figure 3, a current profile is applied to both the single particle model and the real battery cell. Voltage responses from both simulation and experiment are compared. The RMSE of voltage is about 41mV.

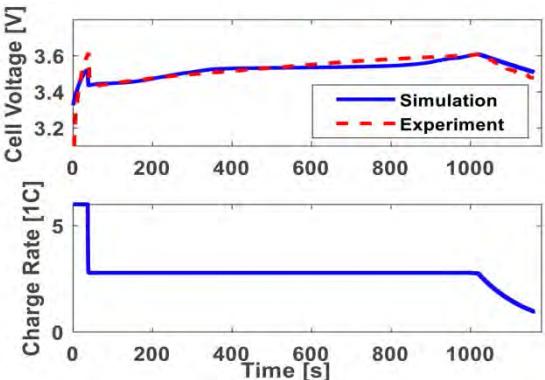

Figure 3. Experiment results for fast charging strategy.

### III. CHARGING STRATEGY OPTIMIZATION

Based on the validated single particle model, an optimal charging problem is formulated with the aim to reduce the charge time while ensuring the safety constraints. The cost function is given by

$$\min_{(t), t_f} \int_{t_0}^{t_f} 1 \cdot dt \quad (15)$$

where  $(t_f - t_0)$  is the charge time. The optimization variables are the input current  $I(t)$  and final time  $t_f$ , with the state variables,  $x_{i,\text{avg}}$  (electrode's SOC) and  $c_2$  (electrolyte concentration).

The above optimal charging problem is formulated over time domain. The final time is a variable. To further reduce the state variables and optimization variables, the problem is converted from time domain into SOC domain. In this paper, the anode electrode SOC,  $x_{n,\text{avg}}$ , is used to represent the SOC for the battery cell. When the battery is being charged, the anode SOC starts at a very low level (close to 0), and increases to a target high level. Therefore, we can formulate the cost function over anode SOC domain instead of time domain. Anode SOC is first divided in to many small segments  $\Delta\text{SOC}$ . Over each  $\Delta\text{SOC}$  segment, the charging time can be calculated by the following equation.

$$t_{\text{char}} = \frac{\Delta\text{SOC} \cdot S_n \cdot F \cdot R_n \cdot c_{n,\text{max}}}{I(\text{SOC})} \quad (16)$$

where  $t_{\text{char}}$  is the charge time for the segment  $\Delta\text{SOC}$ . Therefore, the new cost function in anode SOC domain becomes

$$\min_{(\text{SOC})} \int_{\text{SOC}_{lo}}^{\text{SOC}_{hi}} t_{\text{char}} \quad (17)$$

where anode electrode  $\text{SOC}_{lo} = 0.017$  (fully discharged) and  $\text{SOC}_{hi} = 0.61$  (fully charged). After the time to SOC conversion, the state variable SOC is eliminated, and optimization variable  $t_f$  is also eliminated. The optimization variable is now the input current  $I(\text{SOC})$  only. The only state variable is the electrolyte concentration  $c_e$  at anode current collector. The above time to SOC conversion technique simplifies the optimal control problem, and reduces the states and control inputs.

The optimal control problem has the following constraints for model dynamics, inputs, and states.

$$0 < I(t) \leq I_{\text{max}} \quad (18)$$

$$c_e > 0 \quad (19)$$

$$0 \leq x_{n,surf} \leq 1 \quad (20)$$

$$0 \leq x_{p,surf} \leq 1 \quad (21)$$

$$V_{\text{cell}} < 4V \quad (22)$$

These constrains protect the active particle from overcharge (saturation on anode and depletion on cathode), electrolyte from depletion and cell voltage from overvoltage.

Dynamic Programming (DP) is a very powerful, general tool for solving sequential decision making problems. DP as an extremely powerful approach has been extensively applied to real-world optimal control problems, including hybrid vehicle control system[15], path planning for autonomous vehicles[16], hydroelectric generation scheduling[17], etc...

#### IV. OPTIMIZATION RESULTS

In this section, the optimal charging problem is solved by dynamic programming. The optimized charging strategy is studied and discussed in details.

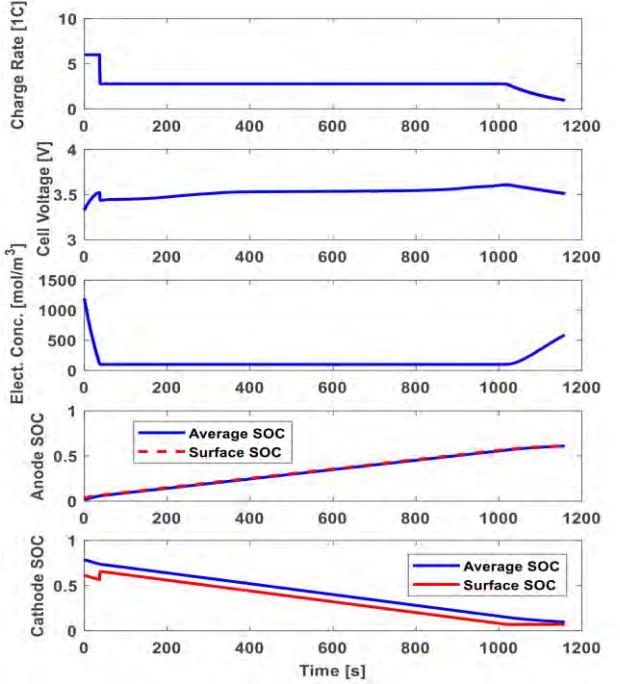

Figure 4. Optimization results for fast charging strategy.

The charging strategy pursued by this work aims to charge a battery as fast as possible. Dynamic programming is applied to find the optimal charging strategy which achieves the minimum charging time. The optimized charging current trajectory is shown in Figure 4. It takes about 19 minutes 18 seconds to achieve a target anode SOC of 61% (fully charged) from an initial anode SOC 1.7% (fully discharged).

As shown in Figure 4, the optimized charging process can be divided into three stages. In the first stage, a high maximum current is applied until the  $\text{Li}^+$  concentration in the electrolyte at the anode current collector depletes. In the second stage, the current is lowered to a level to avoid lithium depletion in the electrolyte and maintain a constant and small  $\text{Li}^+$  concentration in the electrolyte at the anode current collector. In the third stage (close to the end of charge), the lithium concentration on the cathode surface decreases and gets close to zero, the charge current is gradually lowered to avoid the lithium depletion on the cathode surface. The whole charging process follows constant-current / constant-electrolyte-concentration / constant-cathode-concentration (CC/CEC/CCC).

#### V. CONCLUSION

This paper enhances the single particle model with electrolyte dynamics. Based on the enhanced model, the fast charging strategy is investigated. An optimal charging problem is formulated to solve for the fast charging strategy that achieves the minimum charging time. Dynamic programming as an extremely powerful approach has been used to find the optimal fast charging strategy. Multiple techniques, including electrolyte dynamics approximation and time to SOC domain

conversion, have been used in this paper to reduce the computational cost and dimensions of the problem for the dynamic programming. Fast charging strategy is investigated and discussed in details. This charging strategy takes the shortest time to charge the battery, about 19 minutes 18 seconds in this study. The fast charging strategy can be divided into three stages and follows constant-current / constant-electrolyte-concentration / constant-cathode-concentration (CC/CEC/CCC).

#### ACKNOWLEDGMENT

This works was supported by the NSERC Discovery Program.

**Abstract**—The ground topography effect on the wind flow is significant. The knowledge of the flow behavior near ground is crucial in the development of wind power, especially in the choice of suitable sites and for estimation of energy production. In this paper, the numerical prediction of the flow over a three-dimensional hill model and the analysis of placement of Savonius turbines on top of the hill are presented. The numerical analysis is based on the finite volume method implemented in the ANSYS CFX 15 Software using the Shear-Stress Transport (SST) turbulence model. The numerical results for a conventional Savonius rotor and a vertical-axis spiral wind rotor are both satisfactory compared with experimental data. The performances of these turbines, installed on the hilltop, are studied for different height positions. Furthermore, the influence of the hill size on the extracted power is investigated. At TSR=1, the power coefficient of a conventional rotor is increased from 0.15 to 0.32 when the rotor is installed at a height of 0.25 m above the top of the hill, while it reaches 0.40 when the hill is two to three times higher. The helical Savonius rotor tested gives even higher power coefficient of 0.44.

## I. INTRODUCTION

The ground topography affects the velocity, direction and turbulence intensity of the wind and can be used advantageously to increase energy extraction from wind. In this work, a hill topology is considered. Flow separation at the lee side of a hill is still an unresolved issue where the field measurements show a rapid decrease in speed-up ratio. Different explanations are available regarding the issue; for instance: [1] conjectured that this three dimensional flow separation at the lee slope is due to the blockage effect of neighboring hills, but according to [2] the presence of the nearby topography does not affect the flow neither at the top nor at the downstream of the hill. For [2], hills have a significant influence on the wind speed. A smooth and not too steep hill causes acceleration of the wind and makes the wind

accelerate when flowing towards the hilltop. The resultant increase in energy content is called hill impact. [2] and [3], find a good agreement between the experimental results and the computational results both at windward slope and at the lee side of the hill. [4] Investigate two-dimensional numerical simulations of flow over two common types of topographic features (a cliff and a hill) and three types of turbulence models. The standard  $k-\epsilon$ , Durbin's model and Shin's model are tested for predicting flow over this topographic. In this study, Shin's model gave better results compared to other models.

The wind flow over terrains can provide an important advantage when installing wind turbines. An appropriate selection of a suitable land for wind turbines can lead to an increased output of energy. However, understanding the many factors to be taken into account and the interaction with the turbine is needed. In this study, the interaction of the flow over the hill and the helical Savonius vertical axial wind turbine is analysed to increase the energy extraction.

The main objective of this paper is to analysis the improvement of the power output when the helical Savonius wind rotor developed by [5] and [6] are placed on top of a hill. The paper will show that a significant improvement of the power coefficient ( $C_p$ ) can be achieved. In this study, the Savonius rotor is placed at different vertical locations on top of the hill and for different heights of the hill.

## II. HILL AND SAVONIUS WIND TURBINE GEOMETRIES

The hill geometry employed in this work is shown in Fig. 1. It is a three-dimensional axisymmetric defined by [7] as follows:

$$z(x, y) = \frac{H \cos^2 \pi (x^2 + y^2)^{\frac{1}{2}}}{2s} \quad (1)$$

The specific height used in the comparison with experimental data is  $H=40$  mm and length  $S=100$  mm. It gives a maximum slope of about  $32^\circ$ . For the turbine mounted simulations,  $H = 2$  m and  $S = 5$  m. Fig. 1 shows the details of the side view of the three dimensional hill and the coordinate system.

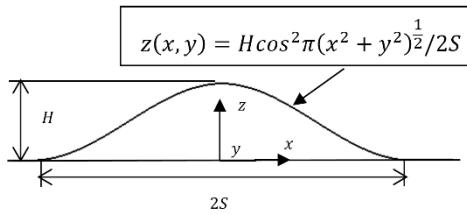

Figure 1. Topographic features [7]

The placement of turbines in complex land topology is becoming more and more common, although these areas are not always ideal sites, due to the high shear and turbulence levels in the wind flow. In this context, for a systematic analysis, the Savonius rotor is placed at a distance ( $L$ ) above the hill. The Savonius rotor has an “S-shaped” cross-section constructed by two semicircular buckets. [6] conducted experimental investigations on a single stage helical Savonius rotor placed between end plates but without shaft. The helical rotor has a  $90^\circ$  twist angle of the two blades evenly distributed around the vertical axis. The three-dimensional geometrical model of each blade can be approximately created by sweeping a base profile at  $90^\circ$  along a spirally ascending curve, as shown in Fig. 2 and Table 1.

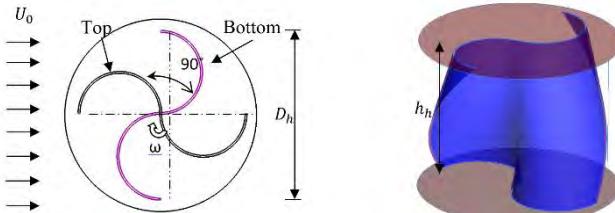

Figure 2. Schematic representations for a helical Savonius rotor .

TABLE I. BASIC PARAMETERS OF THE CONVENTIONAL SAVONIUS ROTOR [5] [6].

Parameter	Value (m)
D	0.33
d	0.184
e	0.038
$h_r$	0.23
$D_h$	0.23
$h_h$	0.202

## 2. ANALYSIS PARAMETERS

Savonius turbines are mainly drag-driven devices made up of two or multiple blades. The difference in the drag forces acting on the rotor blades causes the Savonius turbine to rotate. The performance is defined by [5] as the power coefficient that

is a function of power  $P$ , rotor swept area  $A_s$ , and free stream speed  $U_0$  as follows:

$$C_P = \frac{P}{\frac{1}{2}\rho A_s U_0^3} \quad (2)$$

The moment coefficient ( $C_m$ ) of a Savonius turbine is determined as a function of torque  $T$ . It is defined by [5] as follows:

$$C_m = \frac{T}{\frac{1}{4}\rho A_s D U_0^2} \quad (3)$$

The Tip Speed Ratio TSR or  $\lambda$  is the ratio between the rotational speed at the tip of the blade and the velocity of the wind. It is defined by [5] as follows:

$$\lambda = \frac{\omega D}{2U_0} \quad (4)$$

The Reynolds number,  $Re$ , based on the rotor diameter is calculated as follows:

$$Re = \frac{\rho U_0 D}{\mu} \quad (5)$$

where  $\mu$  is the dynamic viscosity of atmospheric air.

## 3. NUMERICAL SIMULATION

A hexahedral mesh is used for the stationary domain as shown in Fig. 3, and a tetrahedral mesh is used for the rotating domain containing the turbine as shown in Fig. 4. The total number of grid cells equals to 1.5 106. Note that the number of cells for both the conventional and helical rotors is almost the same. The meshes are generated using the ICEM CFD code. The grid node density in the rotating domain is higher than in the stationary domain. The prism layer of grid elements were extruded from the edges of the blade and the surface of the hill to improve the grid quality and to capture with sufficient precision the boundary layer flow. The height of the first prism layer above the surface was set such that the  $y^+$  value for the first layer of elements from the wall is below 2, depending on the rotation velocity of the rotor. There were nine layers in total, and a layer growth rate of 1.2 was chosen.

#### 4. GRID AND TIME STEP INDEPENDENCE ANALYSIS

A mesh independence test is conducted in order to select the mesh needed to be in the converged spatial discretization regime for the moment coefficient value. The computational domain meshes are progressively refined until the observed physical quantities are stabilized. The grid refinement is performed using three types of meshes consisting of 1.0, 1.5, and 2 million grids. The convergence of each case needed more than 6 cycles. Fig. 6 shows the moment coefficient during the last two rotations of the conventional turbine rotor versus the total number of cells used. The computed moment coefficient does not show a significant difference when the total number of cells used is more than 1 million. The difference in moment coefficients between the grids of 1.0 and 1.5 million is in the order of 4%, and this difference decrease to 0.4% between grid of 1.5 and 2 million grids. Based on these results, the following computations were carried out using a mesh consisting of 1.5 million cells.

Several studies also present a temporal discretization analysis: [10] uses 1 degrees/step, [11] reports 0.25 degree/step, while [12] uses 0.12 degrees/step, and [13] uses 0.02s. Based in these results, a verification study was performed using time steps ranging from 0.5 degrees/step to 1.5 degrees/step at a tip speed ratio of 1.0 and a free stream speed of 9 m/s. Periodic convergence of the rotor torque output was then evaluated by monitoring the dynamic torque for the selected time steps over the last two revolutions. Fig. 6 demonstrates that time step independence is achieved with a time step of 1 degree/step as for 0.5 degrees/step only a slight change in the torque is observed. The maximum difference is 3.13%. Therefore, to reduce the time of calculation, the conservative choice in this study is to select a time step of 1 degree/step.

$$U(z) = \frac{u_*}{k} \ln\left(\frac{z}{z_0}\right) \quad (6)$$

where:

$u_*$  : Frictional velocity.

$k$  : Von Karman coefficient ( $k=0.4$ ).

$z_0$  : Roughness parameter ( $Z_0=0.01\text{mm}$ ).

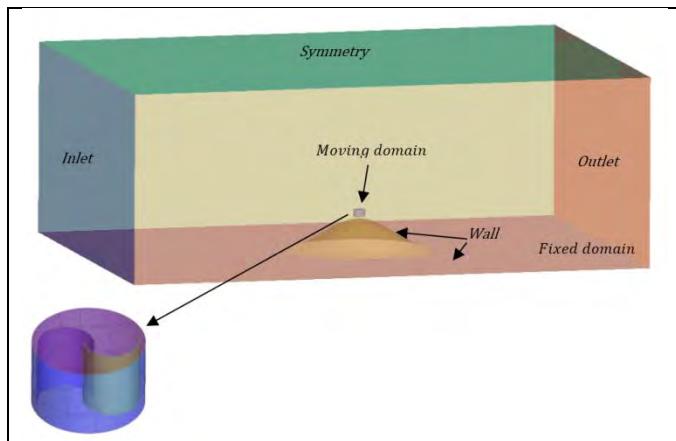

Figure 5. Computational Domain and Boundary Condition.

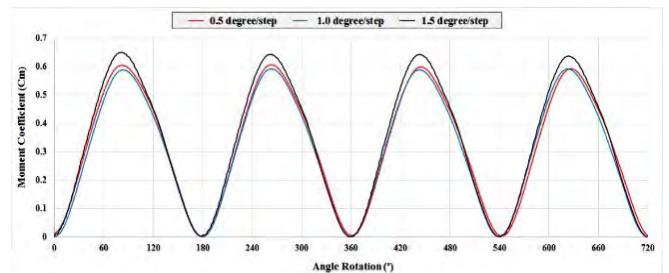

Figure 6. Torque variation during the last two revolutions at  $\lambda = 1.0$  and 9 m/s for different time steps (conventional rotor).

#### 5. VALIDATIONS OF THE NUMERICAL METHODOLOGY

In this part, two validations are performed to evaluate the proposed numerical methodology. The simulation results of the flow around a helical wind turbine Savonius with two blades using the SST turbulence model, were compared with the experimental results from [6]. Fig. 7 shows the comparison of the predicted average power coefficients with the measured

data for various tip speed ratios (TSRs). A maximum power coefficient for conventional rotor  $C_{Pmax}$  of 0.155 is computed for the tip speed ratio of 0.8, and a maximum power coefficient for the helical rotor  $C_{Pmax}$  of 0.169 was found at around 0.70 tip speed ratio. The computational results have a good agreement with experimental data for both cases.

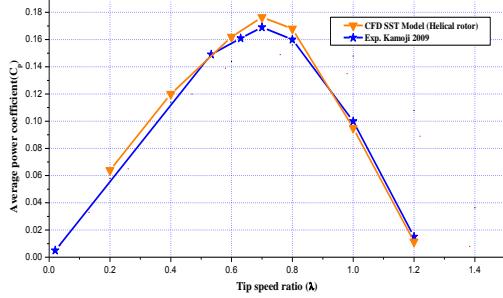

Figure 7. Comparison of the power coefficients from numerical and experimental results.

The second validation is related to the numerical simulation of the flow over the three-dimensional hill. The experimental data is obtained from a wind tunnel investigation by [13]. Fig. 10 shows the good agreement of the vertical profiles of the normalized velocity component of ( $U$ ) at various positions on the centerline of the hill.

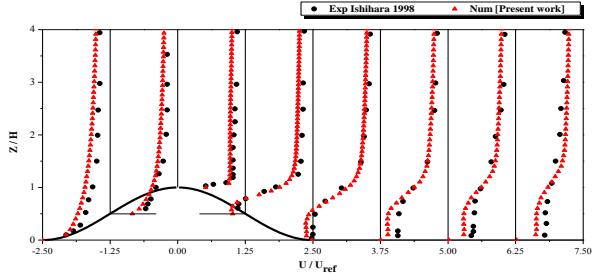

Figure 8. Comparison of the vertical profiles of mean velocity component ( $U/U_{ref}$ ).

## 6. RESULTS AND DISCUSSION

### A. Effect of different height positions ( $L$ )

Numerical simulations of the flow over the hill mounted wind turbine were conducted for different placement height  $L$ :  $L=0.25$  m,  $L=0.5$  m and  $L=1$  m above the hill. The results of the average power coefficient extracted from both wind turbines, as a function of the tip speed ratio, for a wind velocity inlet of 9 m/s are presented in Fig. 9.

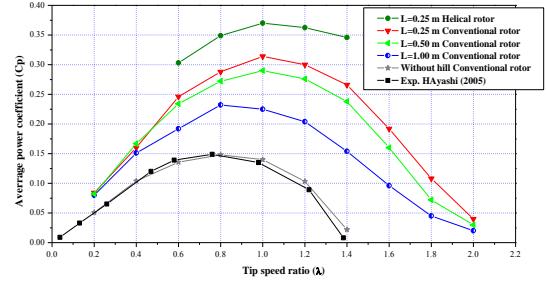

Figure 9. Average power coefficient at different vertical locations of the rotor.

In order to evaluate the power coefficient obtained from an isolated wind turbine both experimental and numerical cases are also reported. One can observe that the maximum values of the average power coefficient is obtained at a height of  $L=0.25$  m from the top of the hill. The position closest to the hill provides the higher power coefficient as the velocity is highest when measured close to the surface of the hill. The increase in maximum  $C_p$  is more than double than for an undisturbed flow. The maximum also occurs at a higher TSR as the effective wind reaching the turbine is higher. In fact, the ratio of maximum velocities squared ( $12.372/92=1.89$ ) is almost double and is close to the observed  $C_p$  increase. Taking this best position ( $L=0.25$ ) obtained for the conventional rotor, and calculating the  $C_p$  for the vertical-axis helical wind rotor gives an even higher maximum  $C_p$ . The maximum value of power coefficient for helical rotor is approximately 0.37 while, it is 0.32 for the conventional rotor in the tip speed ratio of 1. This increase in power coefficient is due to the generation of swirling flow generated inside the wind turbine, these observations are also reported by [6] and [14]. This increase is also about twice the difference between the two turbines in an unperturbed flow.

### B. Effect of hill height

In this section, the effect of the hill size on the power production is analyzed for the best position of the turbine rotor found previously. Numerical simulations were performed for the turbine position at  $L=0.25$  m for different hill heights. Three cases are studied: hill height =1H, hill height =2H and hill height =3H. Note that H is the standard height of the hill used in the previous section. The atmospheric boundary layer is set such that it has 9 m/s velocity at the respective height, i.e. H, 2H or 3H. A very important increase of the power coefficient was obtained, as shown in Fig. 10.

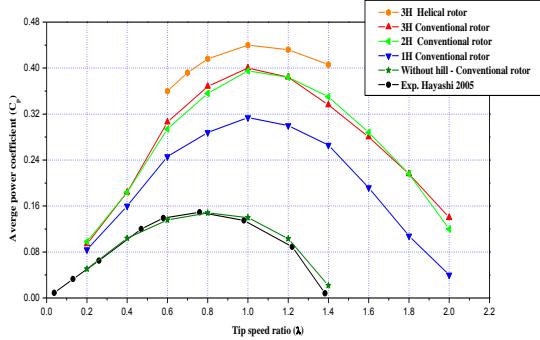

Figure 10. Variation of average power coefficient at different hill heights.

This figure illustrates the influence of the hill height on the performances up to a certain height. The cases of hill height =2H and 3H give approximately the same maximum power coefficient which is close to 0.4. The same boundary conditions and the hill height are applied to simulate the helical rotor. Again, the power coefficient of this newer design is higher than that obtained by the conventional rotor at the same conditions. A  $C_p=0.44$  is reached which is very high for a Savonius turbine. The difference between the three cases is quite clear in Fig. 11; the velocity in the case of 1H arrives at 18 m/s, while it reaches 25 m/s in the case of 2H and 3H, which explain that the velocity is growing by 25% when the height is doubled.

Fig.12. The pressure distribution and contours of the velocity at the maximum power coefficient are presented and compared in Fig. 13 for different sections. The flow fields at each horizontal section are not identical due to its helical geometry along the rotor axis. At this angle, plan 4 and 5 report that this part of the blade contributes significantly to the creation of clockwise torque. These results show that the wind did not directly influence the concave surface of the blade. Instead, it impacted on the convex surface of blade 2, and then hit the concave surface of blade 1

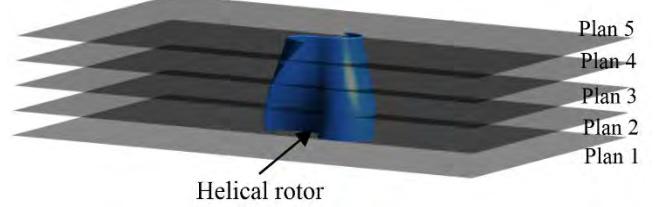

Figure 12. Fig. 18. Vertical sections of blades.

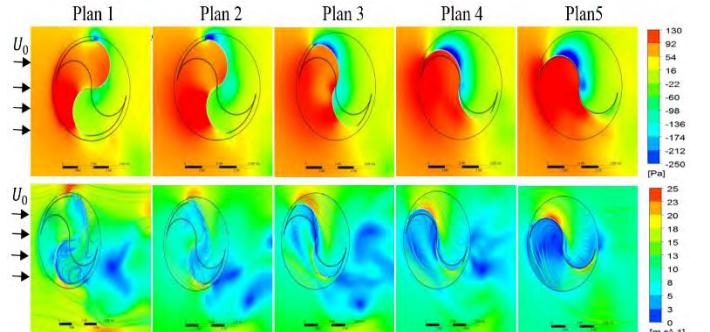

Figure 13. Velocity and pressure contours at different section vertical of helical rotor.

Figure 11. Velocity and pressure contours at different plane with different hill heights (Conventional rotor). a) Longitudinal plan (XZ), b) Transversal plan (YZ).

These planes are vertical to the rotor axis to display the turbulent features around the helical rotor as indicated in

### C. Influence of wind velocity

The main factor affecting the power output of wind turbine is the incoming wind velocity. The importance of wind speed is that the power is directly proportional to the cube of wind speed according to equation 2. The power coefficient

represents the aerodynamic efficiency of the wind turbine, which differs from one turbine to another. Three simulations are performed for different incoming wind velocities using the same computational domain and boundaries conditions as well as the best position from the previous cases ( $L=0.25\text{m}$  and hill height  $=3H$ ). The objective is to analyze the effect of the velocity on the coefficient of power.

Fig. 14 shows the numerical results of the average power coefficients at different Reynolds numbers calculated by equation (5) for three speeds (6, 9, 12, 15 m/s). The difference between the three cases is clearly illustrated in this figure, there is a proportional relation between wind velocity and power coefficient, it can be noted that the average power coefficient increases slightly with increasing wind velocity. The maximum value of the power coefficient appears in the range of the tip speed ratio of ( $\lambda = 0.8$  to  $\lambda = 1.2$ ), which agree with the previous studies [5].

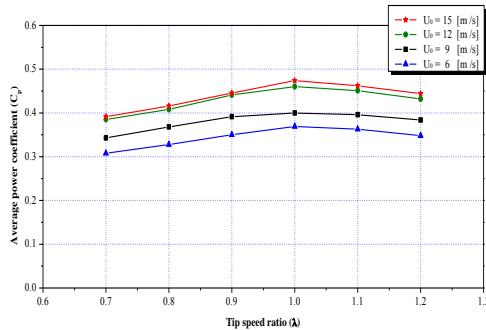

Figure 14. Power coefficient as a function of tip speed ratio at different wind velocity.

## 6. CONCLUSION

In this study, the flow analysis over a three-dimensional hill with a one-stage Savonius turbine is carried out numerically. Results obtained by the SST turbulence model are analyzed and compared with experimental data. The proposed methodology indicates that the numerical predictions of the flow field as well as power coefficient calculations are in reasonable agreement with experiment data. The flow around a three dimensional hill is characterized by an acceleration of the wind towards the hilltop and deceleration on the leeward side. It is demonstrated that it is possible to improve the low performance of the Savonius turbine by placing them at the top of a hill, which is clearly the best position. The extracted power increases significantly, more than doubles, when placed on top of a hill. The study of the aspect ratio of the Savonius turbine indicates that the optimum aspect ratio is different when the turbine is placed on the hill. The paper also shows that a Savonius rotor with a helical geometry always performs better than the conventional Savonius turbine.

**Abstract**— The main purpose of using cutting fluid during machining processes is to reduce the cutting temperature and friction, and to wash away chips from the cutting zone. However, excessive use of conventional cutting fluid negatively influences human health and environment. Therefore, much research has attempted to improve cutting fluid performance with superior tribological and thermal properties, and to reduce the amount of cutting fluid to minimize machining cost and impact on environment. Recently, Minimum Quantity Lubrication (MQL) technique has been widely investigated as a good alternative to flood coolant. Although MQL improves machining results, its removal heat capability still needs to improve. In this paper, in order to enhance the thermal conductive and viscosity of MQL, nanoparticles were dispersed to make nanofluid coolant. Nanofluids have attracted the attention of investigators due to their good high thermal conductivity and ability to remove heat. In this study, the effect of the cutting speed, feed rate, and nanoparticle concentrations on machining titanium Ti-Al6-V4 alloy were investigated by performing ANOVA analysis. The nanofluid coolant was prepared by adding Aluminum Oxide ( $\text{Al}_2\text{O}_3$ ) nanoparticles to base fluid (vegetable oil) at different weight concentrations (0, 2, and 4%wt).

The ANOVA analysis found that the nanoparticle concentrations and feed rate had a significant influence on surface roughness. The tool wear was also observed to be affected by nanoparticle concentration significantly. The nanoparticles concentration had a significant impact on the flank wear as it could improve the thermal conductivity and lubrication properties of the cutting fluid and reduce the coefficient of friction between the tool- workpiece and tool-chip. In terms of the effect of nanoparticle concentrations, 4% wt provided better improvements in both surface roughness and tool wear compared to 2% wt concentration and the pure MQL.

**Keywords-component:** Titanium Ti-Al6-V4 alloy, Tool wear, Surface roughness, Minimum Quantity Lubrication (MQL), Nano-cutting fluid

## I. INTRODUCTION

The effectiveness of machining processes is greatly dependent on the use of cutting fluid to reduce cutting forces and cutting temperature. However, such cutting fluids have negative effects on environment and health. In an effort to eliminate these contrary impacts, many experiments have been conducted using minimum quantity lubrication (MQL) as the main cooling technique. MQL can be also identified as near-dry machining (NDM) or micro-lubrication [1, 2]. Klocke et al. [3] identified the MQL as a cooling technique that uses only a small amount of lubricant, about 3 to 4 orders of magnitude less than flood coolant, at the flow rate of 50 to 500 ml/h. As a result of the lubricant penetration ability into the chip/tool interface, MQL reduces cutting temperature and friction, and extends tool life. Therefore, MQL improves the surface finish of the product. Several investigations have revealed that the MQL technique is a viable alternative to the flood coolant under similar performance parameters [4, 5, 6]. In addition, from the environmental perspective, the MQL method has been shown to be suitable for green machining.

Spraying cutting fluid during machining difficult-to-cut materials, such as titanium, is crucial to reduce the high generated temperature at the cutting zone, thus extending tool life. The MQL technique provides relatively effective machining results, but enhancing its heat removal capacity is still required. MQL with nanoparticles has been suggested to be an effective method for reducing environmental and machine operator hazards due to its good tribological property and antibacterial feature [7, 8].

At present, efforts have been made to develop advanced machining processes utilizing less lubrication [10]. For further enhancement, adding nanoparticles into MQL (better known as MQL-nanofluid) may provide much better product quality due to the rolling action of nanoparticles, which could remarkably minimize cutting forces. Also, dispersing nanoparticles into base fluid of MQL would enhance the thermal conductivity and viscosity of the coolant [10, 11]. Nano-cutting fluids make an important contribution toward meeting the heat dissipation challenge during machining processes as they provide a high practical thermal conductivity value compared to the base fluid [12]. This value can be attributed to the outstanding properties

of the added nanoparticles (e.g. high heat convection coefficient and thermal conductivity). Moreover, the appropriate dispersion of nanoparticles into the base fluid provides a promising advantage in cutting processes as it helps to reduce the coefficient of friction in the tool-chip interface zone [13]. It has also been revealed that nano-cutting fluids have superior cooling properties due to their effective heat extraction properties [14].

Generally, most research agrees that nanofluids provide higher thermal conductivity in comparison with base fluid; however, determining the appropriate concentration of the nanoparticles is a big challenge. The addition of excessive nanoparticles could result in nanoparticle agglomeration which reduces the lubrication property. Lee et al. [7] stated that the physical parameters such as size and shape of nanoparticles affect their tribological properties. The study was found that determining the appropriate concentration of nanoparticles in base fluid is important to achieve better surface quality and lubrication. Sharma et al. [15] have also observed that an increase of nanoparticle concentration improves the thermal conductivity and viscosity of the nanofluid. Zhang et al. [16] carried out grinding experiments on 45 steel under the jet MQL nanofluid (soybean oil + MoS<sub>2</sub>) with different mass fraction concentrations (2, 4, 6, 8, and 10 %) of MoS<sub>2</sub> nanoparticles. It was noted that increasing mass fraction nanoparticle concentration from 2 % to 6 % noticeably reduces the specific grinding energy, grinding forces, and friction coefficient. With further increases in nanoparticle concentration (above than 6%), grinding forces, specific grinding energy, and friction coefficient increased. This increase can be attributed to the agglomeration of nanoparticles which cannot lubricate the grinding zone, thus negatively affecting the surface finish. It was concluded that 6% mass fraction concentration of nanoparticles provided the lowest specific grinding energy, tangential grinding forces, and friction coefficient. Vasu et al. [17] performed turning machining on Inconel 600 alloy under MQL with different volume fractions of Al<sub>2</sub>O<sub>3</sub> (aluminum oxide) and regular MQL vegetable oil. It was reported that the MQL with 6% nanoparticle concentration resulted considerable improvement in the surface roughness, tool wear, cutting forces, and cutting temperature compared to MQL with 4% volume fraction and regular MQL.

## II. EXPERIMENTATION AND METHODOLOGY

Experiments were conducted by turning titanium Ti-Al6-V4 alloy in order to investigate the effects of cutting speed, feed rate, and concentration of nanofluid on tool wear and surface roughness. The tests were performed on a CNC lathe machine using standard coated carbide turning inserts (CNMG120416MR) with a 1.6 mm nose radius. The machining tests were carried out using MQL nanofluid with different concentrations of volume fraction (0, 2, and 4 wt %), at different levels of cutting speed (120, 170, and 220 m/min), and feed rate (0.1, 0.15, and 0.2 mm/rev) as shown in Table 1. The depth of cut for each cutting pass was 0.5 mm with cutting length of 50 mm. Each test was repeated twice for

more reliable data, and findings were recorded for maximum flank wear (VB) and surface finish (Ra).

The air-oil mixture of the MQL system was supplied by the stand-alone booster system (Eco-Lubric) with a nominal oil flow rate of 80 ml/min and air pressure of 0.5 MPa. In addition, the vegetable oil ECOLUBRIC E200 was used as a base cutting fluid. This fluid, rapeseed, is environmentally harmless, suitable for industrial application, and has a biodegradability of 90% in 28 days [18]. The position and the angle of the MQL nozzle were adjusted by experimental observation to avoid being blocked by chips.

For the preparations of the nano-cutting fluid, Aluminum Oxide gamma nanoparticles (Al<sub>2</sub>O<sub>3</sub>) were used as nano-additives. Al<sub>2</sub>O<sub>3</sub> nanoparticles were selected because of their superior tribological property and anti-toxic aspect. It has 20 nm average diameter, 95% purity, and 138 m<sup>2</sup>/g specific surface areas. Dispersion of nanoparticles into the base fluid vegetable oil is an important aspect, which effects on thermal conductivity and viscosity of resultant nano-cutting fluid. An ultrasonic machine (AQUASONIC-50HT) was used for 3 hours at 60°C to disperse nanoparticles into the base cutting fluid. However, the dispersion of nanoparticles into the base fluid is considered as challenge, due to the strong van der Waals interactions which result in nanoparticle agglomeration, clogging, and sedimentation. Thus, using a physical or chemical treatment such as surfactants is recommended to ensure sufficient dispersion of nanoparticles [19, 20]. Sodium Dodecyl Sulfate (SDS) was used as a surfactant (i.e. 0.2 gm). Surfactants are believed to make the nanoparticles performance more hydrophilic, and to increase the nanoparticles surface charges, thereby increasing the repulsive forces between the nanoparticles.

In this work, experiments and analysis of variance (ANOVA) analysis was conducted for each of the design parameters and labelled as A (cutting speed), B (feed rate), and C (nanoparticles concentration) as in Table 2. MINTAB 17 software was used to do design of ANOVA, which was performed to investigate the effect of design parameters on tool wear and machined surface quality. Using the ANOVA, the importance of cutting parameters and nanoparticle concentration with respect to surface roughness and tool wear was studied in order to find out the optimum combination of cutting parameters. All ANOVA analysis were conducted with confidence level of 95% ( $\alpha = 0.5$ ).

TABLE 1. SCHEME OF EXPERIMENT

Experiment No.	Speed (m/min)	Feed rate (mm/rev)	Nanoparticles (wt %)
1	120	0.1	0
2	120	0.15	2
3	120	0.2	4
4	170	0.1	2
5	170	0.15	4
6	170	0.2	0
7	220	0.1	4
8	220	0.15	0
9	220	0.2	2

### III. RESULTS AND DISCUSSION

In the current paper, the findings were recorded for max flank tool wear (VB) and surface roughness (Ra). Table 2 describes the max flank wear and surface roughness determined on the cutting tool and machined surface of ADI respectively. The flank wear varied from 0.162 to 0.721 mm, and surface roughness varied from 0.512 to 2.81 $\mu$ m. The main effects plots for Ra and VB are shown in Figures 1 and 2 respectively. Based on the analysis, low surface roughness was obtained at a feed rate of 0.1 mm/rev, a cutting speed of 170 m/min, and a nanoparticle concentration of 2 wt%. Feed rate and nanoparticles wt % were found to have the greatest impact on surface roughness quality (Figure 1), contributing 46.55% and 40.75% respectively (Table 3). As known in machining process, the feed rate has a significant effect on the surface roughness. In addition, the impact of the increase in nanoparticle concentration can be attributed to the increase in nanoparticles which can penetrate in the chip and workpiece surface and settle in any micro-grooves or slits in the workpiece surface.

TABLE 2. THE MACHINING PARAMETER LEVELS AND THE OUTPUT MEASUREMENTS

Experiment No.	A	B	C	Surface roughness ( $\mu$ m)	Maximum flank wear (mm)
1	1	1	1	0.891	0.481
2	1	2	2	0.852	0.241
3	1	3	3	1.692	0.162
4	2	1	2	0.512	0.192
5	2	2	3	1.421	0.171
6	2	3	1	2.812	0.721
7	3	1	3	0.563	0.211
8	3	2	1	1.890	0.561
9	3	3	2	0.951	0.242

In terms of tool wear, the lowest max flank wear (VB) was obtained at a cutting speed of 120 m/min, a feed of 0.2 mm/rev, and a nanoparticle concentration of 4 wt%. Generally, the cutting speed significantly affects the tool wear due to the high heat generation at the cutting zone. However, in Figure 2, it can be seen that nanoparticle concentration was found to be the most significant factor, at 90% contribution (Table 4), with regard to the tool wear. This effect on tool wear behavior was likely because of the good thermal conductivity of the nanoparticle and its ability to penetrate into the chip/workpiece zone, which improve the machining performance, viscous property, and heat removal ability of the nanofluid.

Total	8	0.331		100

#### IV. CONCLUSION

In this study, cutting speed, feed rate, and different nanoparticle concentrations (wt %) in MQL were selected as cutting parameters. According to ANOVA, the feed rate (40.75 % contribution) and nanoparticle concentration (46.55 % contribution) were the most significant parameters that determined the surface roughness on the titanium Ti-6Al-4V alloy. The ANOVA analysis also showed that the nano-fluid at 2 and 4 wt% concentration of Al<sub>2</sub>O<sub>3</sub> provided better results than regular MQL in determining surface roughness. The tool wear was also found to be affected by nanoparticle concentration. The analysis indicated that the nanoparticles concentration had a significant influence on the flank wear, at 90 % contribution, as it could enhance the thermal conductivity and lubrication properties of the cutting fluid and minimize the coefficient of friction between the tool- workpiece and tool-chip. Ultimately, it can be concluded that the nano-fluid improves the surface finish and tool life as a coolant during machining titanium Ti-Al6-V4 alloy. Furthermore, Al<sub>2</sub>O<sub>3</sub> nanoparticles are improved the machining performance of MQL. However, determining the appropriate nanoparticle concentration needs more investigations.

**Abstract**—Several properties make titanium and its alloy the primary candidate to attain weight and functional advantages because of its promising properties such as high strength to weight ratio, high corrosion resistivity, and high yield stress. Although titanium alloys have superior properties, some inherent characteristics such as high chemical reactivity and low thermal conductivity lead to poor machinability and result in premature tool failure and shortened tool life. In order to overcome the heat dissipation challenge during machining of titanium alloys, nano-cutting fluids are utilized as they offer higher observed thermal conductivity values compared to the base oil. Thus, in the current work, multi-walled-carbon nanotubes (MWCNTs) cutting fluids along with minimum quantity lubrication (MQL) have been employed during machining Ti-6Al-4V. On the other hand, developing a multi-objective optimization model for machining titanium alloys is a promising step in order to minimize machining cost, achieve excellent surface quality, and increase the cutting tool life by selecting the optimal cutting conditions (i.e. cutting speed, feed rate, depth of cut). In this study, response surface methodology (RSM), and genetic algorithm (GA) are employed to model and optimize three main machining responses: tool wear, surface quality, and power consumption. Three main independent processes parameters are considered when machining titanium alloys, namely; cutting speed, feed rate, and percentage of added nano-additives.

**Keywords-machining; optimization; modeling; response surface methodology (RSM); nano-cutting fluid; genetic algorithm (GA), NSGA-II**

## I. INTRODUCTION

Titanium alloys are broadly used in various industrial applications in military, aerospace, power generation, automotive, and other fields due to their promising mechanical, physical, and chemical characteristics; such as, high yield strength, high strength to weight ratio, high toughness and high creep, corrosion, and wear resistance [1]. These materials also retain their hardness and strength at high temperatures [2] which make them one of the primary candidates for aerospace, nuclear, power generation, and automotive applications.

However, despite the above-mentioned superior characteristics, titanium alloys are inherently difficult to cut due to their high stresses and high cutting temperatures generated when they are being machined. This is mainly attributed to low thermal conductivity of titanium which adversely affects the tool life and can lead to a premature tool failure. Because of their low thermal conductivity, the generated heat during machining titanium alloys is mainly dissipated through the cutting tool and cooling media other than the workpiece or chip. In addition, titanium alloys become chemically reactive at a high cutting temperature and react with some tool materials which also deteriorate the cutting tool and accelerate the tool failure. Moreover, the resultant chip shape in titanium machining is serrated or saw-toothed as localized adiabatic shear bending and intense shear strain rate exist in the primary shear zone due to the high temperature at the chip–tool interface. Some other properties, which make titanium alloys difficult to cut and impose barriers towards their widespread applications, are low elastic modulus, strain hardening, tendency to adhesion, and forming built-up edges [3, 4].

A promising technology in the application of cutting fluid is known as minimum quantity lubricant (MQL). MQL is a cooling/lubrication method in which an optimal amount of cutting fluid is forced to penetrate into the cutting zone by means of compressed air. Among the available lubrication techniques, the MQL technique with vegetable oil offers the best environmental friendly solution. Not only does this technique provide the optimum amount of lubricant, utilizing vegetable oil presents a promising alternative to overcoming harmful environmental impacts of commercial cutting fluids, such as mineral oil. The major important factor to improve the cooling and lubricant functions in the MQL method is utilizing certain cutting fluids such nano-fluids which can develop its wettability aspects [5, 6]. Carbon nanotubes (CNTs) are among the nano-additives that have superior properties. The diameters of these nano-additives vary from few nanometers to hundreds of nanometers, and their lengths range between tens of nanometers to several centimeters [7]. Proposing new nano-cutting fluids is contributing to overcome the heat dissipation challenge during the cutting processes as it offers a highly observed thermal conductivity value in comparison with the base lubricants.

Additionally, it is shown that nano-cutting fluids have superior cooling properties due to its good heat extraction capabilities [8]. Nano-cutting fluids have shown promising effects on the cutting performance characteristics through different cutting operations such as turning, milling and grinding as has been presented in some previous studies [9-14, 22-26]. Also, a previous work introduced a detailed model to assess the sustainability aspects (including cutting fluids application) for machining processes [27]. The proper dispersion of nano-additives into the base cutting fluid shows a promising advantage in cutting processes as it helps to reduce the induced friction between the workpiece and cutting tool [15]. Also, nano-cutting fluids can contribute in facing the heat dissipation challenge during cutting processes. The main objective of this paper is to model and optimize the machining process of Ti-6Al-4V with MQL-nano-fluids using RSM and multi-objective evolution algorithm (i.e., NSGA-II). Three main machining responses are tool wear, surface quality, and power consumption, while three main independent process parameters, as decision variables, are considered during machining titanium alloys as follows: cutting speed, feed rate, and percentage of added nano-additives. The experimental design and methodology will be discussed in the next section, while section 3 will discuss the experimental results, machining responses modeling and multi-objective optimization results. Finally, section 4 will discuss the study conclusions.

## II. EXPERIMENTATION

In order to investigate the effects of dispersed MWCNTs-nano-fluid on the cutting quality performance, experiments are carried out by turning of Ti-6Al-4V. Ti-6Al-4V (UNS R56400) is utilized as the experiments workpiece. The tests are performed on CNC lathe machine using standard carbide turning inserts CNMG 432MMH13A (ANSI standard). Cutting tests are performed under MQL strategy, using different levels of cutting speed, feed rate, and weight percentages of added nano-additives. The depth of cut for each cutting pass is 0.2 mm. The cutting tool information is listed in the Table I. Regarding the MQL system, the air-oil mixture was supplied by the stand-alone booster system (Eco-Lubric) installed on the machine tool with a nominal oil flow rate of 40 ml/hr and air pressure of 0.5 MPa. The average surface roughness parameter has been used to evaluate the machined surface quality using a surface roughness tester (i.e., Mitutoyo SJ.201). Through the use of a toolmaker's microscope, flank wear was measured subsequent to each cutting pass. In addition, a Power Sight Manager was employed throughout the machining process in effort to assist with logging power consumption.

TABLE I. THE USED CUTTING INSERT AND TOOL HOLDER DURING MACHINING Ti-6Al-4V

	Cutting tool information during machining Ti-6Al-4V
Cutting tool	Coated carbide insert (CNMG 120416MR (ISO))
Tool holder	SANDVICK SCLCR-2525M12 with clearance angle 5o and rake angle 0o, nose radius of 1.58 mm

Multi-walled carbon nanotubes (MWCNTs) with 13-20 nm average diameter, 95% purity, 10-30 µm length, and 110 m<sup>2</sup>/g specific surface area were used for nano-cutting fluid

preparations. Dispersion of MWCNTs into the base cutting fluid is an important factor which affects the resultant nano-cutting fluid thermal conductivity and viscosity. The dispersion of MWCNTs into the base cutting fluid is performed using an ultrasonic device (AQUASONIC-50HT) over the course of 3 hours at 60°C, which is then followed by a step that offers thorough mixture, using a magnetic stirrer (Hot Plate Stirrer-3073-21) for 30 minutes to ensure full dispersion of MWCNTs into the resultant nano-cutting fluid.

In this work, three design variables (i.e., cutting speed, cutting feed, and added nano-additives percentage) are used at three levels each. Table II indicates the design variables studied and the assignment of the corresponding levels. L9 orthogonal array (L9OA) based on the Taguchi method is employed in Table III [16]. Tests are replicated three times and average response values are calculated. The full factorial array in this work is L27OA (3<sup>3</sup>); however, fractional factorial array L9OA based on the design of experiments methodology has been employed to save time and cost.

TABLE II. THE LEVELS ASSIGNMENT TO DESIGN VARIABLE

Design variables	Symbol	Level 1	Level 2	Level 3
Cutting speed (m/min)	A	120	170	220
Feed Rate (mm/rev)	B	0.1	0.15	0.2
Nano-additives (wt. %)	C	0%	2%	4%

7	220	0.1	4
8	220	0.15	0
9	220	0.2	2

## III. RESULTS AND DISCUSSIONS

### A. Cutting tests results

The flank wear, surface roughness, and power consumption results are listed as shown in Table IV. Regarding the flank wear results, a maximum flank wear of 0.4 mm [17] is used as the tool life criteria otherwise, in case of not reaching the end of tool life

criteria, the cutting stopped after nine cutting passes. Test 3 showed the lowest flank wear value. The cutting conditions at test 3 are cutting speed of 120 m/min, feed rate of 0.15 mm/rev and 4 wt. % of added MWCNTs. The highest wear value was found after test 8 (after 6 cutting passes) and after test 6 (after 5 cutting passes). Both of cutting tests 8 and 6 have been performed without using nano-additives.

When 2 wt. % of added MWCNTs is utilized, the results showed that cutting test 2 offered the lowest power consumption. The cutting conditions at this test are cutting speed of 120 m/min and feed rate of 0.15 mm/rev. While the highest power consumption value has been obtained at cutting test 8 which has been performed using classical MQL without nano-additives. In general, MWCNTs nano-fluid has shown better performance in reducing the power consumption compared to the tests performed without any nano-additives. For surface roughness results, it is clear that MWCNTs nano-fluid showed promising results to improve the induced surface quality; however, cutting tests 3 and 9 didn't show effective results compared to the other tests performed using nano-additives as these tests have been performed at the higher value of feed rate level (i.e. 0.4 mm/rev). Cutting test 4 showed the best surface quality. The cutting conditions of this test include cutting speed of 170 m/min, feed rate of 0.1 mm/rev and 2 wt. % of added MWCNTs. The obtained results will be used in the next step to build three different mathematical models for the studied machining responses.

TABLE IV. THE MACHINING OUTPUTS RESULTS

Cutting test #	The studied machining responses		
	F <sub>1</sub> : Flank wear (mm)	F <sub>2</sub> : Surface roughness (µm)	F <sub>3</sub> : Power consumption (Watt. h)
1	0.44	0.89	2325
2	0.18	0.85	2084
3	0.16	1.85	2192
4	0.29	0.51	2138
5	0.21	1.063	2230
6	0.62	2.8	2454
7	0.45	0.55	2410
8	0.56	1.89	2634
9	0.42	1.43	2344

### B. Cutting processes modeling

The modeling of the studied cutting processes is implemented using response surface methodology (RSM) to study the effects of the studied design variables on the measured responses. RSM has been employed in previous studies to optimize the machining parameters effects on different machining characteristics [18]. The developed models are used to express; the generated power consumption, surface roughness, and flank wear. It should be stated that all studied responses have “lower-the-better” criteria. The purpose of

mathematical models relates the process responses to ease the optimization of the process. The model's validation is demonstrated using the average percentage of deviation ( $\Delta$ ) which can be calculated as shown in equations (1-2) where  $R_m$  is the measured response,  $R_p$  is the predicted response,  $n$  is the number of runs, and  $\Delta_i$  is the percentage of deviation per run (i).

The developed models using MWCNTs nano-fluid for flank wear, power consumption, and surface roughness are provided as shown in equations (3-5), respectively. The design variables quadratic and interaction effects are used to express the developed model as all studied design variables have three levels (2<sup>nd</sup> degree of freedom). The average model accuracy for the flank wear under using MWCNTs nano-fluid is about 89.31%, while 98.6% average model accuracy is calculated for the power consumption model, and the surface roughness model provides an average model accuracy of 93.71%. It should be stated that all mathematical models are valid within the studied the range for the independent process parameters

$$\Delta_i = \text{ABS} \left( \frac{R_m - R_p}{R_m} \right) * 100\% \quad (1)$$

$$\Delta = \frac{\sum_{i=1}^n \Delta_i}{n} \quad (2)$$

$$VB_1 = 7.2 * 10^{-6} A^2 + 10.96 B^2 + 188.6 C^2 - 7 * 10^{-3} AB - 2.2 * 10^{-3} AC - 94 BC + 0.22 \quad (3)$$

$$PC_1 = 0.01 A^2 - 2579.76 B^2 + 399783 C^2 - 0.35 AB - 75.26 A - 52343 BC + 2071.63 \quad (4)$$

$$120 \leq A \leq 220$$

$$0.1 \leq B \leq 0.2$$

$$0 \leq C \leq 0.04$$

$$A, B, C \geq 0$$

### C. Cutting processes optimization

In the current study, the non-dominated sorting genetic algorithm (NSGA-II) has been utilized to solve the current multi-objective problem. The NSGA-II [19, 20] is one of the popularly used evolutionary multi-objective optimization algorithm which attempt to find optimal Pareto-front solutions. This technique is mainly based on using an elitist principle, and explicit diversity preserving mechanism, called crowding distance. The evolutionary operators of the NSGA-II are based on genetic algorithm's, which are namely cross-over, mutation, and selection. The three mathematical models developed using RSM have been used in the optimization stage.

A constant population size of 50 has been used in this work, while the cross-over rate was 0.8, and the mutation probability was 0.01. Tournament selection scheme has been used. Also, an example for the solution converges stages for objective functions 1 and 2 is provided as shown in Figure 2, and The Pareto-front for the three objectives with same GA parameters is provided as shown in Figure 3. The Pareto-front progress is provided as shown in Figure 1. In addition, different values for population number (Np), and cross-over probability (Cp) have been applied to check the results sensitivity, and no significant changes have been observed. Also, a partial consistency between the Pareto-front results using different values of population size, and cross-over probability with the experimental data has been noticed. The chart for the corresponding design variables with its Pareto-front values for each case has been created, and the last case with Np=200, and Cp=0.6 has been presented as shown in Figure 1 and Table V. Depending on the literature review of selecting the optimal machining parameters, and the obtained results from the multi-objective optimization algorithm (i.e., NSGA-II), the optimal machining settings have been chosen.

The optimal levels for cutting speed, feed rate, and the percentage of added nano-additives are obtained at index #13 (see Table V), which were; 136.5 m/min, 0.123 mm/rev, and 2.82 wt.%. Regarding the optimal levels of the nano-additives concentration, it has been found that lowest flank wear has been observed when using 4wt. % MWCNTs, while the lowest power consumption and surface roughness have been obtained when using 2wt. %. On the other hand, the multi-objective algorithm (NSG-II) results showed that the optimal nano-additives concentration was 2.82 wt. %. The selected optimal level (nano-additives weight percentage) obtained from optimization procedure provides more physical sense as the highest percentage of nano-additive (4 wt. %) could cause more deteriorations to the cutting processes because of the highest occurrence possibility of the drastic ploughing effects which could increase the induced nano-additives wear and accordingly increase the overall tool wear. When there is an abundance of nano-additives in the resultant nano-fluid, they collide with and are impeded by the asperities on the work surface and hence stronger cutting forces are generated. As a result, the nano-additive induced wear is increased with increasing the nano-additives concretion as similarly discussed in a previous work [21] (see Figure 3). On the other hand, decreasing the nano-additives concentration would decrease the resultant nano-fluid thermal conductivity and would affect the heat dissipation

performance. In addition, decreasing the nano-additives concentration means less nano-additives in the workpiece-interface area, and therefore the induced friction would increase as can be seen in Figure 3. Based on the above explanations, it can be concluded that 2.82 wt. % MWCNTs provides more physical sense as it strikes a balance between achieving reasonable heat transfer performance, and avoiding the drastic ploughing effects.

#### IV. CONCLUSIONS

In the current work, multi-walled-carbon nanotubes (MWCNTs) cutting fluids along with minimum quantity lubrication (MQL) have been employed during machining Ti-6Al-4V. On the other hand, a multi-objective optimization model has been utilized for machining titanium alloys, which is a promising step in order to minimize machining cost, achieve excellent surface quality, and increase the cutting tool life by selecting the optimal cutting conditions such as cutting speed, feed rate, depth of cut. In this work, MWCNTs nano-fluid showed promising results in enhancing the machining performance during cutting Ti-6Al-4V. It is mainly attributed to the improved heat transfer and tribological characteristics of the employed oil. Also, response surface methodology (RSM), and multi-objective genetic algorithm (NSGA-II) are employed to model and optimize three main machining responses, namely, tool wear, surface quality, and power consumption. Different values for population number, and cross-over probability have been applied to check the results sensitivity; however, no significant changes have been observed. Also, the results showed a partial agreement between Pareto-front solutions using different values of population size, and cross-over probability with the experimental data. Depending on the literature review of selecting the optimal machining parameters, and the obtained results from the multi-objective algorithm, the optimal machining settings have been chosen, as selected solution form Pareto-front set. The optimal levels for cutting speed, feed rate, and the percentage of added nano-additives are obtained at index #13, which are 136.5 m/min, 0.123 mm/rev, and 2.82 wt.%, respectively. The selected optimal level (nano- additives weight percentage) obtained from optimization procedure provides more physical sense as it strikes a balance between achieving reasonable heat transfer performance, and avoiding the drastic ploughing effects. Finally, studying and analyzing the MQL-nano-fluid tribological and heat transfer mechanisms is still required in order physically obtain the nano- additives size and percentage effects on the cutting processes performance.

**Abstract**—This research work presents the results of a comparative study conducted to compare the coatings properties of WC-10Co-4Cr coats produced by two different Oxy-fuel coating process; high velocity oxy-gas fuel (HVOF) and high velocity oxy-liquid fuel (HVOLF) thermal spraying techniques. The coats were deposited directly on low carbon steel substrate without bonding coats. Scanning electron microscopy (SEM) was performed to study microstructural analysis and to quantify the porosity and cross-sectional coat thickness. Furthermore, the mechanical properties of both coating processes were defined in terms of bond strength and micro hardness. The results show that the liquid fuel sprayed coatings (HVOLF) produced higher adhesion strength coats ( $\sim 73$  MPa) compared to ( $\sim 68$  MPa) for HVOF. Similar results observed for micro-hardness of 1255 VHN and 1032 VHN, respectively. The surface roughness and porosity were less for HVOLF  $4.32\mu\text{m}/0.85\%$  compared to HVOF results of  $5.26\mu\text{m}/1.29\%$  porosity. This superior result in coats properties of HVOLF compared to HVOF was attributed due to less decarburization in HVOLF and hence less production of hard secondary phases of  $\text{W}_2\text{C}$ .

**Keywords-component;** HVOF; HVOLF; WC-10Co-4Cr;  
**Coating properties**

## I. INTRODUCTION

Engineering components in service under sever operational conditions i.e. erosive, corrosive and wear requires continuous maintenance using coated alloy materials [1,2].

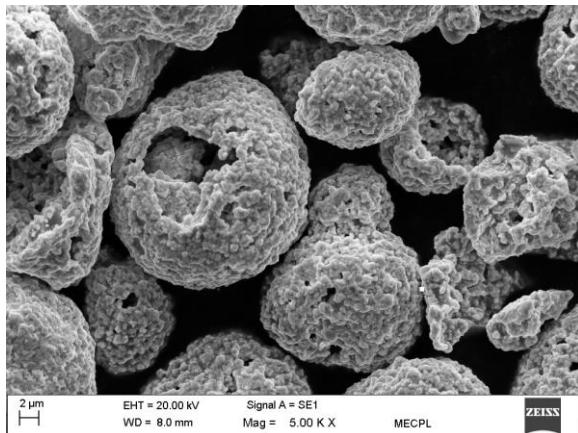

Thermal spraying techniques such as HVOF and HVOLF can be utilized to produce a variety of wear/erosion resistance coatings onto a wide range of substrate material with numerous possibility of coating powders [3]. Semi-molten material state is deposited onto the substrate through the acceleration of powder particles to high velocity through the coating nozzle while physical interlocking occurred at substrate surface and splat deformation occurred due to high kinetic energy hence the process produces dense coat with superior wear and corrosion resistance [3–7].

Ceremet coating of WC-CoCr composed of hard WC phase and relatively softer Co and Cr have been developed and studied extensively by many researchers [8] and resulted in dense, good toughness and high corrosive resistance coatings [9,10].

In this paper, the effect of fuel type either gaseous (propane) in HVOF compared to liquids aviation turbine fuel (ATF) in HVOLF is studied on the produced coats in terms of hardness, adhesion strength, porosity, thickness and microstructure.

## II. METHODOLOGY

Commercial feedstock powder of WC-10Co-4Cr was sprayed by two techniques HVOF and HVOLF, Fig.1 shows the SEM micrograph of feedstock powder. As shown in the figure the shape and morphology of the powder particles are not uniformed for the WC-10Co-4Cr powder.

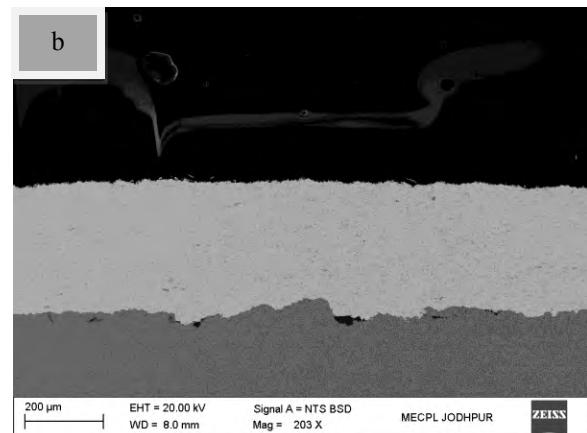

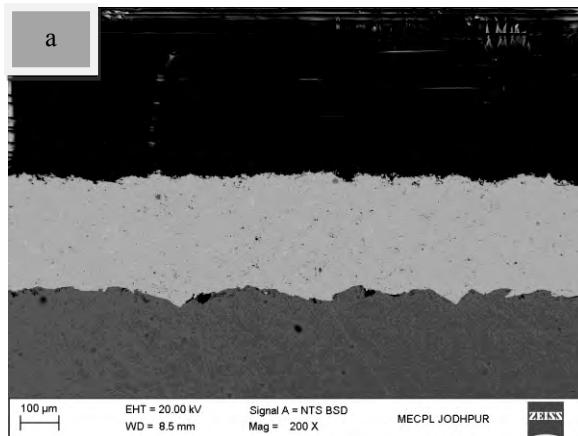

**Figure 1. SEM micrograph of WC-10Co-4Cr feedstock powder**

The grain size of the powder was measured as 15–45 $\mu\text{m}$  of agglomerated grains. Round specimen of 30 mm diameter and 10 mm high were prepared by blasting with alumina powder ( $\text{Al}_2\text{O}_3$ ) and air blown for cleaning. The HVOF and HVOLF spraying process was carried out at the laboratories of Metallizing Equipment Company Pvt. Ltd. a Nobal accredited laboratory (CERT. No. T-3514). Adhesion test was carried out at universal testing machine UTM Instron USA - Model 5969 (50 kN Capacity) according to ASTM C-633:2013 standards. A Shimadzu HVM-G Vickers micro-hardness tester was used to measure micro hardness according to ASTM E384-2011 where five measurements are taken for each sample with test force of HV0.3 and 8 seconds dwell time. Carl-Zeiss (UK) scanning electron microscopy (SEM) model EVO-18 was utilized to measure porosity as per ASTM E-2109:2007 standards cross sectional thickness as per EN ISO 1463:2003 standards, and for microstructural analysis.

### III. RESULTS AND DISCUSSION

#### A. Microstructural and surface analysis

The microstructure of the coatings were examined using the SEM, and the micrographs of the WC-10Co-4Cr HVOF and HVOLF are shown in Fig. 2 a & b, respectively.

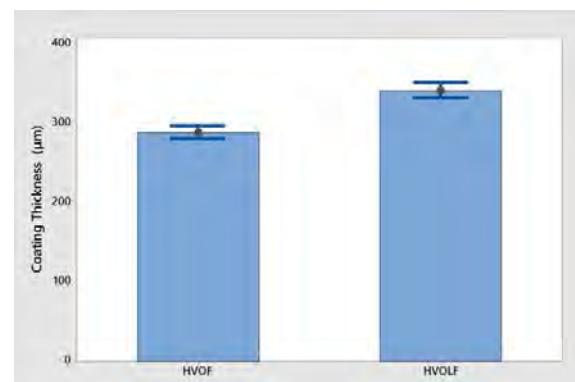

**Figure 2. SEM micrograph for WC-10Co-4Cr (a) HVOF and (b) HVOLF sprayed coating**

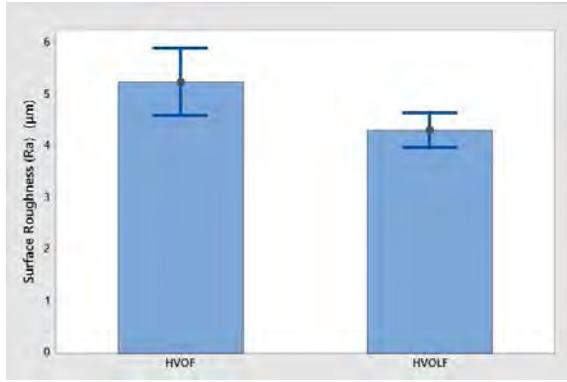

It can be seen that the coatings produced by both processes HVOF and HVOLF resulted in a homogenous coats. The microstructural analysis showed that HVOF coating contained higher percentage porosity of 1.29% at a total magnification of 200X compared to 0.85% for HVOLF coating under same total magnification.

Furthermore, the produced coating thickness were higher for HVOLF coatings compared to HVOF under same spraying conditions for both processes. The Fig. 3 below shows the average coating thickness measured on a diagonal of the cross section for both samples.

The surface roughness of the as sprayed coatings ( $\text{Ra}$ ) were lower for HVOLF compared to HVOF, which indicates smoother surface finish produced by HVOLF, Fig. 4 shows the average surface finish for both processes in the as sprayed condition.

**Figure 3. Average coat thickness measured on the cross section for HVOF and HVOLF**

**Figure 4. Average surface roughness measured for HVOF and HVOLF**

#### B. Microhardness measurements

The average microhardness value for the HVOF was 1032 VHN and a higher average hardness value of 1255 VHN was obtained for the HVOLF process. The coatings in both processes showed a uniform hardness profile by the five hardness measurements taken at different locations at the coatings through the entire thickness of the coatings confirming the homogeneity of the produced coatings.

**Table 1. Microhardness measurements at coatings produced by HVOF and HVOLF**

	1	2	3	4	5
<b>HVOF</b>	955	1026	989	1087	1102
<b>HVOLF</b>	1286	1324	1166	1206	1292

The higher coating density in HVOLF using the liquid fuel can explain this increase in microhardness.

#### C. Adhesion strength

The strength tests were performed in order to compare the bondability and adhesion of the coatings to substrate. In both HVOF and HVOLF a failure in glue were observed, Fig. 5 shows the bond strength results of both coatings in MPa.

In thermal spray, processing of WC a decarburization occurs during the spraying producing reaction products  $\text{W}_2\text{C}$ , W and C. It was reported by Saha et al. that W and C may dissolve in the Co matrix and promote the formation of amorphous Co matrix [11]. In the current research work, it is expected that less decarburization occurred in case of HVOLF. Less formation of hard phases  $\text{W}_2\text{C}$  may explain the higher bond strength of HVOLF compared to HVOF as  $\text{W}_2\text{C}$  may work as a stress raiser within the coating matrix and resulted in coat failure.

**Figure 5. Average bond strength for HVOF and HVOLF**

#### IV. CONCLUSIONS

In this study, two thermal spraying processes of HVOF and HVOLF deposited WC-10Co-4Cr successfully. The results showed that liquid fuel process (HVOLF) sprayed coatings have less porosity (0.85% compared to 1.29% in HVOF), higher coating thickness (341  $\mu\text{m}$  compared to 288  $\mu\text{m}$ ), higher microhardness of 1255 VHN, and higher bond strength with 73 MPa in HVOLF compared to 68 MPa in HVOF.

The increase in the mechanical properties of the coatings and therefore the performance was attributed to the formation of less hard phases due to less decarburization effect of WC and formation of amorphous Co matrix.

**Abstract**—Lightweight structures directly contribute to the sustainability of aviation, as their use reduces the structural weight of aircraft which in turn reduces fuel burned during flight. One family of lightweight structures are metal-coated polymers. Hybrid nanocrystalline microtrusses are a member of this family. These structures are fabricated by 3D printing complex truss-like structures out of polymer material, and electrodepositing nanocrystalline metal onto the polymer. Recent work has shown that buckling instabilities govern the strength of these systems. Hence this study focuses on modelling local shell buckling, one of the critical buckling mechanisms. This paper briefly reviews existing models for filled-shell local shell buckling, and outlines the development of an improved model.

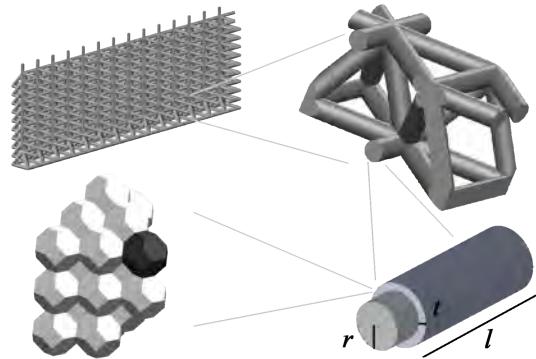

**Index Terms**—*compression; buckling; filled-shell; microtruss; nanocrystalline; instability*

## I. INTRODUCTION

Electrodepositing nanocrystalline metals onto 3D printed polymers creates hybrid materials with exceptional properties, including high strength and stiffness-to-density as well as nearly limitless geometric control. These hybrid materials can be used to reduce the weight of aircraft and other transportation vehicles, directly decreasing fuel consumption, cost and environmental impact. To achieve this, accurate models of the mechanical behaviour of hybrid nanometal-polymer materials and structures must be developed. This paper will explore the compressive properties of polymer struts enhanced with nanocrystalline metal coatings.

A nanometal polymer hybrid structure is produced by creating a polymer preform through 3D printing and subsequently coating the preform with nanocrystalline metal [1], as seen in Fig. 1. The reduced grain sizes of nanocrystalline metals relative to conventional metals allow for increased strength as per the Hall-Petch effect [2]. While other properties of nanocrystalline metals, such as wear resistance, also benefit by reducing grain size [3], ductility and modulus tend to decrease. Truss-like structures are very appealing because of their high ratio of stiffness-to-mass. These structures exhibit mass-efficiency and low-weight while combining the high strength benefits of nanocrystalline metals.

The production methods of nanometal-polymer hybrids also support the goals of sustainability. 3D printing of polymer structures yields less material waste than typical subtractive techniques, while also allowing for the manufacturing of complex geometries with ease. Furthermore, the use of electro-deposition techniques is cost-efficient and is relatively benign environmentally [3]. Electrodeposition also allows for controlling the deposited nanometal crystal sizes [3, 4]. Together

**Fig. 1:** Various scales of a nanocoated microtruss structure. Clockwise from upper left: coated microtruss structure, truss unit cells, individual struts, atoms at the material level [image modified from [4]]

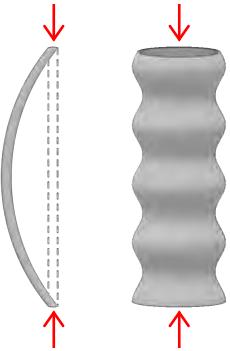

with control over the geometry of the struts ( $r$ ,  $l$  and  $t$  in Fig 1), this provides four length scales over which the behaviour of the nanocoated microtruss structure can be controlled.

Previous studies on nanocoated microtrusses have shown that their failure mechanisms are driven by compressive instabilities of the struts [4]. As the truss elements of nanocoated microtrusses are metal-coated polymer cylinders (as seen in Fig. 1), the present research explores the compressive instabilities associated with metal coated polymer cylinders.

## II. LITERATURE REVIEW

The two compressive instabilities of interest for metal-coated polymer cylinders are local shell buckling and global (or Euler) buckling, as seen in Fig. 2. Local shell buckling is characterized by the appearance of waves on the surface of the cylindrical shell [5, 6], while global buckling results in the lateral deflection of a column relative to its original undeformed axis.

For a nanometal-polymer hybrid, the nanometal coating provides all of the structural strength, and hence failure of the hybrid is governed by failure of the nanometal coating. Past investigations of metal-coated microtrusses assumed that the failure mechanisms of the struts only depended on the geometry and material properties of the metal shell [4], and that the polymer core provided no structural contribution. However, for thinly coated microtruss structures, where the cross-sectional area of the polymer is much more than that of the shell, the polymer contributes to the load-bearing capacity

**Fig. 2:** Appearance of global buckling (left) and local shell buckling (right)

of the struts, while increasing their resistance to buckling [7–9].

#### A. Hollow Shell Buckling

Local shell buckling of filled cylindrical shells – or simply filled-shell buckling – is closely related to local buckling of hollow shells. The local shell buckling load for a thin cylindrical shell in axial compression was found independently [10] by Lorenz [11], Timoshenko [6], and von Karman and Tsien [12]. At the inception of buckling, the strain energy of the shell consists only of the direct compressive stress and strain. Buckling occurs when it is more energy efficient to deform the shell in sinusoidal waves than to continue to deform the shell by direct compression. For a thin cylindrical shell in axial compression, the buckling stress is found to be [6, 11, 13–15]:

$$\sigma = \frac{E}{\sqrt{3(1-\nu^2)}} \frac{t}{r}, \quad (1)$$

where  $E$  is the Young's modulus of the shell's material,  $\nu$  is its Poisson's ratio, and  $t$  and  $r$  are the thickness and inner radius of the shell, respectively.

Various derivations of (1) have shown that the buckled shape of the shell – be it axisymmetric or non-axisymmetric – is not a factor in determining its buckling load [6, 12]. In addition, the end conditions also do not affect the buckling load provided that the cylinder is sufficiently long [6, 12, 13, 15].

Experimental investigations of hollow-shell buckling have shown that buckling loads in practice are strongly affected by geometric imperfections, material imperfections, and loading asymmetry [13, 16]. This was confirmed through the experiments of Tennyson [17], who manufactured nearly imperfection-free cylinders and ensured careful axial load distributions around the circumferences of the cylinders.

#### B. Filled shell buckling

Filled-shell buckling models utilize separate treatments of the shell and core behaviours. Most models for filled-shell buckling are intended for foam-filled metal or polymer tubes and experiments to validate them have used these material combinations.

The problem of local shell buckling of filled cylindrical shells was driven by the need to understand buckling of solid

propellant rockets under axial loads [7, 8, 18]. The earliest attempt at a filled-shell buckling model by Myint [8] emulated the approach used by von Karman and Tsien [12]. Uniquely, the Myint model assumed that a shear interaction between the shell and core was important. Later studies showed that the shear interactions between the shell and the core were negligible [7, 9]. More recently, Karam and Gibson [7] utilized a foundation model derived by Gough et al. [16], which was originally intended for buckling of face sheets on sandwich panels subject to axial compression.

A variety of experimental investigations were also undertaken to investigate the phenomena of filled shell buckling. The majority of the experiments were performed using metal tubes filled with polymer or polymer-like foams [18, 19], intended to mimic the structure of solid propellant rockets or natural materials like plant stems. Through these experiments, it was reported that the filler material prevented or hindered the formation of some buckling deformations. It was also found that a better agreement between theory and experiment occurred with shells when the thickness-to-radius ratios were large [18, 19], due to the fact that buckling loads for thick shells are less prone to imperfection sensitivity.

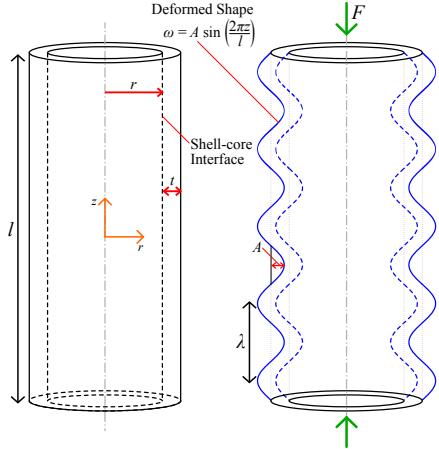

While the Karam and Gibson model is currently the best available model for filled-shell buckling, there are several drawbacks. The Karam and Gibson model utilizes a stress function originally intended for buckling of face sheets on composite sandwich beams [16, 20], and is thus not axisymmetric. Moreover, their model becomes less accurate when the coating thickness is large [20] as the core shear stresses become too large to properly capture using their model.

### III. CORE MODEL

The development of a core model requires an understanding of the behaviour of a solid polymer cylinder. During local shell buckling of a filled cylinder under an axial load, the core is subject to radial sinusoidal displacements which are the consequence of buckling, as shown in Fig. 3. The following assumptions are utilized:

- the shell and core are perfectly bonded;
- both the shell and core materials behave elastically;
- the buckling displacements are sinusoidal;
- there are many waves that form when the shell buckles;
- the core conforms to the buckled shape of the shell; and
- the shell is very thin compared to the radius (i.e.  $t/r < 0.1$ ).

The Southwell model employs stress functions to calculate the stress field in an axysymmetrically-loaded isotropic cylinder [21]. This describes the stress state of a thick hollow or solid cylinder, depending upon the boundary conditions. Fig. 4 shows the generalized geometry and appropriate boundary conditions for which the Southwell model is valid. The solution to this domain using the Southwell model provides the complete stress state of the axisymmetric section, and hence the entire cylinder.

**Fig. 3:** A metal-coated polymer cylinder prior to buckling deformations (left) and at after buckling (right). The cylinder has radius  $r$ , length  $l$  and shell thickness  $t$  while the buckle wavelengths have amplitude  $A$  and wavelength  $\lambda$  caused by the axial load  $F$

While commercial finite element packages are effective in determining the stress state of many geometries quite readily, the use of a custom-written program developed solely for analysing this geometry is a more efficient solution. The solution of the Southwell model is tailored to represent the specific stress states of an axisymmetric domain, allowing the use of coarser meshes to achieve an accurate solution. The governing equations for the Southwell model are [21]:

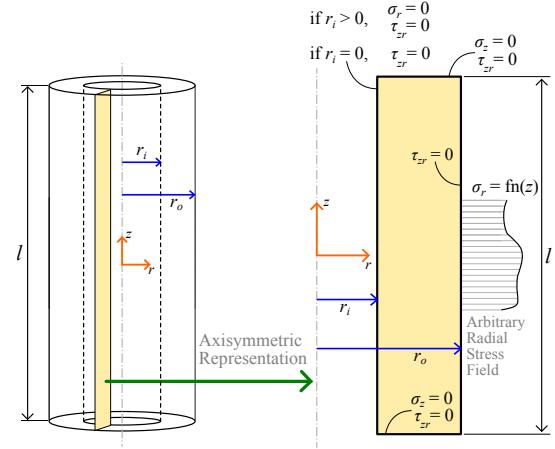

$$\begin{aligned} \frac{\partial^2 \phi}{\partial r^2} - \frac{1}{r} \frac{\partial \phi}{\partial r} + \frac{\partial^2 \phi}{\partial z^2} &= 0 \\ \frac{\partial^2 \psi}{\partial r^2} - \frac{1}{r} \frac{\partial \psi}{\partial r} + \frac{\partial^2 \psi}{\partial z^2} &= \frac{\partial^2 \phi}{\partial z^2}, \end{aligned} \quad (2)$$

where  $r$  is the radial ordinate direction,  $z$  is the axial ordinate direction, and  $\phi$  and  $\psi$  are stress functions which must be determined. Once  $\phi$  and  $\psi$  are obtained, the individual stress components can be calculated using their equations written in terms of  $\phi$  and  $\psi$  [21]:

$$\begin{aligned} \sigma_r &= \frac{1}{r} \left( \frac{\partial \phi}{\partial r} + \frac{\partial \psi}{\partial r} \right) - \frac{1}{r^2} [\psi + (1 - \nu)\phi] \\ \sigma_\theta &= \frac{\nu}{r} \frac{\partial \phi}{\partial r} + \frac{1}{r^2} [\psi + (1 - \nu)\phi] \\ \sigma_z &= -\frac{\nu}{r} \frac{\partial \psi}{\partial r} \\ \tau_{zr} &= \frac{1}{r} \frac{\partial \phi}{\partial z}, \end{aligned} \quad (3)$$

where  $\sigma_r$  is the radial stress,  $\sigma_\theta$  is the circumferential stress,  $\sigma_z$  is the axial stress and  $\tau_{zr}$  is the shear stress as seen in Fig. 4. It is to be noted that the Karam and Gibson model does not account for the circumferential stress [7, 20].

A general analytical solution is not obtainable for (2). A finite differencing solution was developed by Allen et al. [21] which utilizes second-order central differencing throughout the domain. Since the stress components are written in terms of  $\phi$  and  $\psi$  (i.e. (3)) the governing equations of these stress functions (i.e. (2)) are discretized. Details of the discretization can be found in Allen [21]. With the stress distributions known

**Fig. 4:** Cylinder geometry (left) and axisymmetric domain (right) for Southwell model. The cylinder has length  $l$ , inner radius  $r_i$  and outer radius  $r_o$ . Boundary conditions for the domain extremes are given in terms of the values of the shear stress  $\tau_{zr}$ , axial stress  $\sigma_z$  and radial stress  $\sigma_r$

for the axisymmetric domain of Fig. 4, the internal energy of the cylinder can be readily calculated.

A modified domain is used in conjunction with the Southwell model in order to determine the stress state in the core of a filled cylindrical shell undergoing buckling deformations. A sinusoidal stress loading is utilized because buckling deformations are sinusoidal [6–9, 12, 14, 15, 19], and these lead to sinusoidal stress fields. A section of the core undergoing buckling deflections is analysed using the Southwell model, as shown in Fig. 5. Comparing Fig. 4 and Fig. 5, the new domain makes use of periodic boundary conditions, while a sinusoidal radial stress loading acts on the cylinder and the axisymmetric section. The periodic boundary conditions ensure that a calculation done for one buckle wavelength  $\lambda$  can be reused when many waves are present [6, 7, 12]. The sinusoidal radial stress field is of the form:

$$\sigma_r = \sigma_0 \cos\left(\frac{m\pi z}{l}\right) \quad (4)$$

where  $\sigma_0$  is a given load magnitude,  $m$  is the number of half waves, and  $l$  is the length of the cylinder. Since the loading configuration represents one full wavelength,  $m$  is set to 2. The application of the radial stress field (i.e. (4)) leads to sinusoidal radial deflections with a magnitude of  $A$  as seen in Fig. 3.

Analyses using the Southwell model, as well as finite element analyses, reveals that for small wavelengths to radius ratios (i.e. small  $\lambda/r$ ) the value of the internal energy,  $U$ , is insensitive to the buckle wavelength  $\lambda$ . This implies that one calculation using the Southwell model for a given core material will provide the fitting constant  $K$  using:

$$K = \frac{2U}{mA^2\pi r}, \quad (5)$$

where  $K$  is the fitting constant. Once  $K$  is determined, the expression for the core energy  $U_p$  is found for any core radius  $r$  and number of buckle wavelengths  $m/2$ :

$$U = U_p = \frac{m}{2} KA^2\pi r. \quad (6)$$

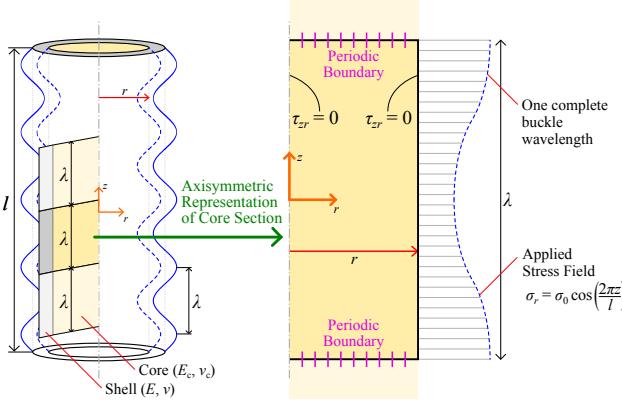

Fig. 5: Geometry, boundary conditions, and load for modified Southwell domain corresponding to buckling deflections of a filled cylindrical shell

This surrogate model is required for the core behaviour so that the core energy can be calculated for various core geometries, while also providing a differentiable function for the internal energy. The value of  $K$  is dependant only on the material properties of the core, and must be recalculated when a new core material is used. The core energy expression (Eqn. 6) is used together with the shell energy terms to determine the buckling load for the filled shell system.

#### IV. BUCKLING LOAD DERIVATION

While undergoing buckling, the energy sinks of a hollow cylindrical shell include the bending energy ( $U_b$ ) and the circumferential stretching energy ( $U_c$ ). The geometry and relevant material properties of a filled shell system are shown in Fig. 3 and Fig. 5.

The shell bending energy refers to the energy associated with the bending action of the shell sections as they undergo sinusoidal buckling deformations. It takes the form [6]:

$$U_b = \int_0^l \left[ \frac{A^2 m^4 \pi^4}{l^2} \sin^2 \left( \frac{m\pi x}{l} \right) \right] \left[ \frac{\pi r E t^3}{6(1-\nu^2)} \right] dx \\ = \frac{\pi E r t^3}{24(1-\nu^2)} \frac{m^4 \pi^4}{l^4} A^2 l, \quad (7)$$

where  $t$  is the shell thickness,  $E$  is the Young's Modulus of the shell material,  $l$  is the length of the shell,  $r$  is the shell's radius, and  $\nu$  is the shell material Poisson's ratio.

The energy resulting from the circumferential tension or compression of the shell hoop sections is defined as [6]:

$$U_c = \int_0^{2\pi} \int_r^{r+t} \int_0^l \int_0^{\epsilon_{rc}} \frac{E}{r} A \sin \left( \frac{m\pi z}{l} \right) r d\theta dz dr d\epsilon \\ = \frac{\pi E t A^2 l}{2r}. \quad (8)$$

During buckling, the total internal energy ( $U_i$ ) of a filled cylinder is the sum of the shell bending energy (7), the shell circumferential stretching energy (8), and the core energy (6). The external energy ( $U_e$ ) arises due to the applied axial force,  $F$  (see Fig. 3). These two energy terms, respectively, are:

$$U_i = U_b + U_c + U_p \quad (9)$$

and

$$U_e = \frac{F m^2 \pi^2 A^2}{4l} \quad (10)$$

At the inception of buckling, the following differential relation holds:

$$\frac{\partial U_e}{\partial A} = \frac{\partial U_i}{\partial A}. \quad (11)$$

This is known as the bifurcation point: a further increase in  $F$  will either lead to buckling or continued axial loading without buckling. While in perfect systems buckling will not take place, imperfections will always cause real systems to buckle [13].

Equating (9) and (10) and applying the operation as in (11), the elastic buckling load of a metal-coated polymer cylinder in axial compression is found. Adding on the load-bearing capacity of the core gives an expression of the form:

$$F = \left( 1 + \frac{E_c}{E} \frac{r}{2t} \right) \left[ \frac{2\pi^3 r E t^3}{3(1-\nu^2)} \frac{1}{\lambda^2} + \frac{E t}{2r\pi} \lambda^2 + \frac{K r}{\pi} \lambda \right]. \quad (12)$$

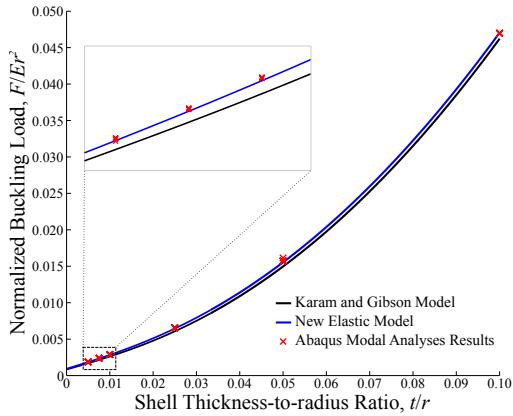

Equation (12) applies for any  $\lambda$ , but only one critical  $\lambda$  value exists for a given cylinder with known material properties. This critical  $\lambda$  value is found by finding the positive real root of the polynomial expression  $\partial F / \partial \lambda = 0$ . Once found, the critical  $\lambda$  value is substituted into (12) to give the critical load for the filled shell system of interest.

#### V. FINITE ELEMENT VERIFICATION

Buckling analysis was undertaken in Abaqus to verify the predicted loads. This was done for ranges of cylinder length-to-radius ( $l/r$ ) ratios and thickness-to-radius ( $t/r$ ) ratios. Many  $l/r$  ratios were used to ensure that the buckling load was insensitive to cylinder length. All geometries were represented axisymmetrically, and the subspace algorithm was used to solve for the eigenvalues and corresponding buckled shapes. A perturbation was applied in the form of an axial displacement at one end of each cylinder, while keeping the opposing end fixed and allowing both ends to expand radially. There were at least 5 elements through the coating thicknesses after meshing was carried out. The lowest eigenvalue calculated by the solver was taken to be the buckling load.

The  $t/r$  ratios studied ranged between 0.005 and 0.1. Ratios below 0.005 indicate very low thicknesses which are not practical for nanocoated microtruss structures, while those above 0.1 correspond to very thick coatings which are outside of the range of thin-shell buckling assumptions.

Fig. 6 shows a graph of the non-dimensional buckling loads as predicted by Abaqus along with the theoretical buckling loads predicted by both the new elastic theory (i.e. (12)) and the Karam and Gibson theory [7]. The theoretical curves and Abaqus results were found for  $E_c/E = 0.01$ , this value being typical for metal-coated polymer cylinders where the polymer material is ABS or a similar 3D printed material. The buckling loads for different  $l/r$  values (overlapping points at each  $t/r$  value in Fig. 6) are not identical due to slight differences in mesh characteristics. However, they are sufficiently close

**Fig. 6:** Non-dimensional loads calculated for the new elastic model and the Karam and Gibson model, with Abaqus modal analyses results included ( $E_c/E = 0.01$ ,  $\nu = 0.3$  and  $\nu_c = 0.35$ )

to indicate no dependence of the buckling load on cylinder length.

As seen in Fig. 6, both the Karam and Gibson theory and the new elastic theory predict lower loads than the Abaqus results. The Karam and Gibson theory predicts loads that are up to 10% lower than those predicted by Abaqus, while the new theory predicts loads that are no less than 3% of the values. The agreement between the Abaqus results and the new model theory improves at higher  $t/r$  values.

#### A. Discussion

The improved predictions of the new elastic model are in accordance with the increased energy that this model predicts. The circumferential stress component found using the Southwell model is not accounted for in the Karam and Gibson model, leading to lower energy predictions and lower predicted buckling loads. While the Southwell model is a more complete description of the stress state of a core subject to buckling deformations, the Karam and Gibson theory is simpler to implement in practice.

Though the Southwell model involves more steps to find the behaviour of the elastic core (i.e. finding the fitting,  $K$ ), the loading configuration can be changed for several other situations involving filled shell buckling. This can include hollowing out the core or assuming no adhesion between the shell and the core. These cases have not been studied in the existing literature.

While the present model predicts the buckling strength of metal-coated polymer cylinders, adapting it for use with hybrid microtruss structures will require topological information of a given microtruss.

#### VI. CONCLUDING REMARKS

A new model has been developed that accurately accounts for the energy state in the polymer core of a metal-coated polymer cylinder as the cylinder undergoes sinusoidal buckling deformations. The model utilizes the Southwell stress model, which describes the stress state in cylindrical geometries under

axisymmetric loads. This model has been used to represent the core behaviour of a filled-shell system undergoing buckling, and agrees more closely with finite element results. Although the model is more complex to implement than existing theories, such as the Karam and Gibson method, it is more adaptable to different cylinder geometries or adverse shell-core adhesion situations.

# Simulating Layup Defects During Tow Steering in Automated Fiber Placement

Nima Bakhshi and Mehdi Hojjati

Concordia Center for Composites (CONCOM),  
Concordia University,  
Montreal, Canada.

**Abstract**—Automated Fiber Placement (AFP) offers valuable advantages which make this technology a suitable candidate for producing high-quality parts in the aerospace industry. However, there are limitations: number of defects may arise during the fiber placement including wrinkles at the inside edge, and blisters in the middle of the prepreg tows. These defects have severe effects on the layup quality and consequently, on the performance and quality of the final part. Therefore, efforts shall be pointed to avoid them. A deeper understanding of the defect formation processes as well as tools and techniques for modeling them is indispensable for fully harnessing the potential of AFP technology. In the present study, a physics-based modeling approach is presented for *the global modeling of defects* in AFP. The application of this approach for detecting and modeling the blisters and out-of-plane wrinkles that appear during fiber steering, is discussed, although it should be noted that the application is *not limited* to the case of fiber steering and can be expanded to different scenarios. Preliminary results of the simulations are presented. AFP trials are performed to validate the model. The trends and patterns of both wrinkles and blisters are found to be in good agreement with experimental results.

**Keywords** - *Automated Fiber Placement; layup defect; simulation; manufacturing.*

## I. INTRODUCTION

Automated Fiber Placement has been increasingly used in the aerospace industry to manufacture high-quality aerospace parts. Manufacturing objectives including increasing productivity and reproducibility as well as decreasing labor intensity and minimizing the number of parts can be accomplished using this technology. One of the unique features of AFP is its ability to deliver up to 32 prepreg tows in a course with different speeds. This feature namely, the differential tow pay-out is what enables the AFP machines to laminate complex geometries and Variable Stiffness Composites (VSC). In complex geometries, steering the fiber path away from the geodesic path of the mold to maintain the desired fiber orientation is inescapable. Moreover, differential tow pay-out allows engineers to design a family of composites with curvilinear fiber paths, called VSCs. A more efficient load path

between supports and load points is formed by curvilinear fibers which allows exploiting the full potential of the directionality of composite laminae [1].

Despite its numerous advantages and capabilities, AFP comes with its own limitations. The productivity of the lamination process and the quality of final parts are significantly influenced by the complexity of the part, as well as the process parameters such as lay-up temperature and speed, compaction force and fiber tension. Several different defects may appear in AFP (especially during fiber steering) such as out-of-plane wrinkles at the inside edge of the tow, blisters (circular delaminations in form of a blister) in the middle of the tow, tow pull ups and shearing effects. These defects will cause lower part quality with reduced reproducibility by deviating the fibers from the original prescribed path, increasing resin rich areas, etc. Consequently, efforts must be aimed at avoiding them [1, 2].

The key mechanism resisting against the formation of most layup defects is prepreg tack [3-5]. Tack is a complex systemic property of prepreg-tool interface that can be reasonably controlled by process parameters. Experimental trials performed during this study as well as a review of the literature demonstrated that tack levels as a function of process parameters can be generally understood considering the formation of strong Intimate Contact (IC), stress relaxation effects in the prepreg resin and the resin's cohesive strength. Perhaps layup temperature is the most sensitive process parameter that affects the prepreg tack and layup quality. By increasing the temperature, the resin viscosity decreases and a better IC is achieved, resulting in higher tack. Experimental observations, however, have reported a peak in the tack of preps and pressure sensitive adhesives as a function of temperature. This is due to the fact that reduction of resin viscosity (with increasing temperatures) is accompanied by the decline of resin strength. Consequently, at very high temperatures, a good contact is formed, whereas the lower strength of the resin results in cohesive failure within the prepreg (as opposed to interfacial failure at the prepreg-tool interface for lower temperatures). Layup speed in the AFP is inversely proportional to the contact time. As such, the lower speed means more time for IC formation, lower strain rates and more time for relaxation of stresses in the prepreg resin, all of which result in higher tack levels. Increasing compaction force,

again, helps to establish a good IC and increases the prepreg tack. A peak is also observed for the tack as a function of compaction force, since the further increase of the force will result in redistribution of resin content and a contraction after the loading is released. Both these effects help the prepreg to detach from the tool surface (lower tack). Tack also has a peak around moderate values of relative humidity (50–60%), which is generally attributed to the changes in resin viscosity and strength. Another important factor is the age of prepreg. As the material ages, crosslinking reaction occurs in the resin and the degree of cure increases. This will result in a stiffer material with lower tack. Using fresh preprints within their shelf life helps in having a better quality layup. Other parameters such as tool's surface roughness, and, resin and tool surface energies also play a role in both establishing the IC and the amount of work of adhesion, however, their macroscopic effects on tack is not very well understood at the moment and further investigation is required.

The formation of wrinkles at the inside edge of the prepreg tow has been studied from both experimental [7–10] and modeling [11–13] perspectives. These approaches usually state a steering limit as the minimum radius that results in a defect-free layup. Experimental approaches are expensive, time-consuming and increase material wastage since they are based on trial and error. On the other hand, modeling approaches take advantage of the incremental deposition of prepreg tows in the AFP, and assume that wrinkles are formed individually, in isolation from each other [12]. It has been noted that the assumption employed in the local modeling approach does not always follow the experimental observations [11]. Although these methods have gained some success, they both have limitations as stated. Recently, Hörmann [11] has recommended changing the modeling strategy for the future work by considering the global behavior of the prepreg tow, instead of using the local approach's assumption.

In the present paper, a framework for simulating the layup defects in the AFP is presented in the finite element software ABAQUS. The application of this approach for modeling the out-of-plane wrinkles at the inside edge of the steered prepreg tows is presented. The cohesive zone modeling technique with a bilinear traction-separation law is used to represent the prepreg tack at the prepreg-tool interface. In addition, it is found that the location of blister sites can be found using the simulations, which can be used to further explore the causes behind the blister formation. Preliminary results of the simulations are presented. Automated Fiber Placement trials are performed to validate the model. The trends and patterns of both wrinkles and blisters are found to be in very good agreement with experimental results.

## II. MODELING STRATEGY

### A. Prepreg feeding and steering mechanisms

The ABAQUS [14] model constitutes five parts: A rigid tool, a rigid bar which simulates the steering path, a compaction roller, a guide for the movement of prepreg tow, and finally the prepreg tow. The assembled model with the used boundary conditions are presented in Fig. 1. Appropriate boundary conditions and kinematic coupling constraints are

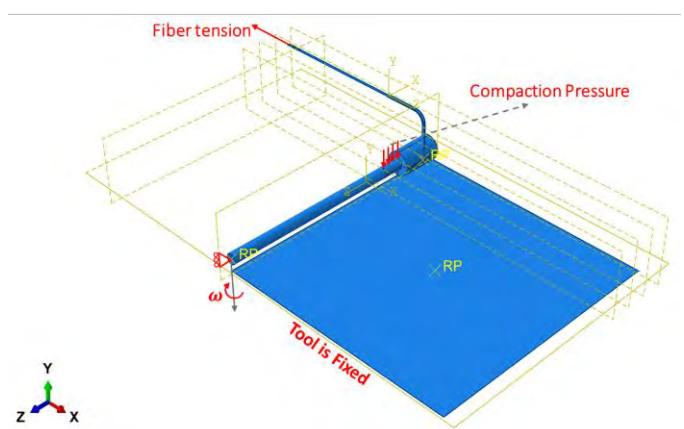

Figure 1. The assembled model.

created between the free end of the prepreg tow and the guide, to simulate the prepreg feeding mechanism. A light pressure simulating the compaction force is applied on top of the rigid bar, and a light force is applied to the free end of the tow to simulate the fiber tension which keeps the tows straight. A constant angular speed is applied to the free end of the rigid bar, such that it simulates the linear speed of the AFP head during the experiments.

### B. Prepreg tack

Several different approaches are available for modeling fracture and delamination including continuum mechanics, fracture mechanics, XFEM and damage mechanics. For modeling the prepreg tack, an especial approach in the damage mechanics, called Cohesive Zone Modelling (CZM) is utilized [15]. Tack is merely intended to be modeled as an interfacial property; the delamination surface is known in the AFP process (at the prepreg-tool interface); and finally, since the location of out-of-plane wrinkles (and more generally, layup defects) are not known, the approaches requiring specification of an initial crack *cannot* be employed. Since CZM complies with all of the modeling requirements of prepreg tack, it has been chosen for the present study. CZM is well established in commercial finite element codes and more importantly, effective methods are available for characterizing the cohesive zone properties. They can be introduced into the ABAQUS model with the surface-based cohesive zone modeling technique as a contact property. The cohesive contact is defined such that any node on the prepreg that comes into contact with the tool surface experiences the cohesive interactions. This modeling technique employs a bilinear traction-separation law to define the traction between the surfaces as a function of the separation between the surfaces. It is worthwhile to mention that in addition to the aforementioned desirable properties, viscoelastic material properties can be defined for the first part of the traction-separation law which in conjunction with an exponential softening (damage evolution) can account for the rate-dependent viscoelastic properties of prepreg tack.

Here, a bilinear traction-separation law for the CZM is employed which constitutes two linear sections (Fig. 2). The first section (elastic section) is defined through the slope of the line while the second part, corresponding to the damage evolution, requires a damage initiation criterion and a second

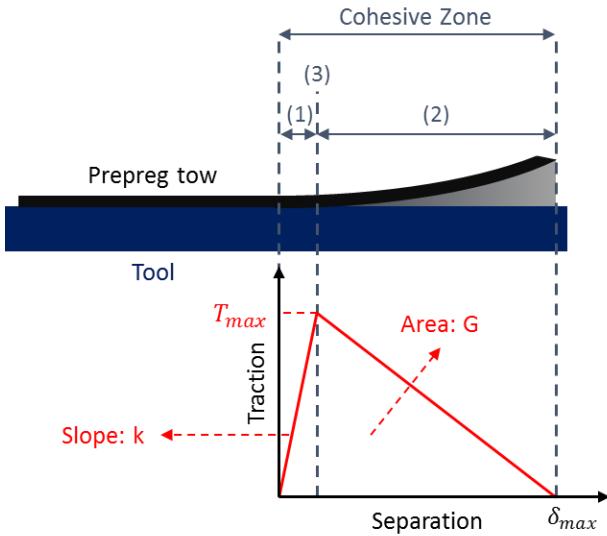

Figure 2. Bilinear traction separation law:  
(1) Damage initiation (elastic), (2) Damage propagation (softening),  
(3) Damage initiation criterion.

measure, for controlling the damage. Maximum nominal stress is chosen to establish the damage initiation and total fracture energy with linear softening is used to define the damage evolution.

From the fact that the maximum separation is, obviously, bigger than the separation at which the damage initiates, a simple relation should hold between the fracture energy (i.e. work of adhesion/tack),  $G$ , the maximum traction,  $T_{max}$ , and stiffness (or the slope of the damage initiation part),  $k$ :

$$k > T_{max}^2 / 2G.$$

### C. Solution method

Several models with different mesh sizes were studied to find the appropriate trade-off between the computation time and resolution of the models. Abaqus / Explicit solver with full geometric nonlinearities was used to solve the model. The explicit solver can handle the nonlinearities that arise as a result of large deformations in the prepreg tow and material degradation in the traction-separation law, very well. It should be noted that on the contrary to the Standard solver, the value of stiffness,  $k$ , does matter in the Explicit solver. It is known that in order to avoid convergence problems, Standard solver treats the stiffness of the CZ in a manner similar to the penalty method, therefore the stiffness value should be large and it does not affect the final results significantly [14].

TABLE I. PREPREG MECHANICAL PROPERTIES

$E_1$ (GPa)	$E_2$ (MPa)	$G_{12}$ (MPa)	$\nu_{12}$
31	0.046	3.025	0.2

### III. MATERIAL CHARACTERIZATION

The mechanical properties (except for the transverse modulus) of the uncured prepreg are experimentally measured in the previous work [13], using the tensile tests and bias extension tests. The transverse modulus was calculated using Puck's formula. These values are used in the present study since the same material was used in the AFP experimental trials. The material properties are summarized in table 1.

A commonly used method for measuring the unknown parameters required to fully characterize the prepreg tack using bilinear traction-separation laws is probe tack test method [4, 6]. This method was initially introduced in the Pressure Sensitive Adhesives industry to quantitatively measure the tackiness of adhesives and later was adopted to be used for measuring prepreg tack. In this testing method usually, a circular probe comes into contact with the prepreg at a controlled temperature and relative humidity, until a specified force is reached. Then it remains in contact with the prepreg for a given amount of time (dwell time), and subsequently, it is pulled away. During the retraction stage, force and displacement data are recorded to be further analyzed. Generally, the maximum recorded stress or the work of adhesion can be used to represent the quantitative value for tack.

Fig. 3 shows a typical *normalized stress-displacement* data obtained from the probe tack test (figure is reproduced from previous work [13]). As can be seen in this figure, the stiffness and maximum traction can be directly measured using probe test. The fracture energy (i.e. work of adhesion) can also be easily obtained by calculating the area under the traction data. These three parameters are sufficient for fully defining the bilinear CZ traction-separation law.

It should be noted that, although probe tack test provides a straightforward method for finding the required information for the model, its results might be hard to be related to the actual process parameters. The correlation between the AFP head's speed, on one hand, and the dwell time and probe speed (during both compression and retraction stages of probe test), on the other hand, is not clear. Moreover, the effects of temperature on the prepreg tack that is measured through probe test might be contrary to what actually occurs during the AFP. Increasing

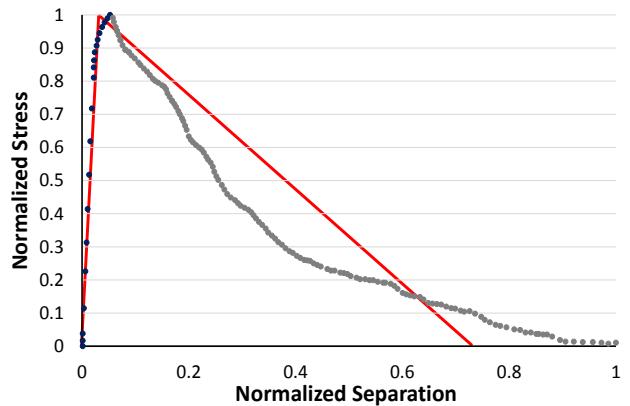

Figure 3. Typical data from probe tack test (reproduced from [13]),

Figure 4. Blisters and in-plane waviness are appeared in the steered tows.

the temperature (which results in lowering the resin viscosity) in the probe test generally causes the resin to flows away from the probe surface. Consequently, lower tack results are usually recorded for increasing temperatures, while increasing temperature in the AFP clearly strengthens the interface (at least in the practical process range). Developing a more realistic approach for measuring prepreg tack with regards to AFP will remain for the future investigation. Here, available data in the literature [6, 13] that are in a close range of the experimental process parameters are used.

#### IV. RESULTS AND DISCUSSION

AFP trials were performed using the 0.2 mm-thick and 6.35 mm-wide prepreg tows with the material properties presented in table 1. Tows are steered with the radius of 558.8 mm (22"). Results of the experiments and simulations are presented in this section.

In addition to the in-plane fiber waviness (Fig. 4) which is the most primitive result of length discrepancies between the inside and outside edges of a steered tow, a very commonly observed defects were blisters in the middle of the prepreg tows (Fig. 4 and 5). Initially, it was postulated that the blisters are occurring due to the high flow rate of the hot Nitrogen gas (heating system of the AFP). However, decreasing the flow rate proved to be ineffective in preventing their formation. During the simulations, it was found that in configurations similar to those in which blisters have appeared, several small zones are formed that have reached the damage initiation criterion but the damage has not progressed much. The results of the corresponding simulation are presented in Fig. 6. The red color represents the areas where the damage initiation criterion of the traction-separation law is met. Those areas that have not completely buckled yet (i.e. the damage has not evolved 100% and consequently, wrinkles have not been formed) correspond to the blister zones and are marked with yellow circles. It can

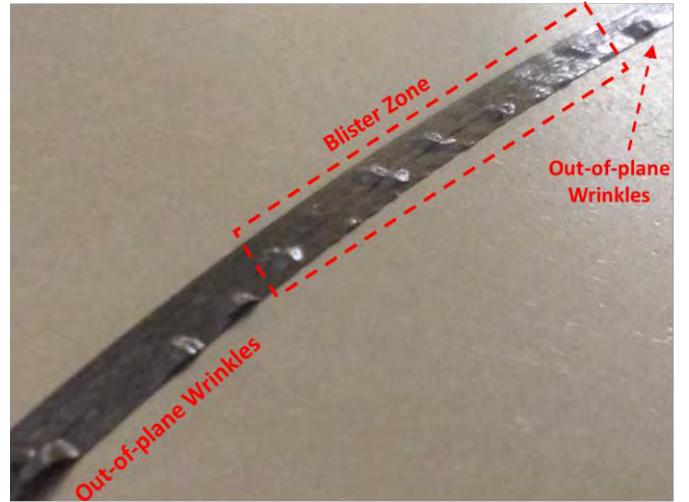

Figure 5. Blisters and out-of-plane wrinkles are appeared in the steered tows.

be observed from this figure that the wrinkles are clearly distinguished by the large deformation of the tow while the blister zones look intact (although they have a damaged interface which causes the blisters to appear in practice).

A qualitative comparison of Fig. 6 with the experimental results (Fig. 5) shows an excellent agreement, meaning that blisters are in fact mainly originating from the stress distribution resulted from fiber steering, and interface failure (i.e. not sufficient levels of tack) rather than other physical factors. Moreover, the pattern and frequency of appearance of out-of-plane wrinkles are also in good agreement between the simulation and experiments.

A commonplace result of the simulations is presented in Fig. 7. As it is demonstrated in this figure, the outside edge of the prepreg tow is under sever tensile stress. This tensile stress has two origins: the fiber tension force that is exerted on the free end of the tow which partly helps in keeping the loose tow straight (in reality this load is indeed induced in the prepreg tow in the delivery system), and the tensile stress that is induced as a result of fiber steering (bending stress). In the viewpoint of Fig. 7, two wrinkles are appeared. It is evident that compressive stress is built up at the inside edge of the tow

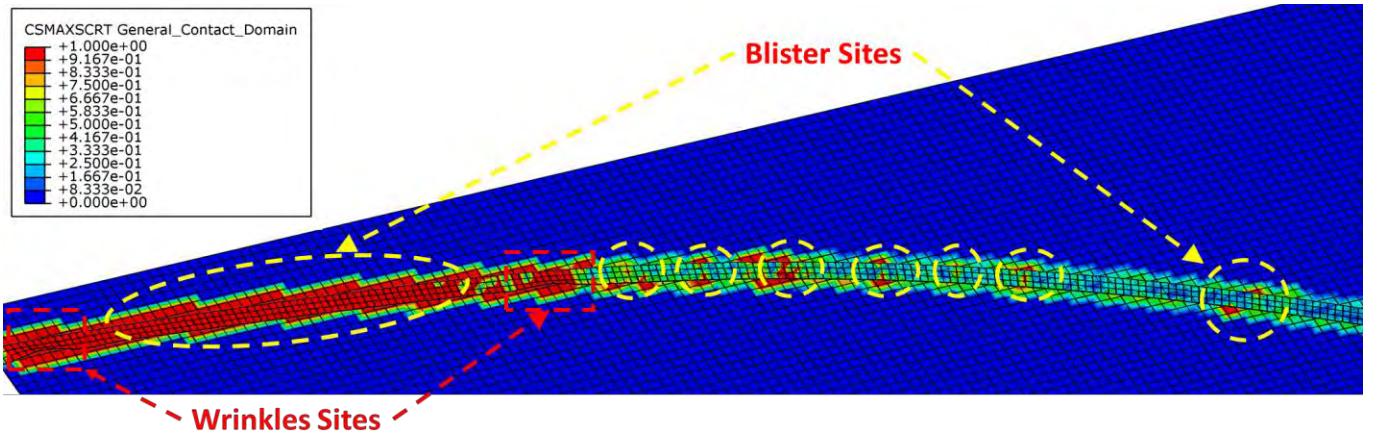

Figure 6. Simulation results: the damage initiation criteria.

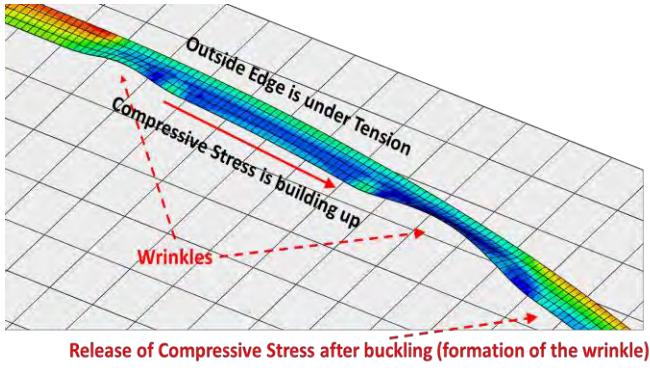

Figure 7. A commonplace result of the simulations.

between the two wrinkles. More importantly, small low-stress zones are visible in the vicinity of both wrinkles indicating that wrinkles are indeed acting as a stress relief mechanism.

## V. CONCLUSION

A new *global defect modelling approach* for the layup process of Automated Fiber Placement is presented in the present work. A simple mechanism is created to simulate the feeding mechanism of the prepreg tow. The surface-based cohesive zone modelling technique using a bilinear traction-separation law is used to model the prepreg tack. Application of the proposed approach for the challenging and commonplace case of fiber steering which is one of the major defective layup scenarios in AFP is discussed. Experimental AFP trials were performed and a very good agreement between the simulations and experimental results is found. It is shown that using the index representing the damage initiation criterion and the deformed shape of the prepreg tow, two of the major defects occurring during the tow steering namely, out-of-plane wrinkles and blisters, can be predicted and identified.

## ACKNOWLEDGMENT

The authors would like to acknowledge the financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC). Also, we would like to thank Mr. Jeffrey Fortin-Simpson of CONCOM's AFP laboratory for his help and assistance in sample preparations.

# Computational Modelling of Radiofrequency Cardiac Ablation to Study the Effect of Cooling on Lesion Parameters

Carolyn Berkmarotel, Hamed Avari, Eric Savory

Department of Mechanical and Materials Engineering

University of Western Ontario

London, Ontario

cberkmor@uwo.ca

**Abstract**— Radiofrequency ablation (RFA) is a technique used to treat cardiac arrhythmias. It creates lesions in the heart by creating thermal damage. Due to limitations associated with *in vivo* as well as *in vitro* studies, computational methods assist in further analysis of the problem by allowing for quicker and more diverse parametric studies and hence, a more thorough understanding of the physics involved. These computational models have been proven to be good representations of the process by accurately modelling the catheter with simplified geometry and boundary conditions. Although these studies have inconsistencies in material properties (due to the variation of thermal and mechanical properties in biological tissue) as well as different methods of creating the geometry and applying the boundary conditions, overall they are quite similar. The effects of esophageal cooling were investigated to understand its effect on the process. It was determined that using the standard model found within the literature, the esophageal cooling changed the lesion depth by less than 18%, while changing the maximum tissue temperature by as much as 13.4%.

## I. INTRODUCTION

Radiofrequency ablation (RFA) is used in patients to treat cardiac arrhythmias (a cardiovascular disorder involving irregular heart rhythm). Atrial fibrillation, the most common type of cardiac arrhythmia, is where the atrial electrical signal is chaotic. This condition can be life threatening and must be treated [1]. For the past decade RFA has been the most common and effective method for treating atrial fibrillation that is resistant to drug treatment [2]. In this procedure, the tissue surrounding the pulmonary arteries is heated by a radiofrequency current (causing joule heating in the tissue) until the tissue is permanently damaged and a lesion is formed. This process isolates the incorrect electrical signals that originate there, so normal heart electrical function can resume [3,4]. One of the risks of this process is the development of an atrial-esophageal fistula. This is a rare (it only occurs in less than 1% of patients after RF procedures) but serious condition that can

potentially result in a patient's death [5]. Atrial-esophageal fistula is caused by thermal damage to the esophagus; however, the exact mechanism of injury is not yet well understood [6]. Studies have been conducted, both experimentally and computationally, to further understand the heat transfer in RF ablation, but there are still many unknowns regarding how thermal damage to the esophagus occurs and how it can be prevented.

## II. LITERATURE REVIEW

The first RFA study [7] employed a 2-D axially symmetric mathematical model but no computational simulations were conducted. The first models with a geometric domain that discretized the equations for voltage and temperature distribution (that were solved by a computer program) were based on 2-D geometry [8-10]. Experiments were conducted in these studies to determine convective heat transfer coefficients in the heart as well as the heart tissue properties [8-10]. Much of the subsequent research drew heavily on this initial work for geometry, tissue properties and convection coefficients for blood flow in the heart, notably Berjano and co-workers [4, 11-14]. A proven computational model strategy has emerged from the research and several aspects of that model will be considered in detail here.

### A. Geometry

The geometry of these models varies, as each study considers a different situation, or models a specific experiment. Most studies model the catheter as a cylinder with a hemispherical tip. The catheter diameter is specified in French (where 1 Fr = 1/3 mm), ranging from 6-8 Fr, whilst the length ranges from 3-5 mm. The catheter is modelled partially embedded into the tissue in almost every scenario, with only one study accounting for tissue deformation [15]. Above the tissue is the blood, which is sometimes modelled and sometimes excluded (see blood modeling section for more information). The overall size of the model is determined through a Cauchy independence test which involves seeking the smallest domain possible without affecting the results. For most studies, the overall size of the domain is less than a cube with 80 mm sides. Studies often use axial symmetry or face symmetry. Axial

symmetry cases cannot model blood flow and must use convection coefficients, but computation time is reduced significantly.

Most studies consider the orientation of the catheter to be perpendicular or parallel to the tissue. One study has considered the effect of catheter angle on lesion size and found that the parallel orientation produces smaller lesions [16], and so, for the purposes of finding the maximal lesion size, the perpendicular orientation is recommended. When the catheter is perpendicular to the tissue, the depth of the catheter into the tissue must be considered. In most studies, the depth used comes from previous research or is obtained from experimental measurements of ablated tissue. Currently, there is one experimental study relating catheter force to tissue depth [17].

The final parameter that varies in the model geometries is tissue thickness. In humans, the myocardium thickness in the posterior wall of left atrium is not uniform and varies from patient to patient. Therefore, it would be expected to vary in models as well. Many studies use very thick and unrealistic myocardial thicknesses to ensure that the bottom boundary condition does not affect the lesion size. For example, one recent study uses 20 mm thickness [4] in place of modelling multiple layers of tissue which would complicate the model. Some studies do include other layers, such as fat and esophageal layers, instead of using an unrealistically thick myocardium thickness [5,18].

### B. Governing Equations

The governing equations are consistent across all of the literature. The Bioheat equation is used in conjunction with Laplace's equation to take into account joule heating in the tissue and to give accurate temperature distributions. Fluid flow (if included) is governed by the continuity equation and the laminar, incompressible Navier-Stokes equations. For several studies, the vaporization of tissue is included. To account for the vaporization, the latent heat is included as the latent heat of water and there are different properties for the liquid and gaseous forms of tissue. It has been noted by some researchers that this method is inaccurate and should not be used. Instead, the focus should be on keeping the temperatures below the vaporization temperature of water, 100°C [19]. For most studies heat loss caused by blood perfusion and the metabolic heat generation terms in the Bioheat equation are negligible and, hence, neglected [7].

### C. Catheter Boundary Conditions

The boundary conditions on the tip of the electrode vary in the present models. The types of boundary conditions used are: constant temperature, constant temperature through voltage regulation, constant voltage, constant power through voltage regulation, and constant maximum tissue temperature through voltage regulation. In addition to these five boundary conditions, the catheter may be modeled with or without saline irrigation (depending on the type of catheter modelled). The irrigated catheters slightly change the geometry of the model but leave most parameters and boundary conditions unchanged as they simply add another inlet to the blood flow. Irrigated catheters are more clinically relevant at the present time [4].

Applying a constant voltage boundary condition to model a constant power ablation is shown to be an acceptable approximation with a relatively high accuracy. However, if constant voltage is used, then other parameters are in a state of flux which affects how the lesion develops over time. For this reason, a constant voltage boundary condition is not always used. The next most common boundary condition is using voltage regulation to hold either temperature or power constant. In order to model these boundary conditions, the voltage applied at the active electrode must be regulated through a control feedback loop. These changing boundary conditions are implemented through the use of software modifications such as MATLAB integration into the program ANSYS, user defined functions (udfs) within the program, or other program macros [4].

### D. Modelling The Effect of Blood

Most of the modelling research uses experimental measurement to determine the convective coefficient in the myocardium. Then, they apply a convective boundary condition to the tissue surface rather than modelling actual blood flow. The main methods to model blood flow in RFA include: using convection coefficients excluding the blood from the model; using convective coefficients with the blood included in the model (stagnant); the same as the previous method but with temperature-dependent blood conductivity; and, finally, modelling the blood flow itself. Interestingly, no study has yet included pulsating or turbulent blood flow (or both) in their model. The studies that use convection coefficients do take into account these parameters, often averaging the high and low turbulent blood flow conditions [8]. Most papers use a similar method. In future work, it is recommended to investigate a more accurate representation of the actual blood flow in the heart by studying the effects of pulsatile flow and turbulence.

### E. Other Boundary Conditions

For all models, the boundary conditions other than the electrode and blood boundary condition are the same. There is a specified temperature at all surfaces far away from the electrode, which varies from 37.5°C to 36°C. There, zero electrical flux is specified on all the walls and surfaces. The bottom surface is the only one that is different with a specified temperature and a specified voltage of 0 V to mimic the effect of the grounding pad. All of the studies for RFA in the heart that were reviewed here, used these boundary conditions except for one, which studied the effect of using a cooling balloon in the esophagus to prevent thermal injury [5]. This study applied a convective boundary condition to the bottom face (where the esophagus is located) rather than a prescribed temperature. This is the only study of that kind and is a potential method of preventing atrial-esophageal fistula. The aspect of esophageal cooling is one that needs further investigation. Overall, one may trust that these standard boundary conditions are justified in their use and produce accurate lesion sizes.

### F. Material Properties

The material properties, like density, viscosity and thermal conductivity, used in these models represent one of the greatest differences between the different models [20]. Tissue properties are very variable and inconsistent and so any material property

introduces error in the results. There have been several studies examining the effect of material properties on the results obtained [21-25], including changing thermal and electrical conductivity as well as determining how those conductivities should be changed as temperature changes in the model. Material properties, such as myocardial density, and blood properties, including density, viscosity, electrical conductivity, and thermal conductivity, are important, but they can be taken from previous studies or reliable sources as they do not greatly affect lesion size [22]. Some models have also included tissue vaporization while others have ignored it, or limited the tissue temperatures to below the vaporization point of 100°C. In two recent cardiac studies [4,26] the vaporization is taken into account with the following equation.

$$\frac{\partial(\rho_h)}{\partial t} = \frac{\partial T}{\partial t} \cdot \begin{cases} \rho_l c_l, & 0 \leq T \leq 99^\circ\text{C} \\ H_{fg} C, & 99 < T \leq 100^\circ\text{C} \\ \rho_g c_g, & T > 100^\circ\text{C} \end{cases} \quad (1)$$

$\rho_i$  = density of tissue phase ( $\text{kgm}^{-3}$ )

$c_i$  = specific heat ( $\text{Jkg}^{-1}\text{K}^{-1}$ )

$H_{fg}$  = latent heat ( $\text{Jkg}^{-1}$ )

C = tissue water content (%)

i = l corresponds to the liquid tissue phase

i = g corresponds to the gaseous tissue phase

It was found that the equations chosen to model material properties do not affect lesion diameter significantly [22]. To achieve accurate results the thermal and electrical tissue conductivities must be temperature-dependent, following one of the equations in the in Table 1 in [22]. The tissue properties vary across studies, but the effect on the results appears to be minimal so long as the tissue properties are made temperature-dependent in some way [22]. A 3.5% maximum difference in final lesion size was found between identical models with different material properties [22].

#### G. Lesion Size Measurement

In the beginning of RFA modelling the Arrhenius thermal damage equation was used to calculate the lesion size [7,9,27]. This equation suggests, for heart tissue, a thermal damage temperature of greater than 48.9°C [28]. After this general temperature limit had been established and confirmed [7,9,27], most papers merely used an arbitrarily selected isotherm to measure lesion size because of its simplicity. The majority of studies use a 50°C isotherm. The 50°C isotherm has been tested many times and is shown to be a consistent and accurate measurement for the lesion size created.

Having reviewed the literature concerning RFA modelling, the present work seeks to use the best available strategy to examine the influence of key parameters on the performance of a non-irrigated RFA catheter and investigate the effect of esophageal cooling.

### III. NON-IRRIGATED CATHETER ABLATION MODEL

In the present work an improved model was created to examine effect of esophageal cooling. The geometry of González-Suárez and Berjano [26] was replicated, the same governing equations and material properties were used and, at first, all the same boundary conditions were implemented so

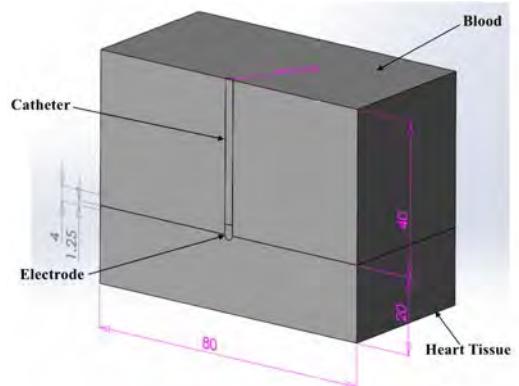

Figure 1. Geometry for non-irrigated catheter model. Dimension not shown is the depth which is 40 mm.

that the present model could be validated. Following this the effect of convective cooling was studied on the bottom face. This study was then repeated with subsequent models that had the same geometry as the first, except for a smaller myocardial thickness to better represent the real-life situation.

#### A. Geometry

The geometry, shown in Fig. 1, consists of a 7 Fr – 4 mm (d = 2.33 mm, L = 4 mm) cylindrical catheter with a hemispherical tip embedded 1.25 mm into myocardial tissue whose thickness, H, was varied from 20 mm to 10 mm and then 5 mm. The overall domain of the model was the same as González-Suárez and Berjano's [26] who obtained those dimensions by means of a convergence test. Symmetry was used to reduce computation time. The model by González-Suárez and Berjano [26] included a thermistor embedded in the catheter to measure the overall temperature of the catheter and regulate the voltage to maintain constant temperature, but this was excluded from the present model as it was an unnecessary complication.

#### B. Governing Equations and Material Properties

The governing equations for this model are as discussed above and the material properties in Table I were used. For this tissue,  $H_{fg} = 2.162 \text{ Jm}^{-3}$ , C = 75%, and  $\rho_l = 958 \text{ kgm}^{-3}$  (at 100°C) [26], so the vaporization latent heat is 2257  $\text{kJkg}^{-1}$ . The equations were implemented in ANSYS Fluent v18.2 by udfs. The viscosity of blood was set to  $0.0021 \text{ kgm}^{-1}\text{s}^{-1}$ .

TABLE I. MATERIAL PROPERTIES USED IN NON-IRRIGATED MODEL

	Density, $\rho$ ( $\text{kgm}^{-3}$ )	Specific Heat, $c$ ( $\text{Jkg}^{-1}\text{K}^{-1}$ )	Thermal Cond., $k$ ( $\text{Wm}^{-1}\text{K}^{-1}$ )	Elec. Cond., $\sigma$ ( $\text{Sm}^{-1}$ )
Catheter	70	1045	0.026	$1 \times 10^{-5}$
Electrode	21500	132	71	$4.6 \times 10^6$
Blood	1000	4180	0.541	0.667
Tissue	$l - 1060$ $g - 370.44$	$l - 3111$ $g - 2155.92$	See Equation 2	See Equation 3

$$k(T) = \begin{cases} 0.531 + 0.0012(T - 37), & 0 < T \leq 100^\circ\text{C} \\ 0.606, & T > 100^\circ\text{C} \end{cases} \quad (2)$$

$$\sigma(T) = \begin{cases} 0.541e^{0.015(T-37)}, & 0 < T \leq 100^\circ\text{C} \\ 1.3 - 0.274(T - 100), & 100 < T \leq 105^\circ\text{C} \\ 1.371 \times 10^{-4}, & T > 105^\circ\text{C} \end{cases} \quad (3)$$

TABLE II. COMPARISON OF RESULTS OBTAINED WITH VARIOUS BOTTOM BOUNDARY CONDITIONS

Boundary Condition On Bottom Face	Lesion Depth (mm)	Lesion Width (mm)	Max Blood Temp (°C)	Max Tissue Temp (°C)	Bottom Boundary Temp (°C)
<b>20 mm Thick Tissue</b>					
$T = 37^\circ\text{C}$	7.53	11.18	65.65	99.85	37.00
$T = 15^\circ\text{C}, h=1000 \text{ Wm}^{-2}\text{K}^{-1}$	7.47	11.10	68.55	99.95	17.37

$T = -5^\circ\text{C}, h=20,000 \text{ Wm}^{-2}\text{K}^{-1}$	3.91	7.23	55.95	98.25	-2.04

TABLE III. COMPARING PRESENT RESULTS TO PREVIOUS EXPERIMENTAL WORK BY GONZÁLEZ-SUÁREZ AND BERJANO [26], 20 MM THICK TISSUE

	Previous Work [26]	Present Results	Percent Difference (%)
Depth (mm)	7.53	7.53	0
Width (mm)	11.92	11.18	6.41
$T_{\max, \text{tissue}} (\text{°C})$	102.4	99.85	2.52
$T_{\max, \text{blood}} (\text{°C})$	79.9	65.65	19.58

### C. Boundary Conditions

The voltage boundary condition on the catheter was set to 25 V for a RF duration of 60 s. The bottom face had a specified voltage of 0 V. All remaining walls and interfaces were specified with zero electrical flux. Thermal boundary conditions were only specified on outside walls and on the bottom face. All outside walls were set at  $37^\circ\text{C}$ . The bottom face was tested with a variety of boundary conditions including a constant temperature of  $37^\circ\text{C}$  and then various convective boundary conditions. All walls for the fluid domain were no-slip and coupled with the adjoining material. The blood had a perpendicular laminar flow with an inlet velocity of  $8.5 \text{ cm}\cdot\text{s}^{-1}$ , and a zero-pressure outlet.

### D. Results

Mesh convergence and time convergence were performed until the results were independent of both. The final step size was 0.05 s for 60 s and the final mesh had 419,362 elements with maximum and minimum face sizes of 1 mm and  $4.99 \times 10^{-2}$  mm, respectively. The lesion size was calculated using the  $50^\circ\text{C}$  isotherm for all models. Lesion depth is the maximum depth from the top of the tissue reached by the lesion and lesion width is the width of the isotherm at its widest point. All studies were run for sixty seconds. The key results can be seen in Table II and Fig. 2.

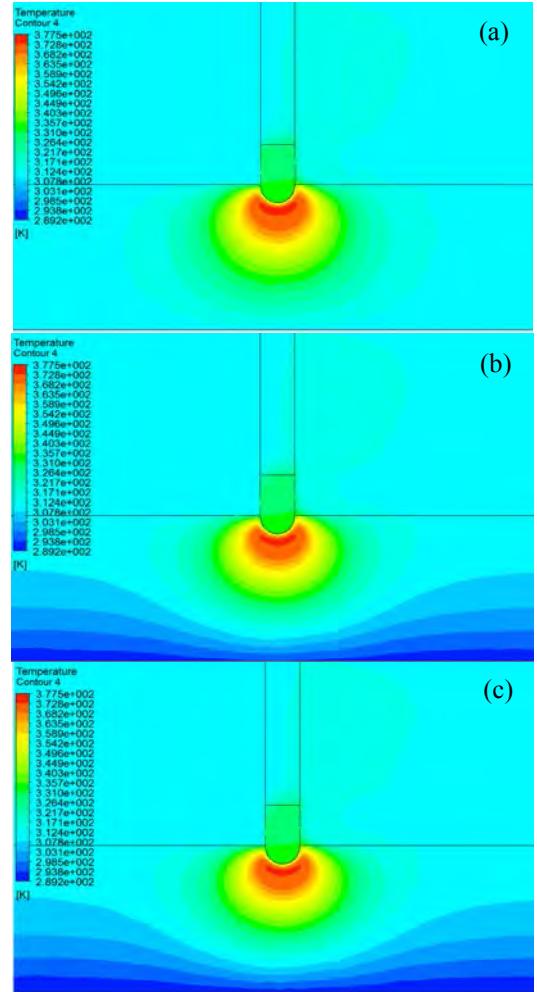

Figure 2. Results for 10 mm thick tissue. (a)  $T = 37^\circ\text{C}$  (b)  $T = 15^\circ\text{C}, h = 1000 \text{ Wm}^{-2}\text{K}^{-1}$  (c)  $T = 15^\circ\text{C}, h = 2000 \text{ Wm}^{-2}\text{K}^{-1}$

For the 20 mm thick tissue the cooling had very little impact on lesion size due to the thickness of the tissue. The  $37^\circ\text{C}$  case was compared with that in González-Suárez and Berjano [26] for validation purposes in Table III. Maximal blood temperature is the only value that is significantly different, which is most likely due to a coarser mesh in the blood domain in the present model. The 10 mm thick tissue allowed for cooling to be much more effective in reducing lesion size. The lesion depth was reduced by a maximum of 18.4%, the maximum tissue temperature was reduced by about 3°C, and the bottom boundary temperature was reduced by 69.4%. The 5 mm tissue was affected the most by cooling as the lesion size was decreased by as much as 16.4%.

### IV. CONCLUSIONS AND SUMMARY

Previous models are, for the most part, experimentally validated; however, they do have some shortcomings. Most notably, the force applied to the catheter and the depth are only related in one published study. Another shortcoming is the lack of accurate blood flow modelling. To obtain an accurate representation of the real system, blood flow should be modelled as pulsatile and turbulent, and not by constant laminar flow or a convection coefficient.

The computational results match previous data which have been verified using experimental data. The 5 mm thickness is representative of the total distance from catheter tip to inner esophageal wall [18] meaning the esophagus tissue and heart tissue layers were combined in this model. In future studies these two layers could be separated and have distinct properties as has been done in previous models [5]. The non-irrigated model demonstrates that regardless of tissue thickness cooling the esophageal wall has less than a 19% effect on the depth of the lesion, and as much as a 13.4% lowering of the temperature on the esophageal wall. This means that cooling on the esophageal wall can be used to effectively lower the damage to the esophagus without adversely affecting the procedure when a non-irrigated catheter is used. This model has temperatures that are too cool and would damage the esophagus, but the temperature of the cooling fluid or the convection coefficient can be easily changed. These results are in agreement with Berjano and Hornero [5], who also examined the effect of esophageal cooling. The present study demonstrates that cooling can be effectively added to the esophagus without comprising the RFA procedure.

#### ACKNOWLEDGMENT

This work was funded by Baylis Medical, the Natural Sciences and Engineering Research Council of Canada and MITACS. The guidance and support of Gareth Davies and Amanda Hartley of Baylis Medical is greatly appreciated.

**Abstract**— It is easier to numerically model the machining process assuming the orthogonal cutting conditions, however the realistic industrial machining arrangements are closer to the oblique machining conditions. In oblique machining the cutting edge is located at a certain inclination angle resulting in a third radial force component. The inclination angle in oblique machining arrangement has a controlling influence over the chip curling and resulting plastic deformation is more complex as compared to the orthogonal machining arrangements. The current study has incorporated a three-dimensional finite element model to predict the machining of Inconel 718 using SIALON cutting tool materials under oblique machining conditions. The study incorporates different cutting edge-based inclination angles and resulting simulated machining performance has been reported. The machining performance has been evaluated by observing the simulated cutting forces, cutting temperature, and chip curling.

## I. INTRODUCTION

As compared to the orthogonal machining setup, oblique machining provides more realistic cutting scenario with respect to the practical application in the metal cutting sector. The predictions about the machining performance under oblique machining arrangement is more reliable and closer to the practical application. Machining performance of a cutting process can be predicted using either analytical or numerical approaches. Numerical approaches are easier to deal with complex geometries and boundary conditions but at the expense of higher computational cost and time. When it comes to the oblique machining performance prediction most of the literature is based on the analytical modelling and very limited studies are available using numerical modeling approaches especially for difficult-to-machine materials such as Inconel 718.

Several researchers have focused their research work to utilize numerical modeling techniques for the prediction of different machining performance indicators. Shaw et al. [1] initially introduced the concept about the normal rake angle. The concept was further evolved in the work conducted by

researchers such as Stabler [2,3], Brown and Armarego [4], and Russell and Brown [5] etc. Luk [6] investigated the chip flow under oblique machining setup. The study was conducted using analytical solution method considering mechanistic approach. Lin et al. [7] explored the orthogonal plane strain machining theory to predict the cutting forces under oblique machining conditions. The study revealed that cutting forces can be predicted using the combined knowledge of cutting parameters, materials flow stress and thermal behavior. Arsecularatne et al. [8] investigated the tool life under oblique cutting. The study utilized the theory of tool life using cutting temperature and investigated the tool life for oblique conditions. The experimental validation of predicted results was performed using the plain carbon steel with different tool geometries and cutting conditions.

Lazoglu and Islam [9] utilized finite difference based numerical method to explore the cutting temperature related 3D simulations under oblique cutting arrangements. The predicted results were found to be in good agreement with the experimental findings. Komanduri et al. [10] investigated the influence of both normal rake and inclination angles for the oblique machining of single crystal aluminum using 3D molecular dynamics simulations. The study measured cutting force components, cutting force ratio and specific energy. The study revealed that normal rake angle has controlling influence over the cutting force components and specific cutting energy. Feng and Zang [11] studied oblique machining process using a thermo-elastic-plastic coupled finite element (FE) model. The study was conducted using high speed steel (H11) and ANSI1045 steel as cutting tool and workpiece materials respectively. The study monitored cutting forces, stresses and cutting temperatures at the cutting interface and chips. The study revealed that role of inclination angle in decreasing cutting forces is very minor.

Song et al. [12] developed a model to predict the cutting forces using the vector transformation method and basic mechanistic approach towards the friction at tool – chip interface. The study considered that friction at interface is same in the orthogonal cutting as well as with different inclination angles. The simulated results were found to be in good agreement with experimental data. Grzesik and Zak [13] investigated the surface integrity of different iron-based

materials such as carbon, low-alloyed, stainless steel and spheroidal iron under oblique machining conditions. The study has incorporated carbide and Al<sub>2</sub>O<sub>3</sub>–TiC ceramic cutting tools using inclination angle of 55°. The study revealed the potential of oblique machining to replace conventional finish turning and grinding operations as at higher feed rates oblique turning provides higher surface finish. The study also revealed that maximum value of compressive stress was produced closer to the machined surface, and sensitive to the strain hardening exponent of the workpiece material.

Moufki et al. [14] conducted a study to develop a thermomechanical modelling approach for the oblique machining and simulated results were validated experimentally as well. The study utilized an analytical method based on materials strain rate sensitivity, strain hardening and thermal softening. The model provided predictions for the cutting forces and chip flow. The model was developed for the continuous chip conditions. The model provided predictions in close agreement with the experimental readings. Abdellaoui and Bouzid [15] developed a thermo-mechanical methodology to model the oblique machining. The study developed a computational algorithm and controlled the oblique machining parameters using a ratio of tool-chip contact length and chip ratio. The predicted results were found in good agreement with the experimental findings.

Grzesik and Zak [16] in another study performed friction quantification under oblique machining arrangements using CBN chamfered cutting tools. The study developed an analytical-empirical model of friction. The study incorporated the effect of equivalent rake face and associated equivalent rake angle. The study was conducted on spheroidal cast iron. The study revealed that at large negative rake angles, friction was highly influenced by the inclination angles. Llanos et al. [17] conducted a study where machining performance of AISI-4140 steel was investigated using uncoated cemented carbide cutting tools. The study utilized finite element (FE) based model using Arbitrary Lagrangian Eulerian (ALE) formulation. The study revealed that accurate chip formation is linked with the proper identification of frictional behavior at the tool - chip interface. Pawade et al. [18] conducted an analytical study to predict the specific shear energy for Inconel 718 under oblique machining conditions. The study incorporated the Inconel 718 material behavior using Johnson-Cook (JC) material model. JC model can incorporate strain hardening, strain rate sensitivity and thermal softening. The study revealed that shear band spacing linearly increases by increasing the feed rate. The specific shear energy model also revealed that it is more sensitive to thermal softening, strain hardening and shearing strain. The predictions were found in very good agreement with the experimental findings.

It is well understood by the metal cutting community that oblique machining arrangements are more practical than the orthogonal cutting arrangements. However, it has been observed that there is very limited finite element based numerical studies available in literature when comes to the oblique machining. It is even more rare to find in literature that such numerical models are developed for difficult-to-cut materials using modern cutting tool materials. The aim of this study is to utilize a finite element (FE) based numerical

approach to predict the machining performance of Inconel 718 under oblique machining conditions.

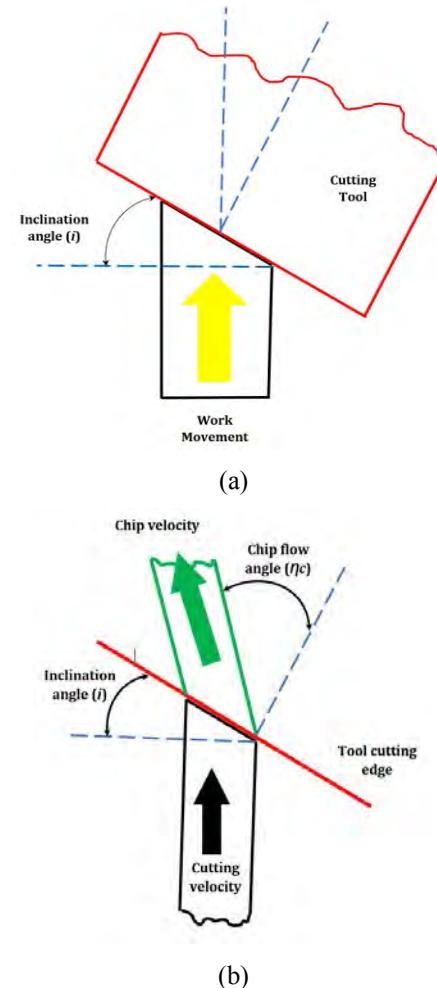

Figure 1. Schematic illustration of oblique machining (a) Inclination angle ( $i$ ), and (b) Chip flow angle ( $\eta_c$ ) (redrawn from [10], [19])

## II. OBLIQUE MACHINING VIEW

In literature it is very frequent to find the numerical models for orthogonal cutting (2D) arrangements. Oblique cutting (3D) is different to orthogonal cutting due to the presence of inclination angle ( $i$ ) as shown in Fig. 1a and 1b.

Inclination angle ( $i$ ) is the angle that tool cutting edge makes with the normal to the cutting velocity vector. Due to the presence of inclination angle, chip flow is also at an angle other than the right angle as seen in orthogonal cutting case.

## III. FINITE ELEMENT MODELING

Finite element (FE) model was prepared by using a customized software for machining application known as Thirdwave AdvantEdge [20]. In Thirdwave AdvantEdge software, chip formation is simulated by utilizing dynamic explicit lagrangian formulation. The software can execute coupled thermo-mechanical transient analysis and adaptive remeshing techniques. The software was first presented by Marusich and Ortiz [21]. Thirdwave AdvantEdge has built in

material library for the cutting tools and workpieces. Fig. 2 represents the schematic illustration from Thirdwave AdvantEdge.

To utilize different engineering materials for different applications, there is a built-in material library in the software package. These material models can mimic the materials behavior by simulating flow stresses, strain rate sensitivity and temperature-based effects (thermal softening). The current study was based on the oblique machining (3D) setup, where cutting tool material was selected to be SIALON and workpiece material was selected to be Inconel 718. By default, AdvantEdge software utilizes power law to model the constitutive behavior of the Inconel 718. The constitutive power law can incorporate the effects related to strain hardening, strain rate sensitivity and thermal softening. The power law is mentioned in Eq. 1.

$$\sigma(\varepsilon^P, \dot{\varepsilon}, T) = g(\varepsilon^P) \Gamma(\dot{\varepsilon}) \Theta(T) \quad (1)$$

In Eq. 1,  $g(\varepsilon^P)$ ,  $\Gamma(\dot{\varepsilon})$  and  $\Theta(T)$  represent strain hardening, strain rate sensitivity and thermal softening respectively, and the functions are further elaborated in equations 2, 3 and 4 [22].

$$(\varepsilon^P) = \sigma_0 \left( 1 + \frac{\varepsilon^P}{\varepsilon_0^P} \right)^{1/n} \quad (2)$$

$$\Gamma(\dot{\varepsilon}) = \sigma_0 \left( 1 + \frac{\dot{\varepsilon}}{\dot{\varepsilon}_0} \right)^{1/m} \quad (3)$$

$$\Theta(T) = C_0 + C_1 T^1 + \dots + C_5 T^5 \quad (4)$$

In Eqs. 2, 3 and 4,  $\sigma_0$  represents initial yield stress,  $\varepsilon^P$  represents plastic strain,  $\varepsilon_0^P$  represents reference plastic strain,  $\dot{\varepsilon}$  represents strain rate,  $\dot{\varepsilon}_0$  is reference plastic strain rate, C0-C5 represents coefficients for the polynomial fit, T is temperature, n represents strain hardening exponent, and m represents strain rate sensitivity coefficient [20].

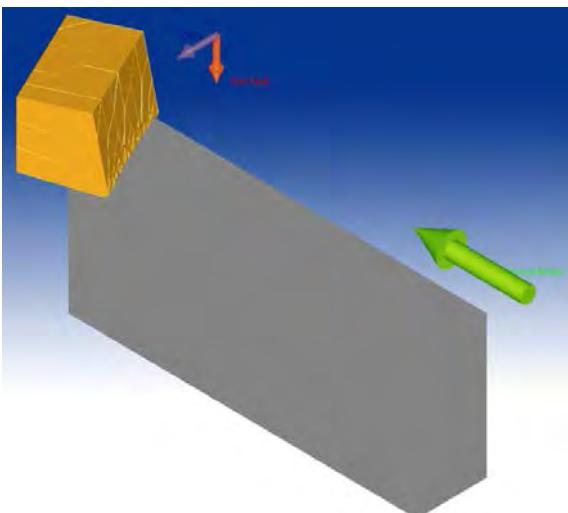

Figure 2. Schematic illustration of oblique machining in Thirdwave AdvantEdge

TABLE I. PARAMETERS USED FOR NUMERICAL SIMULATIONS.

Simulation Parameters	Values
Cutting Tools	SAILON
Workpiece Materials	Inconel 718
Normal Rake angle (°)	10
Cutting Speed (m/ min)	300
Feed rate (mm/ rev)	0.15
Depth of Cut (mm)	1
Length of Cut (mm)	3
Friction Co-efficient	0.5
Lead angle (°)	0
Initial Temperature (°)	20
Relief Angle (°)	5
Inclination Angle (°)	0, 5, 10, 15, 20, 25
Cutting Environment	Dry

Like other FE codes, AdvantEdge software employs a damage model to integrate damage into the material model. The damage function D is stated in Eq. 5 [20].

$$D = \sum_i \frac{\Delta \varepsilon_i^p}{\varepsilon_{f_i}^p} \quad (5)$$

To have a precise cutting simulation, it is very important that proper friction should be modelled at the cutting tool-chip interface. In Thirdwave AdvantEdge friction at tool-chip interface is simulated using Coulomb law as represented in the Eq. 6 [20]. Coulomb law associates shear stresses by taking them proportional to the normal stresses and constant of proportionality is frictional coefficient ( $\mu$ ).

$$\tau = \mu \sigma_n \quad (6)$$

Selection of frictional constant is a difficult task because of complex sliding behavior at tool-chip interface. It is also reported that chip hardness is different and generally harder than the workpiece hardness, and hardness variation can lead to variation in friction coefficient [23,24]. Table 1 provides the information about the cutting parameters utilized for numerical simulations. In the current study the numerical simulations were limited to five different values of inclination angles ranging from 0 - 25°. The 0° inclination angle leads to the orthogonal setup and acts like a reference for other values of inclination angles.

#### IV. SIMULATED RESULTS AND DISCUSSION

The 3D simulated outcomes were studied for the different machining performance indicators such as cutting, thrust and oblique force components, cutting temperature and chip flow.

##### A. Simulated Cutting Forces

Cutting force components are very important machining performance indicators. These components have very significant role as they reveal the power consumption and vibrational effects in the machining process. They also play an important role towards the machine tool construction and fixture designing/ requirements. In this sub-section, simulated cutting forces at different inclination angles ranging from 0° – 25° were compared. The sample cutting force signals from the Thirdwave AdvantEdge softwares have been reported in Figures 3a and 3b.

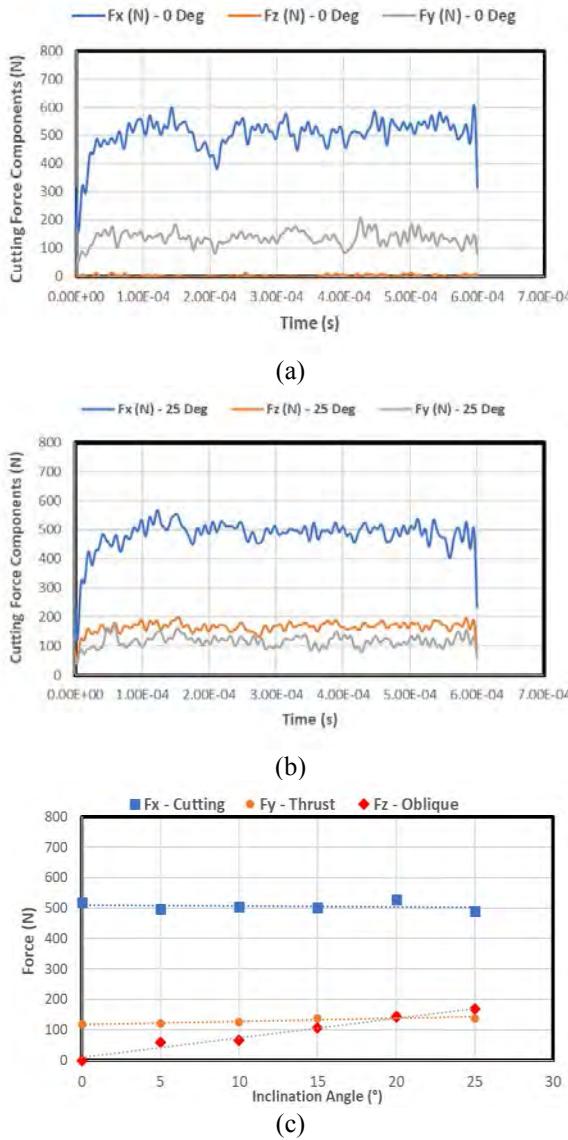

Figure 3. Simulated cutting force components (a) 0° Inclination Angle, (b) 25° Inclination Angle, (c) Simulated average cutting force components, 0° - 25° inclination angles

The cutting force trends for all three cutting force components at all inclination angles have been reported in Figure 3c. It can be observed that minor fluctuation has been reported for the cutting and thrust force components. The Fz-oblique force component was majorly affected by the inclination angle.

#### B. Simulated Cutting Temperature

Cutting temperature has been attributed as one of the major machining performance indicators in the metal cutting sector. It is the deciding factor towards the cutting tool life, and many wear mechanisms such as diffusion and adhesion are linked with the cutting temperature. The sample cutting temperature signals from the Thirdwave AdvantEdge softwares have been reported in Figures 4a and 4b.

The average cutting temperature trends for all inclination angles has been reported in Figure 4c. The trend reveals that cutting temperature decreases slightly by increasing inclination angle.

#### C. Simulated Chip Flow

Simulated chip flow is another important machining parameter that has an important role in overall machining performance. Simulated results of chip flow for different inclination angles 0°-25° have been reported in Figures 5 and 6. Simulated chip flow observations revealed that increasing the inclination angles results in increasing the chip flow angle (labeled c) as shown in Figure 6.

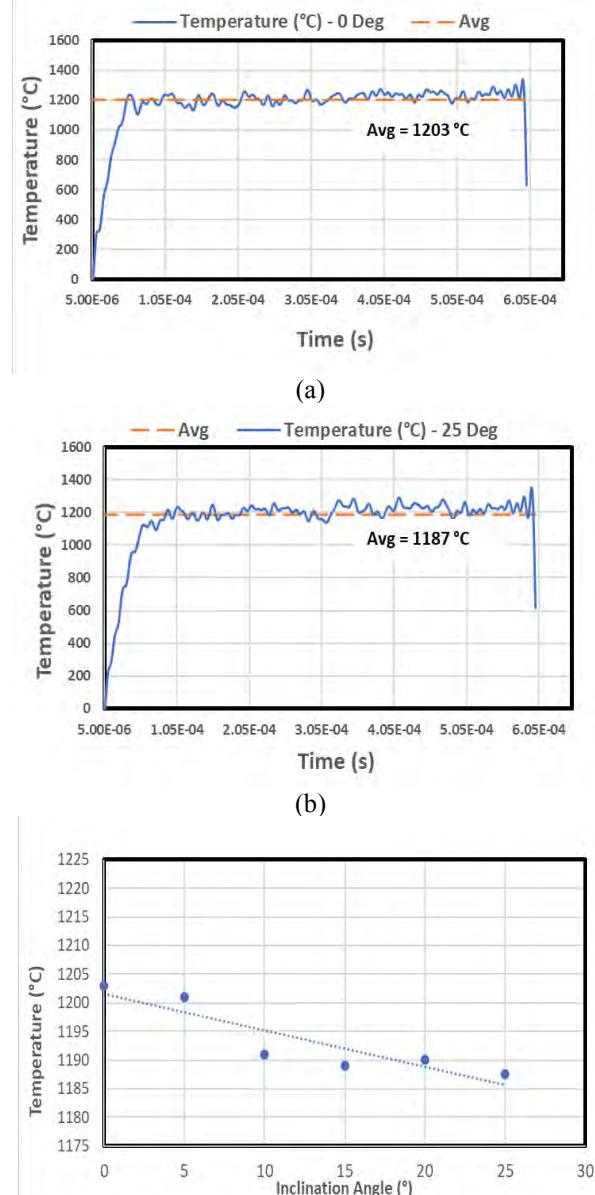

Figure 4. Simulated cutting temperatures (a) 0° Inclination Angle, (b) 25° Inclination Angle, (c) Simulated average cutting temperatures 0°-25° inclination angles

## V. CONCLUSIONS

The conclusions drawn from this study have been reported as under.

Inclination angle has negligible influence over the cutting force component which represents that it has negligible role towards power consumption. Thrust force component was found little sensitive to the inclination angle. Oblique force component was highly influenced by the inclination angle. The results were found in agreement with experimental and analytical studies present in the available literature. The cutting temperature slightly decreased by the introduction of inclination angles.

**Abstract**—A green metallic ink is developed for 3D printing of metallic structures featuring high mechanical and electrical performances. The metallic ink consists of steel micro powders and a water-based chitosan/acetic acid polymer solution which replaces the previously used toxic polylactic acid (PLA)/dichloromethane (DCM) polymer solution. The optimized ink is printed at room temperature to build a metal/polymer hybrid structure. While printing, a fan is used to blow air over the ink filament upon extrusion to accelerate the solvent evaporation and shorten the solidification time, which significantly reduces the sagging and deformation. After a drying period at ambient conditions, the as-printed structure is then thermally treated using a furnace. The polymer binder is decomposed and the metal powders are sintered, resulting in a strong metallic structure. Melted copper is infiltrated into the sintered structure to achieve a fully dense metal/metal hybrid structure. The sintered structure exhibits high stiffness (205 GPa), electrical conductivity ( $9 \times 10^5$  S/m) and low filament porosity (7%).

**Keywords:** 3D printing, metallic ink, environment-friendly, metallic structures, secondary metal infiltration

## I. INTRODUCTION

Recently, 3D printing approaches have been developed to fabricate diverse metallic structures.<sup>[1-3]</sup> They offer many advantages such as more design flexibility, time efficient and less material waste over traditional metal manufacturing methods (e.g., machining). 3D printed metallic structures are applied in many fields such as medical<sup>[4-5]</sup>, energy storage<sup>[6-7]</sup>, sensors<sup>[8-9]</sup>, and microelectronics<sup>[10-11]</sup>. Powder-bed approaches like selective laser sintering/melting (SLS/SLM) are mature, commercialized and progressively more widely used. These approaches are based on fine metal micro powders that are evenly spread out in a powder bed. A high-intensity laser is used to selectively fuse them to build layer-by-layer 3D structures.<sup>[12]</sup> However, the intense laser system is very costly and is a potential safety issue for the operator. In addition, the repeated scanning of the laser beam results in excessive material powder oxidation, loss of alloying elements and dramatical temperature change (which causes residual stresses and defects).<sup>[13-14]</sup>

To overcome these shortcomings, solvent-cast 3D printing (SC-3DP) is proposed, which combines room-temperature 3D printing and subsequent thermal treatments. This extrusion-based printing method employs a viscous metallic suspension consisting of metal powders, polymer binder and volatile solvent, referred as the ink.<sup>[15]</sup> Under applied pressure, the metallic ink is extruded from a fine nozzle and deposited on a substrate in a layer-by-layer fashion. Post the filament extrusion, the volatile solvent quickly evaporates and the ink turns into solid state. The as-printed object is a metal/polymer hybrid structure which is then thermally treated to burn the polymer binder and to sinter the metal powders, resulting in a fully metallic structure.<sup>[15]</sup> Many researchers adapted this approach to fabricate various 3D metallic structures featuring complex 3D geometries and high mechanical and electrical performances.<sup>[15-17]</sup> Although this type of process is simple and practical, it generally uses a volatile and toxic solvent (e.g., dichloromethane (DCM)), as the polymer binder solvent. We developed a nontoxic metallic ink consisting of chitosan, acetic acid, deionized water and metal powders. Chitosan is a biocompatible polymer which is dissolved in acetic acid aqueous solution as a viscous hydrogel. The metal powders are evenly dispersed in the hydrogel, resulting in a metallic suspension (Fig. 1a). The metallic ink is extruded under a certain pressure and deposited on a substrate using a 3-axis deposition robot. After extrusion, the solvent (acetic acid and water) evaporates, whereas the chitosan and metal powders are left in the ink filament. Fig. 1b shows the schematic of subsequent thermal treatments. The as-printed sample is first sintered at 1165°C in order to thermally decompose the chitosan and sinter the metal powder. The sintered sample is a slightly porous metallic structure. To obtain a fully dense metallic structure, the sintered sample can be heated at 1120°C with a piece of copper placed on top of it. At this temperature, the melted copper can infiltrate the sintered structure to achieve a metal/metal hybrid structure.

## II. RESULTS AND DISCUSSION

Fig. 2 shows an optical image and SEM images of the as-printed, sintered and copper infiltrated scaffolds printed with a tapered nozzle (tip inner diameter = 50 µm) at a printing speed

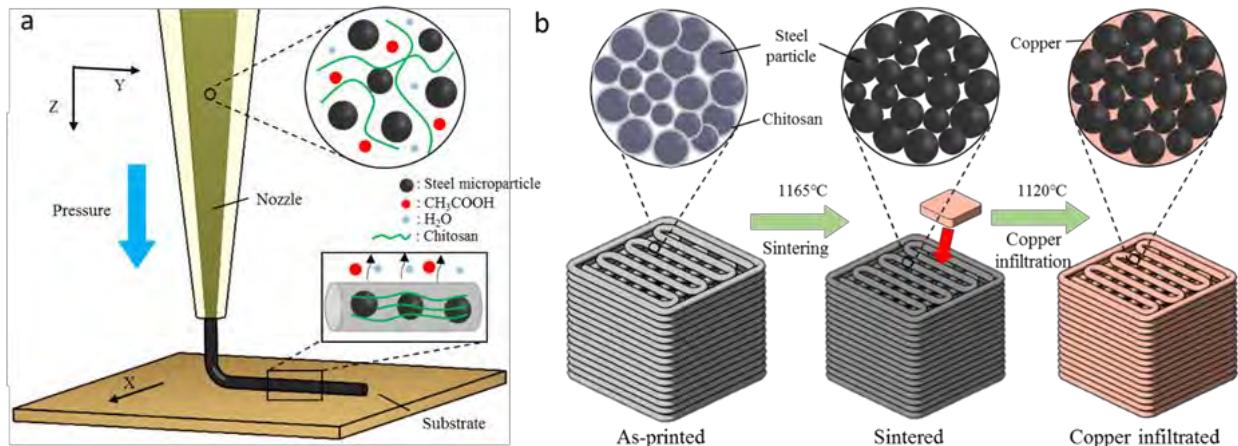

Fig. 1. Schematic of the fabrication process of a 3D metallic scaffold combining the following steps. (a) Solvent-cast 3D printing of a metallic ink consisting of steel microparticles and chitosan/acetic acid polymer solution. The metallic ink is loaded in a syringe and extruded through a micro nozzle under a certain pressure at room temperature. The solvent content evaporates upon extrusion assisted by an airflow. (b) Subsequent thermal treatments: the dried as-printed sample is thermally treated. The polymer is decomposed and the steel particles are sintered. Melted copper is infiltrated into the sintered structures to achieve a fully dense metallic structure.

of 7 mm/s. The three types of scaffolds are placed on a Canadian dollar. The as-printed scaffold has a dark gray color because the steel powders are covered by chitosan. After sintering, chitosan is removed and steel powders are brought closer. The sintered scaffold turns into light grey and shrinks in size. The copper infiltrated scaffold turns to brown red due to the appearance of copper. There are no significant shape distortion or oxidation occurred to the sintered and copper infiltrated scaffolds. The SEM images of the as-printed scaffold shows that steel powders are covered and bound by the polymer binder, chitosan (Fig. 2a). Before sintering, a debinding step is performed to remove the chitosan within the structure. After debinding, the structure integrity is held by the friction forces between the steel powders. The steel powders

are sintered at a temperature slightly lower than their melting point. The powders are connected through the appearance of necks between them. The size and amount of the necks increase gradually, which densifies the sintered structure and reduces the pores. In the sintered scaffold (Fig. 2b), the chitosan is completely removed and the steel powders are directly connected with each other through the necks. For the copper infiltration, a piece of copper is placed on top of the sintered structures inside the oven. The sample is heated at 1120 °C. This temperature is higher than the melting point of copper (1085 °C), but lower than the previously used sintering temperature. Mainly driven by capillary forces, the melted copper fills the pores within the filaments of the structure (Fig. 2c).

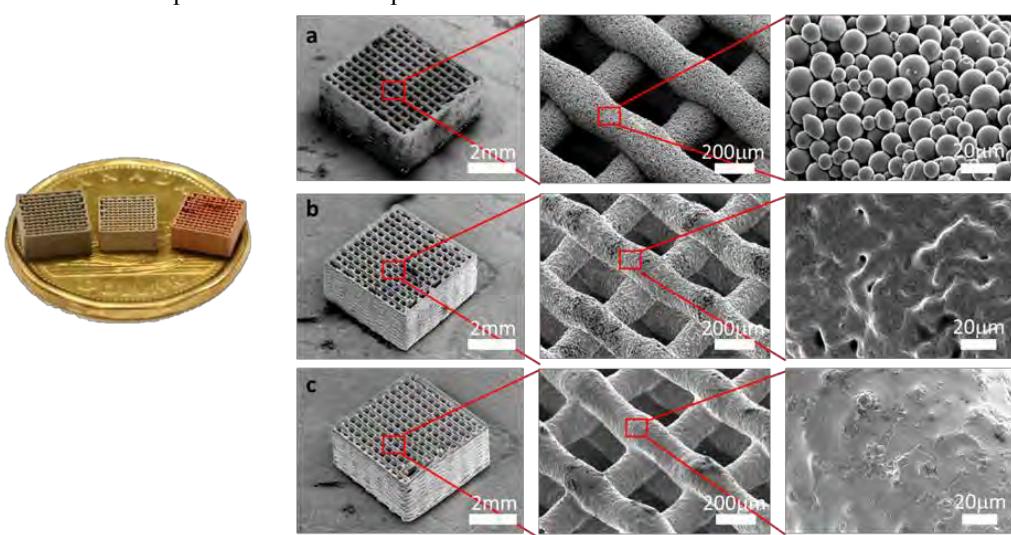

Fig. 2. Optical and SEM images of the scaffolds printed using a tapered nozzle (tip inner diameter = 50 μm) at a printing speed of 7 mm/s, (a) as-printed, (b) sintered, (c) copper infiltrated, and their close-up views.

The linear size reduction, filament porosity, electrical conductivity and mechanical properties of as-printed, sintered and copper infiltrated samples are characterized (Fig. 3). The samples have size variations in every stage compared to the designed size. It is caused by the swelling upon extrusion, solvent evaporation, debinding, sintering and copper infiltration. The linear size reduction is studied and the result is shown in Fig. 3a. The extruded ink filament swells due to the pressure drop and then shrinks as a result of the solvent evaporation. The dried as-printed sample has similar size as the designed one (>1% linear expansion). After debinding and sintering, the sintered structure shrinks by around 12% compared to designed size. The copper infiltrated sample exhibits less size reduction (~ 9% linear reduction) than the sintered one. The filament porosity of sintered samples is around 7% (Fig. 3b). After copper infiltration, the majority of the pores are filled by melted copper. The filament porosity of

copper infiltrated samples is lower than 1%. The conductivity of sintered samples is around  $9 \times 10^5$  S/m, which is 64% of that of the bulk material (Fig. 3c). As copper is more conductive than steel, the copper infiltrated sample presents an even higher conductivity of  $\sim 1.3 \times 10^6$  S/m. Fully dense sintered and copper infiltrated tensile bars, of which the cross section of the narrow part is  $\approx 3.6 \times 1.6$  mm, are prepared for tensile test. It is carried out on a MTS Insight machine with a 50 kN load cell (MTS 569332-01) at a crosshead speed of 1 mm/min and using an extensometer (gauge length = 8 mm, MTS 632.26, C-20). Five specimens for each sample type are tested. The Young's modulus of sintered samples is around 205 GPa, which equals 95% of that of bulk material (Fig. 3d). After copper infiltration, the stiffness is slightly decreased, but the ductility and the ultimate tensile strength are significantly improved.

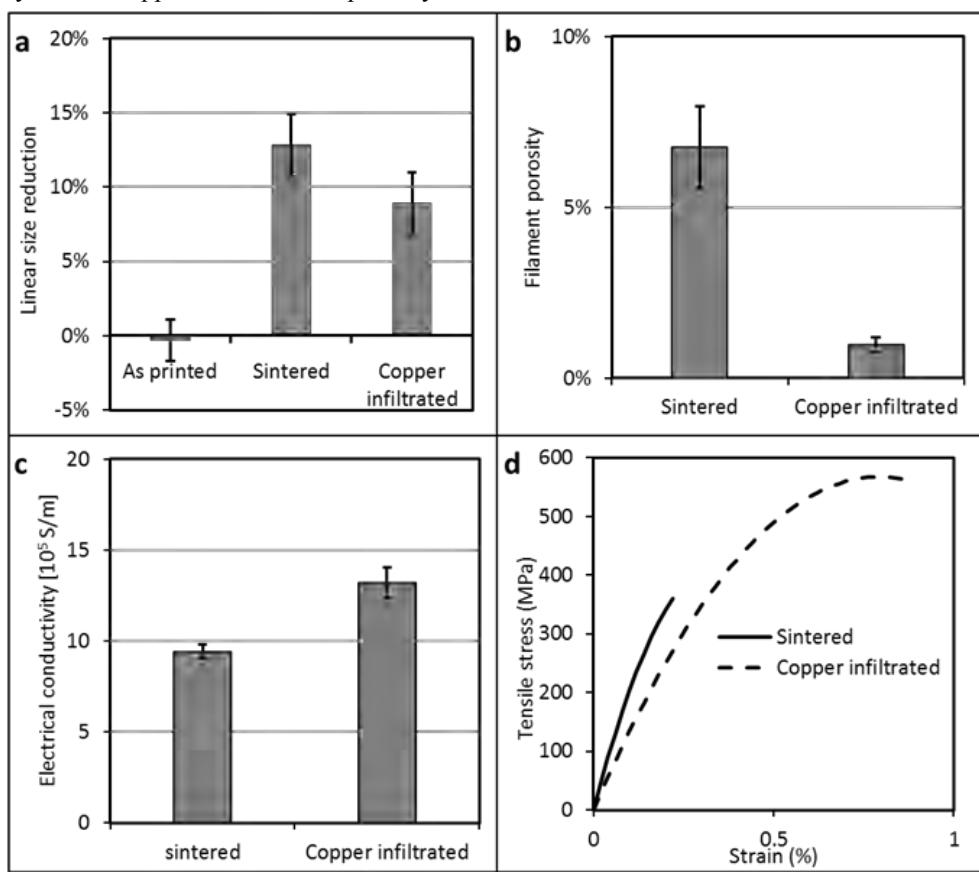

Fig. 3. (a) Linear size reduction, (b) filament porosity, (c) electrical conductivity and (d) mechanical properties of the as-printed, sintered and copper infiltrated samples

### III. CONCLUSION

We developed an environmental metallic ink for SC-3D printing of highly dense metallic structures. The ink contains metal powders, biocompatible polymer binder and a nontoxic volatile solvent. Metallic and metal/metal hybrid structures are fabricated by subsequent thermal treatments. The linear size reduction, filament porosity, electrical conductivity and

mechanical properties of the fabricated structures are characterized. The sintered structure has a Young's modulus close to that of the bulk material. The copper infiltrated structure exhibits less filament porosity, higher electrical conductivity and better ductility. The reported ink can replace the commonly used toxic ink to create 3D metallic structures for higher performances, lower environmental impact and more effective utilization of metallic materials.

**Abstract**— Crosslinked high-density polyethylene (XHDPE) is used to manufacture large and rigid products, such as fuel tanks, using a rotomolding process. Currently, defective and post-consumer parts are not recycled and sent to landfills. Hence, reuse of this material, through compression molding is the objective of this study. Thermal characterization indicated that the recycled XHDPE, in pulverized powder form, could melt although the heat of fusion was less than that of virgin material. However, while the virgin XHDPE could be compression molded at the melting temperature, the recycled XHDPE required higher temperature. The recycled XHDPE started to degrade at lower temperature than virgin XHDPE. Based on this data, optimal compression molding process conditions were chosen to prepare dense tensile test coupons. Both materials exhibited similar tensile properties demonstrating the recyclability of XHDPE.

**Rotomolding; compression molding; recycled XHDPE.**

## I. INTRODUCTION

Rotomolding is a common manufacturing process used to produce large and strong parts with a uniform thickness. One of the main plastics used is the High-Density polyethylene (HDPE). For some applications, the HDPE must be crosslinked to make the parts stronger and increase the barrier resistance

HDPE is a thermoplastic with a density of 0.940–0.965 g/cm<sup>3</sup>[1] and melting between 128°C and 138°C [2]. These properties are slightly changed after crosslinking. The crosslinking process results in bonding of the chain to itself and to other chains [3].

The crosslinked polyethylene is prepared using either a crosslinking agent (peroxide or silane) or electron beam radiation. During rotomolding, the crosslinking caused by the peroxide initiator increases the gel content (>80% as claimed by rotomolder using this materials), which reduces the flow of the material when heated above the melting temperature.

Due to this characteristic, XHDPE cannot be recycled and the industrial and post-consumer waste is currently sent to the landfill. Published studies on recycling this material include energy recovery [4], use of the ground material as a filler [5], degradation to low molecular weight polyethylene using solid

state shearing [6], molten state shearing [7], ultrasonic process [8], and supercritical process [9]. The degraded material was subsequently blended with other thermoplastic polymers to manufacture parts.

This research is focused on reuse of this material, without blends, through compression molding. The thermal behavior of the recycled XHDPE is characterized and compared with the virgin XHDPE to understand the issues in reusing this material. Based on this, the compression molding conditions are chosen to mold tensile specimens. The tensile properties of recycled XHDPE are compared with virgin XHDPE to evaluate former's recyclability. Preliminary results are presented and discussed here.

## II. EXPERIMENTAL

### A. Materials and Methods

Exxon Mobil's Paxton 7000 Series XHDPE was used in this study. Pulverized powder of the virgin and recycled material was supplied by a rotomolder in Manitoba. The melting characteristics of these two materials were studied using TA Instruments' Q2000 DSC (Differential Scanning Calorimeter). Samples were ramped at a rate of 10°C/min from -50°C to 250°C under nitrogen atmosphere. The degradation characteristics was studied using TA Instruments' Q500 TGA (Thermogravimetric Analyzer). Samples were ramped at a rate of 10°C/min from 25°C to 550°C using nitrogen and air as the purge gas. Based on these test results, compression molding temperature was chosen. Molding pressure was chosen based on preliminary trials. ASTM standard tensile test coupons were molded using these conditions and tested as per ASTM 638 using MTS Insight test machine.

## III. RESULTS AND DISCUSSION

### A. Differential Scanning Calorimeter Results

The results from DSC experiments, shown in Fig. 1, indicate that both materials melt around 130°C. A completely crosslinked material would not melt. The results suggest that XHDPE either did not completely crosslink during the rotomolding process or was de-crosslinked by the pulverization process.

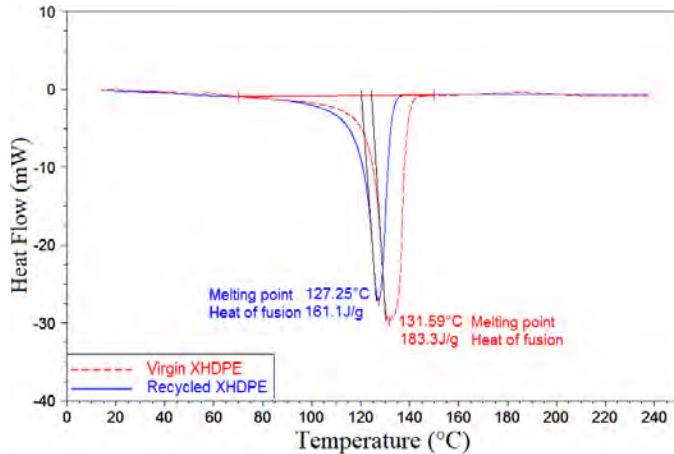

Figure 1. DSC test results for virgin and recycled XHDPE

The lower heat of fusion for recycled XHDPE than the virgin XHDPE suggests that there is residual crosslinking in the pulverized powders of recycled XHDPE. This result confirms that the recycled XHDPE, in pulverized powder form, can melt and hence is recyclable

#### B. Thermogravimetric Analysis

The results from TGA experiments shown in the Fig. 2 (purge gas – nitrogen) indicate that both the virgin and the recycled XDPE degrade similarly.

The decomposition initiation and completion temperatures as well as the weight loss are similar for both materials. These temperatures are much higher than the molding temperatures.

Depending of the molding conditions, the XHDPE may or may not come in contact with air. Hence, TGA test was repeated using air as a purge gas (Fig. 3).

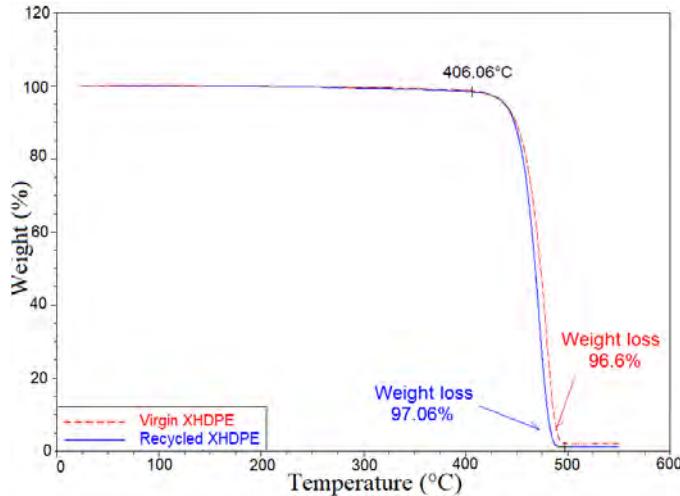

Figure 2. TGA test results for virgin and recycled XHDPE (Nitrogen)

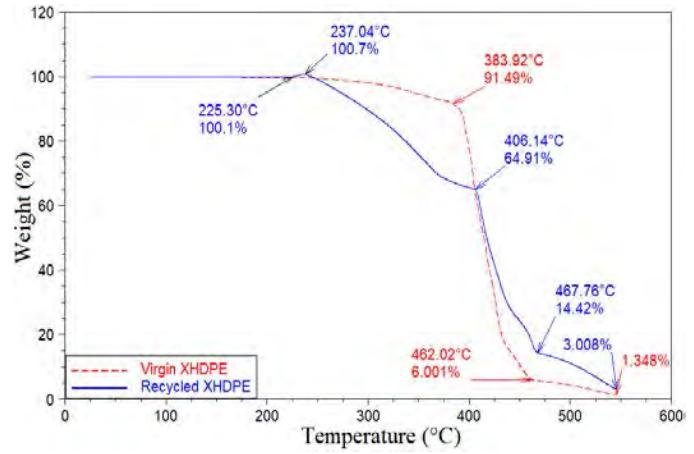

Figure 3. TGA test results for virgin and recycled XHDPE (Air)

The TGA results in Fig. 3 indicate that the recycled XHDPE is affected by the presence of air resulting in the formation of different products, suggested by the various slopes of the curve. Hence, the molding temperature was limited to 250°C.

#### C. Compression molding

Initial trials indicated that while virgin XHDPE could be melted and molded at the melting temperature, recycled XHDPE had to be molded at a considerably higher temperature and pressure. Tab. I presents the final compression molding conditions that resulted in a dense product without defects.

#### D. Mechanical properties

The tensile test results for both materials are presented in Fig. 4. The results show that the recycled XHDPE has a very similar stress versus strain curve when compared with the virgin material.

The tensile strengths of the virgin and recycled XHDPE are 20.25 MPa and 20.5 MPa respectively. The fracture strain of the virgin and recycled material are 344.5% and 273.6% respectively. While there is a slight decrease in the strain to failure of the recycled XHDPE, the tensile strength and modulus for both materials were similar.

TABLE I. COMPRESSION MOLDING SETTINGS

Material	Parameters		
	Temperature	Pressure	Time
Virgin XHDPE	150°C	0.286 MPa	30 min
Recycled XHDPE	230°C	2.86 MPa	30 min

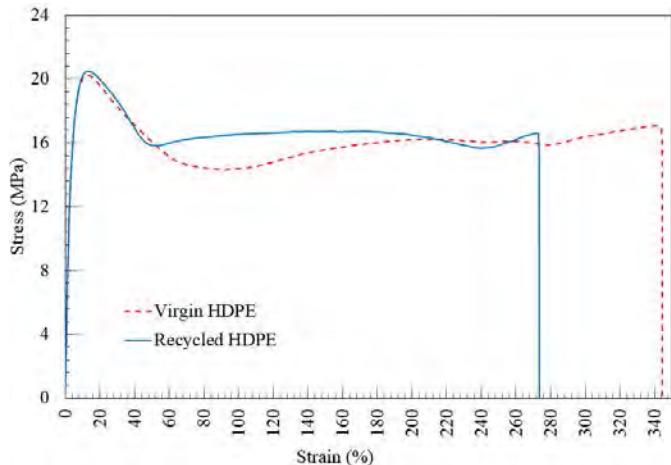

Figure 4. Tensile test results for virgin and recycled XHDPE

#### IV. SUMMARY

The thermal properties of Virgin and recycled XHDPE were investigated using DSC and TGA. Both materials exhibited melting around 130°C, although the heat of fusion for recycled material was less than that for the virgin material. The recycled material was successfully compression molded at a temperature and pressure higher than that used for the virgin material. Both materials exhibited similar tensile properties with the exception of strain to failure, which was slightly less for the recycled material. These results suggest that XHDPE can be reused through compression molding. Further studies are underway to study the mechanism of fusion of recycled XHDPE powder and the effect of pulverization on its recyclability.

**Abstract**— Thin flexible parts are widely used in the aerospace industry and require a more precise surface finish. The main problem in achieving high-quality product is the vibration induced during machining of thin-walled parts. Clamping these thin parts or using rigid supports for parts, such as for propeller blades, lead to distortion. This issue may be solved using a non-contact auxiliary fixture. The new fixture developed in this research is an eddy current damper for passive control of vibrations in electrically conducting workpieces, using neodymium permanent magnets without any external power source. Two thin aluminum beams with different cross-section and same length were used to test the developed fixture. To increase the overall damping, conducting sheets were attached at the free end of beams. Impact and machining tests were conducted to validate the new fixture. The results showed higher damping and better machining stability leading to enhanced surface quality of the workpiece.

**Keywords-** *Thin-flexible parts; vibration; fixture; eddy current damper; passive damping*

## I. INTRODUCTION

Machining of thin-walled workpieces is required in several industries, most notably the aerospace industry. During machining of thin parts, vibration is the main factor affecting the surface finish and tolerance. Milling is one of the most common processes used for thin workpieces. To improve the stability of the workpiece, i.e. to damp the vibrations, various methods are applied including choosing optimized machining parameters or using primary or auxiliary contacting or non-contacting fixtures [1]. In recent studies, distinct theoretical models have been created, and systems have been analyzed for damping of vibration, mainly in the cantilever beams. This research analyzes and controls the vibrations during machining of cantilever beam-like workpieces for better stability and surface finish.

In the aerospace industry, accuracy and precision of the machining process and the manufactured parts, along with the production rate and the tool life, are the primary areas for research. The parts that are more flexible, such as, the impellers, propeller blades etc., need much higher accuracy and a smooth

surface finish. Chatter is widely studied in the literature. Lai et al. [2] studied chatter characteristics of a cylindrical thin-walled workpiece. The relation of the wall thickness and the inner diameter was analyzed to study machining vibration characteristics. Numerical and experimental methods were used to investigate the dynamic characteristics of the workpiece. Campa et al. [3] came up with a method to damp the vibrations in thin-floor milling using a bull-nose end mill. A mathematical model was created to predict the behavior of workpiece during the milling process and to generate a stability lobe diagram for selecting the optimal spindle speed for better stability during machining. Junjin et al. [4] worked on the use of magnetorheological (MR) fluid, which can be tuned using a magnetic field by changing its state from liquid to solid by aligning the magnetic particles in a single direction, to damp the vibrations in a thin cantilever beam and found a considerable change in the vibrations.

## II. EDDY CURRENT DAMPER

Damping of vibrations in thin-walled electrically conducting workpieces can be achieved using magnetism. The use of eddy currents to oppose the motion of the workpiece utilizes the basic principle of using a magnetic field for vibration damping. When a conductor moves in a magnetic field, electrical currents are induced in it, known as eddy currents. These currents generate a counter magnetic field with an opposing force, known as the Lorentz force ( $F$ ) is directly opposite to the direction of movement of the conductor moving with a velocity ( $v$ ) with respect to the magnetic field ( $B$ ), as shown in Figure 1. When the movement of the conductor is perpendicular to the polar axis of the magnet, the radial component of magnetic field does not contribute to the damping effect due to lack of much interaction with the conductor. On the other hand, when the conductor moves parallel to the axis of poles of magnet, only the radial component of magnetic flux is responsible for inducing eddy currents and creating damping forces.

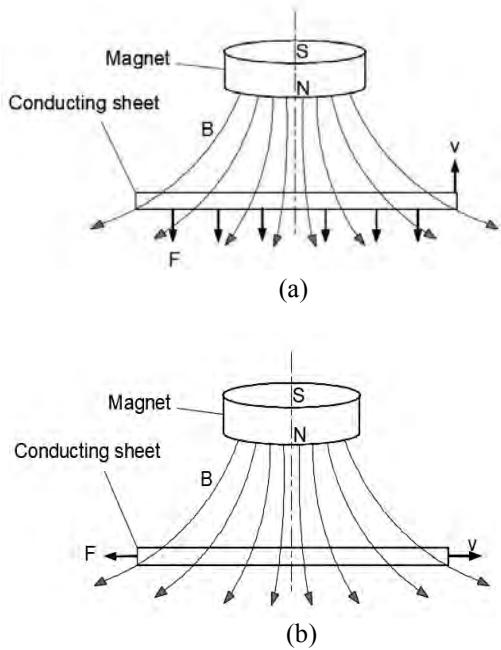

Figure 1: (a) Damping force using radial magnetic flux, and (b) Damping using axial magnetic flux

The induced current density ( $\vec{J}$ ) can be obtained as,

$$\vec{J} = \sigma(\vec{v} \times \vec{B}) \quad (1)$$

In the above equation, the conductor has conductivity  $\sigma$ , velocity  $\vec{v}$  w.r.t the magnetic field and magnetic flux density  $\vec{B}$ .

The damping force of the system due to the magnetic field can be determined analytically. The damping force depends on the magnetic flux density ( $B$ ), the relative velocity of the vibrations ( $v$ ), and the properties of the conductor used, which includes a thickness ( $\delta$ ) and conductivity ( $\sigma$ ).

From the relation given, the damping force due to axial magnetic field lines, as used by Bae et al., [5], is given as

$$F = -(\sigma\delta B^2 S(\alpha_1 + \alpha_2))v \quad (2)$$

Where  $S$  is the area of pole projection, and  $\alpha_1$  and  $\alpha_2$  are the conducting sheet's effect on damping force.

The case of a radial magnetic flux, as studied by Sodano et al. [6] is given as:

$$F = \int_v J \times B dv = -2k\pi\sigma\delta \int_0^{r_c} y B_y^2(y, l_g) dy \quad (3)$$

With  $k$  as the spring coefficient of the system,  $r_c$  as the equivalent radius of conducting sheet, and  $l_g$  as the air gap between the magnet and the conducting sheet.

This eddy current creates an opposing field and force which opposes the motion of the conductor. This damping effect can be used for a thin-walled cantilever beam using a strong magnetic field around it such that the oscillation of the beam in

the magnetic field induces a Lorentz force or damping force. For better results and more control, electromagnets can be used in this vibration damping methods [7]. The eddy current damping process is contact-less, wear-free, fast and safe. Also, with the electromagnets, the magnetic field or the force can be controlled using different input current or coil turns, making it more adjustable for different work conditions [8].

Sodano with Jae-Sung Bae [6] developed a passive eddy current damper which used radial components of magnetic flux for vibration damping, using permanent magnets. The damper showed an increase in damping ratio up to 150 times for a thin cantilever beam, when fixed at the free end. The above study was continued by Sodano et al. [9] to change the passive current damper to an active eddy current damper by using electromagnets instead of permanent magnets. With this active system, the magnetic field strength can be varied actively so as to induce eddy currents even without much movement of the conductor. This system is effective when the movement of the conductor in a magnetic field is not enough to induce significant eddy currents.

Another study was performed by Cheng et al. [10] using a permanent magnet for damping of vibrations. In their work, a conduction coil was attached to the cantilever beam to vary the resistance during induction of eddy currents using a permanent magnet. Ebrahimi et al. [11] worked on passive eddy current damper and developed an analytical model to select the permanent magnets of optimum strength and size.

### III. EXPERIMENTAL SETUP AND METHODOLOGY

This research was conducted to develop a non-contacting auxiliary fixture, as shown in Figure 2, for machining stability of cantilever-like workpieces, such as propeller and impeller blades, to suppress machining vibrations and enhance the surface finish of the end-product. The fixture developed has an aluminum frame to limit interaction with the magnetic field. The 'magnet holder' holds the neodymium magnet and can be moved to change the gap between the magnet and the workpiece. Allen bolts are used to lock the 'magnet holders' at any point. Use of permanent magnets on either side of the workpiece is an ideal option when the workpiece moves perpendicular to the polar-axis of the magnets for maximum interaction of magnetic field lines.

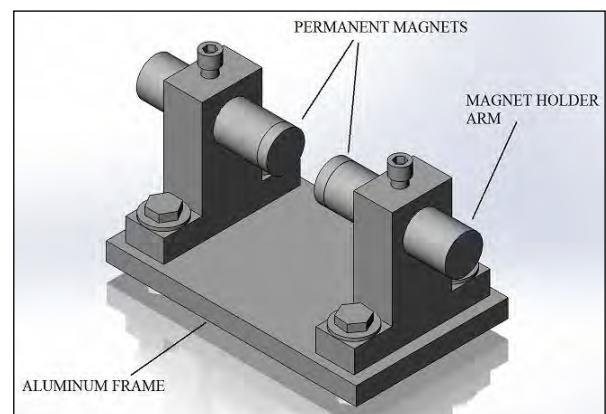

Figure 2: Developed experimental setup

Two Aluminum beams (6061-T6), one of dimensions 170 mm x 25 mm x 6 mm (referred as ‘thick beam’) and the other of dimensions 170 mm x 38.5 mm x 3.58 mm (referred as ‘thin beam’), were selected as the workpiece because of resemblance to a propeller blade. Permanent magnets (Neodymium N-48), of diameter 25.4 mm and thickness 6.35 mm each, were used to induce the eddy currents in the workpiece to produce the damping effect whenever there is a motion in the workpiece due to induced vibrations. The beams were secured on one end in a vise and the eddy current fixture was placed at the free end, as shown in Figure 3. Aluminum sheets (50 mm x 37 mm x 1.5 mm) were glued at the free ends of both beams (as in Figure 3(b) and 3(c)).

(a)

(b)

(c)

Figure 3. Different setups of the test workpiece (a) Beam 1 (without additional conducting element), (b) Beam 2 (thick beam with aluminum sheet), and (c) Beam 3 (thin beam with aluminum sheet element)

The three beam arrangements (Beam-1 i.e. thick beam without the additional aluminum sheet, Beam-2 i.e. thick beam with the aluminum sheet glued and Beam-3 i.e. thin beam with the aluminum sheet glued) used are given in Figure 3, with a constant gap of 0.8 mm between the magnet and the beam for each arrangement. The natural frequencies and the modes of each beam, with and without the fixture, were obtained using impact hammer test through LMS Test.lab by Siemens (as shown in Figure 4). The frequency response functions were then obtained from the LMS Test.lab software to get the average damping ratios and damping ratios for each mode for all the beams. The results of Test.lab, for natural frequencies and modes, were confirmed using ANSYS modal analysis. ANSYS Maxwell was used to simulate the magnets to see the maximum magnetic flux on the beam.

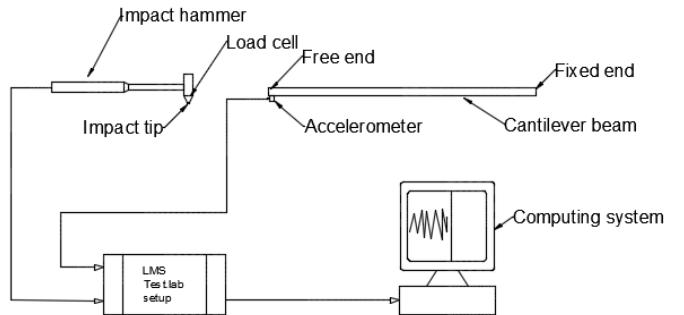

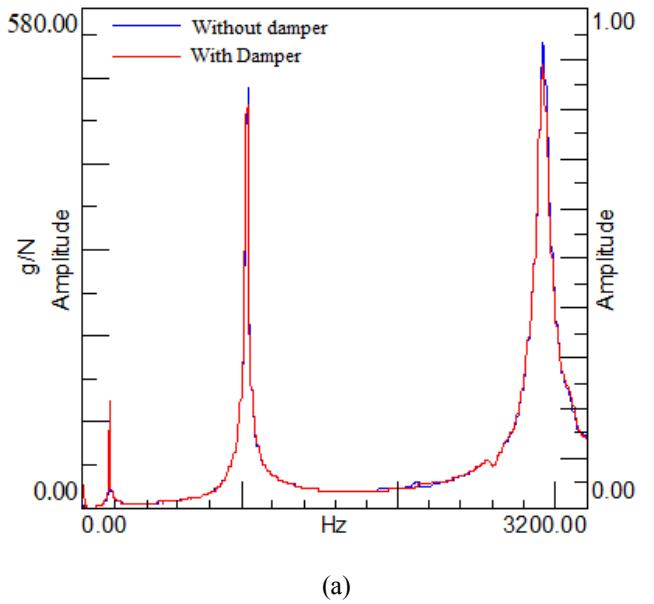

Figure 4: Impact test setup schematic

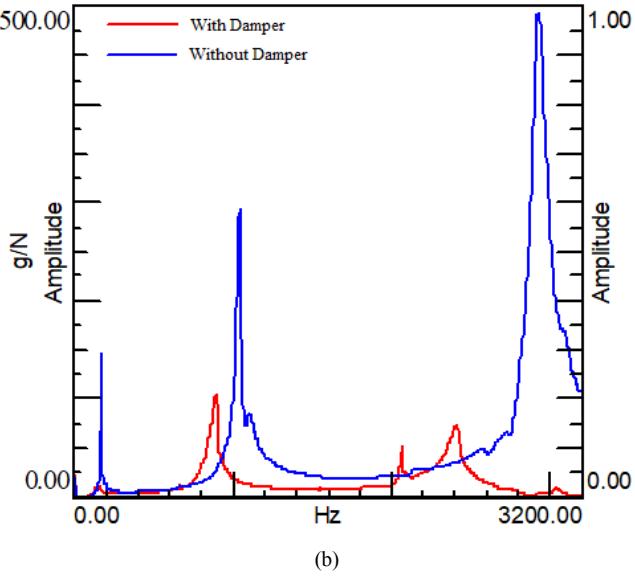

Observing the damping effect, Beam-2 and Beam-3 were machined in HAAS 3-axis milling machine at 2400 rpm of spindle speed with a feed rate of 15 inches per minute to measure the acceleration during machining and to observe the surface finish of the machined workpiece. A 4 flute 3/8-inch HSS flat end mill tool was used for machining of the workpiece to create a 3-inch slot of 20 thou depth from the free end inwards, at the center of beams with aluminum sheets attached. Siemens Test.lab ‘Signature’ module was used to measure the online acceleration signals. A profilometer was used to measure the surface roughness of the workpiece.

#### IV. RESULTS AND DISCUSSION

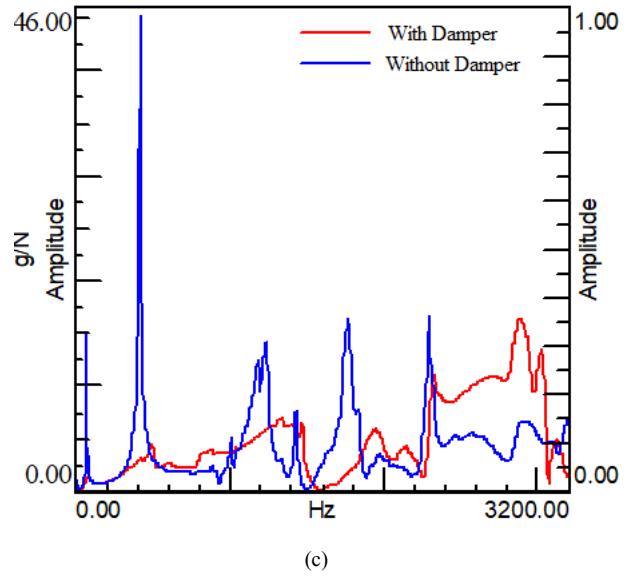

The permanent magnets were simulated using the ANSYS Maxwell software and it was observed that the magnetic flux density increases as the distance between the magnets decreases. Thus, as per the magnetic flux density results, the air gap between the cantilever beam and the magnets on either side was kept constant at 0.8 mm. The damping effect can be clearly seen in the frequency response function plots in Figure 5.

Figure 5: Frequency response function plots for (a) Beam-1, (b) Beam-2, and (c) Beam-3.

#### IV.I. MODAL ANALYSIS

The frequency response function (FRF) plots for the three cases of the beams (with and without aluminum sheet) were obtained from LMS Test.lab software, given in Figure 5. For Beam-1, as from the FRF plot in Figure 5(a), there is not much effect of the damper on the amplitude and damping ratio by the use of damper.

The average damping ratio ( $\zeta\%$ ) for Beam-1 increased from 2.95% to 3.41% with the use of damper. However, for Beam-2, it changed from 3.51% to 12.26% and for Beam-3, it moved from 6.66% to 40.38%. Table-1 and Table-2 shows the change in natural frequency, amplitude and damping ratio for the first three modes of Beam-2 and Beam-3, which were considered for this research. The maximum damping ratio and minimum amplitude for Beam-2 and Beam-3 were observed at mode 1 of each beam arrangement where the damping ratio increased more than 7 times for the Beam-2 and 12 times for Beam-3 and the

amplitude decreased by more than 10 times, when the damper was placed at the free end of the beams.

The Beam-2 and Beam-3, with a conducting sheet attached to the free end, experienced the maximum damping because of use of the axial component of the magnetic field and the close-proximity of the magnets, providing a higher magnetic flux for more eddy currents. The closely packed magnetic field lines passing through the beam had the maximum interaction with the beam, even with minimum movements. The thicker beam with conducting sheet has higher stiffness making it less affected by the eddy currents than the thin beam. The damping force also depends on the thickness of the conducting sheet attached. Making the sheet thicker will increase the eddy current's density but can also make the system unstable.

TABLE 1: Modal testing results for Beam-2

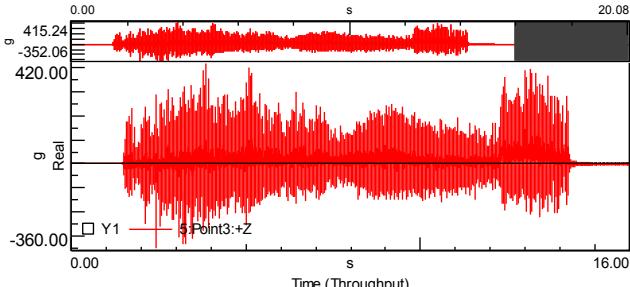

Parameter Modes	Without Damper			With Damper		
	Natural frequency (Hz)	Amplitude (g/N)	Damping ratio ( $\zeta\%$ )	Natural frequency (Hz)	Amplitude (g/N)	Damping ratio ( $\zeta\%$ )
Mode 1	165.6	146.72	1.06	146.8	11.87	7.79
Mode 2	1040.2	293.22	1.00	893.5	104.88	2.25
Mode 3	2930.2	493.46	1.45	2406	72.24	1.56

TABLE 2: Modal testing results for Beam-3

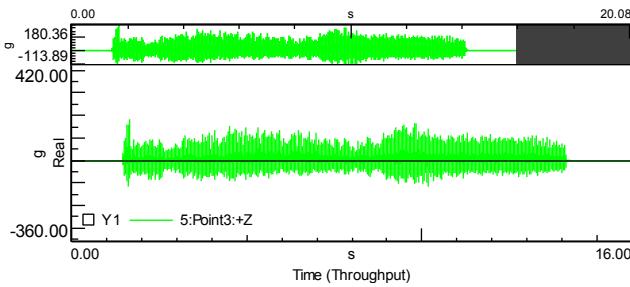

Parameter Modes	Without Damper			With Damper		
	Natural frequency (Hz)	Amplitude (g/N)	Damping ratio ( $\zeta\%$ )	Natural frequency (Hz)	Amplitude (g/N)	Damping ratio ( $\zeta\%$ )
Mode 1	68.7	15.27	1.73	71.8	1.47	21.53
Mode 2	415.6	45.13	1.09	490	4.42	5.48
Mode 3	1232	14.42	1.73	1330	7.01	10.16

#### IV.II. MACHINING TEST

The machining tests were performed for Beam-2 and Beam-3 only, because of the significant damping observed during modal analysis. The machining tests showed a reduction in the acceleration of both the beams during machining. For Beam-2, the maximum positive acceleration reduced from 415 to 180 g. For thin beam with aluminum sheet, the maximum acceleration dropped from 368 g to 164 g, as shown in the Figure 6. This change in the acceleration can be related to the damping shown in the modal testing. However, Beam-3 has lower stiffness which causes it to bend a bit when the cutting tool makes a contact, making the beam in less contact with the tool, as can be seen in the machined surface without the damping fixture. This causes undercutting of the beam. When the damping fixture was applied at the end of the beam, the damping force resisted the motion of the beam, making a better contact with the cutting tool. Also, the irregular pattern of the acceleration was caused by continuously changing of overhung mass when the cutting tool moves toward the clamped end of the beam.

(a)

(b)

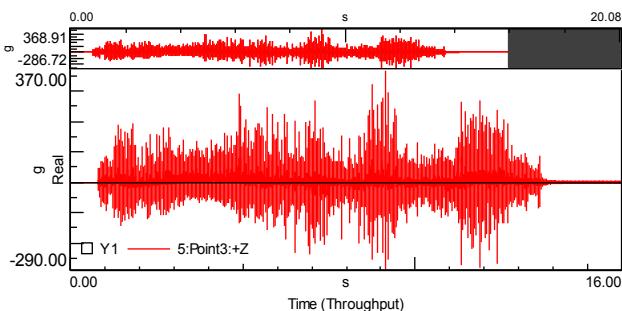

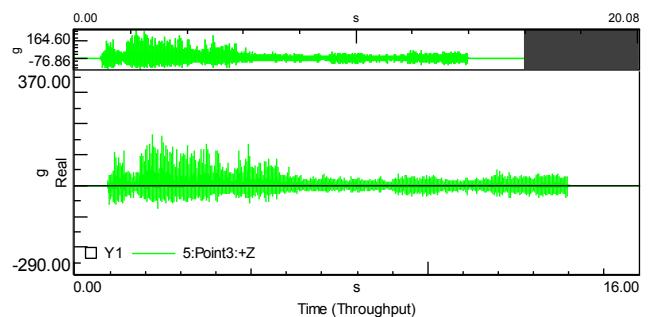

Figure 6(c): Acceleration vs Time plot for Beam-3 without damper. The plot shows two traces: Y1 (red) and 5:Point3:+Z (green). The Y-axis ranges from -290.00 to 370.00 g, and the X-axis ranges from 0.00 to 16.00 s. The red trace shows high-frequency chatter, while the green trace is relatively smooth.

(c)

(d)

Figure 6: Machining results at 2400 rpm spindle speed, 15 inches per minute of feed and 20 thousandth-of-an-inch cutting depth for (a) Beam-2 without damper, (b) Beam-2 with damper, (c) Beam-3 without damper, and (d) Beam-3 with damper.

The average surface roughness of the beams was measured using a profilometer and Beam-2 showed a better surface finish, with average roughness values ( $R_a$ ) changing from 3.52  $\mu\text{m}$  to 2.17  $\mu\text{m}$ , while for Beam-3 the initial impact causes deflection of the beam making it difficult to compare the surface roughness, but a higher material removal rate was observed (undercutting was prevented by the damper).

#### V. CONCLUSIONS

Machining of thin-walled parts is considered a challenge because of the chatter induced due to lower stiffness of workpieces. To counter this issue, an auxiliary fixture, based on eddy currents, was developed to damp the vibrations in a cantilever beam and to improve the surface finish of the product. The fixture developed is a passive eddy current damper which is simple to use and does not need a power supply for its operation.

The damping force (Lorentz force) applied by the eddy current damper reduced the vibrations in the workpiece when there is an interaction of a conductor with the magnetic field. The damping force was increased by attaching a conducting sheet to the workpiece to increase the magnetic flux density with respect to the conductor sheet. The damping force was observed as maximum when the cantilever beam workpiece has low stiffness, a conducting sheet is attached to the free end and the gap between the magnets is kept small. The fixture proposed highly damps the first three modes of the tested beams.

The modal testing and the machining tests validated the usability of eddy current dampers for better machining stability, by suppressing chatter. Better surface finish and high material removal rate was observed by using the proposed auxiliary fixture. Future work will focus on optimizing the thickness of the conducting sheet attached and also on using it as a tuned mass damper.

## VI. ACKNOWLEDGEMENT

This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).

**Abstract**— The vibration and damping characteristics of epoxy composites reinforced with pristine and functionalized multi-walled carbon nanotubes (MWCNTs) were investigated experimentally with potential use as integral passive damping elements in structural composite applications. The MWCNTs were introduced into the acetone solvent and then mixed with epoxy resin through a sonication process and mechanical stirring. The solvent was evaporated by means of magnetic hot plate and the hardener was added to the mixture once it was cooled down to room temperature. The MWCNTs/epoxy mixture was then injected into a mold to form the nanocomposite specimen. Nanocomposite specimens were fabricated for six different MWCNT loadings (0.02, 0.041, 0.061, 0.123, 0.25 and 0.37 wt%). Microstructural analysis, tensile and bending tests were carried out to examine the effects of pristine multi-walled carbon nanotubes (p-MWCNTs) and functionalized multi-walled carbon nanotubes (f-MWCNTs). The frequency response functions (FRFs), coherence and phase diagrams of nanocomposites were measured using a shaker vibration technique. The periodic up-chirp signal was generated by a shaker to excite the cantilever nanocomposite specimen at the base. The damped natural frequencies and damping ratios were obtained for different loadings of MWCNTs. The experimental results indicated that the damped natural frequencies of p-MWCNTs/epoxy and f-MWCNTs/epoxy composites increased by adding MWCNTs up to 0.12 wt.% and, after that, decreased with higher MWCNT content. Another finding was that p-MWCNTs were beneficial to improve the damping ratio of nanocomposites. While the damping ratios of f-MWCNTs with loadings of 0.02-0.06 wt.% were higher than p-MWCNTs ones, they did not increase at higher CNTs contents for the first mode of vibration.

**Keywords**-experimental vibration, carbon nanotubes, polymer composite; vibration damping; functionalize CNTs; epoxy nanocomposite.

## I. INTRODUCTION

Carbon nanotubes-reinforced polymers have attracted considerable interest due to their potential to exhibit physicochemical properties, such as mechanical, electrical, and thermal properties, that are improved compared to those of their hosting polymers[1–4].

In addition, the investigation of the vibration and damping behavior of composites is an important issue in mechanical and aerospace engineering. Many researchers have studied them both experimentally [5–7] and theoretically [1,7]. A review of state-of-the-art in vibration of composite beams and blades was presented by Rafiee et al. [2]. Studies in the recent years have shown that carbon nanotubes can introduce damping to attenuate the vibrations and noise of two-phase and three-phase epoxy nanocomposites by dissipating substantial amounts of vibration energy [5–7]. However, no study has been reported on the vibration and damping characteristics of functionalized MWCNTs-reinforced epoxy composites.

The present research aimed to understand the practical aspects related to the vibration and damping behavior of pristine and functionalized MWCNTs/epoxy composites with potential use as integral passive damping elements in structural composite applications. In addition, th study also focused on evaluating the effect of MWCNT functionalization on mechanical properties of two-phase epoxy resin composites.

## II. MATERIALS, PROCESSING AND FABRICATION

### A. Materials

The pristine multi-wall carbon nanotube (NC7000) and amine functionalized multi-wall carbon nanotube (NC7000-NH<sub>2</sub>) were received from Nanocyl S.A., Belgium, with an average diameter and length of 9.5 nm and 1.5 μm, respectively. MWCNTs were produced via the Catalytic Chemical Vapor Deposition (CCVD) process with carbon purity of 90%. Low viscosity diglycidyl ether of bisphenol-A (DGEBA) epoxy resin PT-2712 Part A and diethyltoluenediamine (DETDA) curing agent PT-2712 Part B1 produced by PTM&W Industries, Inc., USA were used. Epoxy

resin Part A and B mixing weight ratio was 100/22 as per manufacturer recommendation.

### B. Processing and fabrication of MWCNTs/polymer nanocomposites

The two-phase polymer matrix composites reinforced by pristine multi-wall carbon nanotube (p-MWCNTs) or functionalized multi-wall carbon nanotube (f-MWCNTs) were prepared with nanotube loadings of 0.025, 0.050, 0.075, 0.15, 0.3 and 0.45 of DGEBA wt%. The equivalent nanotube loadings with respect to total weight (DGEBA+DETD) were 0.020, 0.041, 0.061, 0.123, 0.246 and 0.369 wt%, respectively. Figure 1 shows a schematic of the method for the preparation of the MWCNTs/epoxy nanocomposites.

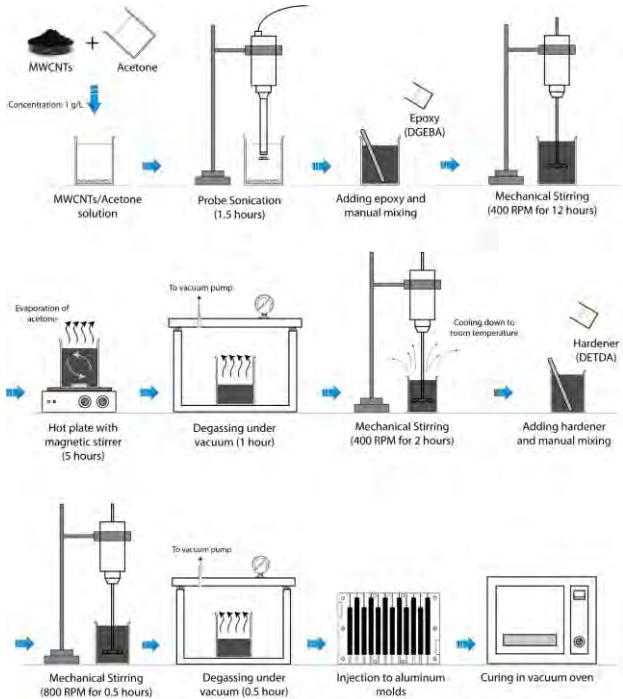

Figure 1. Fabrication process of MWCNTs/epoxy two-phase composites.

The samples were cured at room temperature for 15 hours followed by a post cure of 1°C/min ramp rate, held every 20°C for an hour, then continued until a final hold of three hours at 100°C to remove the possible thermal history.

### III. EXPERIMENTAL SETUP

The shaker vibration test was used to measure the natural frequencies and damping factors of nanocomposites specimens in the form of cantilever beams. The clamped-free beam was excited by a vibration shaker (Brüel & Kjær Sound & Vibration Measurement A/S, Denmark) at the clamped end, and the response of the beam was tracked by means of accelerometers. The computed frequency response functions (FRFs) gave information about the natural frequencies of the composite beam.

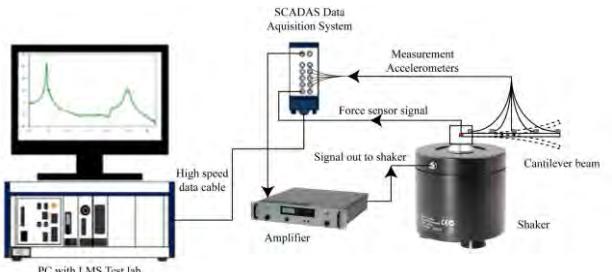

Fig. 2. Schematic diagram of the experimental procedure for vibration testing of MWCNTs-reinforced composites.

Rectangular specimens 12.7 mm (0.5 in) wide, 3.175 mm thick (1/8 in) and 152.4 mm long (6 in) were prepared for vibration tests according to ASTM E756. The free beam length is defined as the distance between the clamp and the specimen tip and was measured as 130 mm. Figure 2 illustrates the instrumentation used for the vibration test. Acceleration was measured at five locations by means of miniature lightweight accelerometers. A piezoelectric crystal force transducer (Quartz ICP® Force Ring, PCB® Model 201B03, measurement range of 2.224 kN) was used to measure the excitation force exerted by the electrodynamic shaker. A power amplifier was required to drive the shaker. Periodic chirp excitation signals were used with a frequency bandwidth of 0–1024 Hz to guarantee the highest quality measurements. The tests were performed using the LMS TestLab by Siemens®, which is an integrated solution for experimental vibrational analysis including tools for data acquisition (LMS SCADAS III with eight measurement channels and two output channels), test execution and data processing (LMS Testing Solution Software). The LMS SCADAS III was used to acquire the signals from the force sensor and the piezoelectric accelerometers and to control the amplifier connected to the shaker, by means of a digital-analog converter output. Spectral Testing module of LMS Testing Solution Software was used for shaker test. The Modal Analysis module was then used to analyze the power spectral density (PSD) of the excitation signal, the FRFs and the coherence functions, and to calculate FRF sum functions (i.e. the sum of the five FRFs). Finally, the PolyMAX frequency domain identification method [27], which is based on a least squares fit, was used to identify the natural frequencies, damping ratios and vibration modes of MWCNTs/epoxy nanocomposites. All measurements were acquired in the frequency range 10–1024 Hz, with a resolution of 0.125 Hz. Each measurement was averaged over 20 acquisitions.

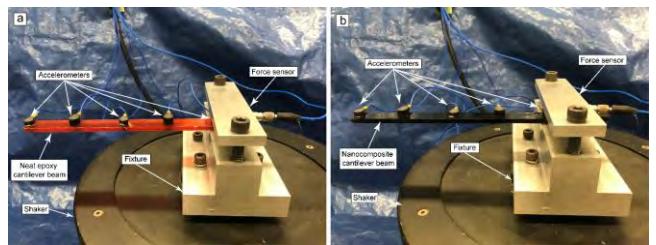

Fig. 3. Experimental set-up with (a) neat epoxy specimen, (b) nanocomposite specimen.

#### IV. RESULTS AND DISCUSSION

Damped natural frequencies, frequency-response functions (FRFs), phase diagram, coherence, and damping ratios about the first three vibration modes were obtained and shown in Figures 4 through 7.

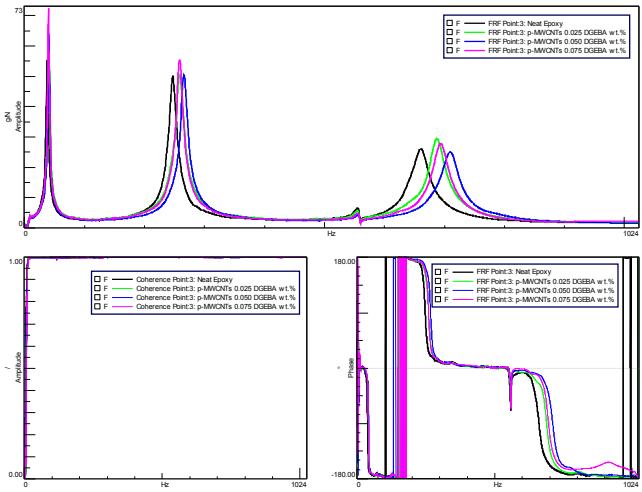

Fig. 4. FRFs, coherence and phase diagrams for neat epoxy and p-MWCNTs (0.025, 0.050 and 0.075 DGEBA wt.%) reinforced composites

As can be seen, the damped natural frequencies of p-MWCNTs/epoxy and f-MWCNTs/epoxy composites increased by adding CNTs up to 0.12 wt.%, and decreased after that with higher MWCNTs content. The maximum damping improvement of 9.4% happened at 0.02 wt% of f-MWCNTs/epoxy composites while it was 7.2% with the equivalent pristine MWCNTs. The improvement in damping of the fundamental natural frequency was more significant than that at higher natural frequencies. For instance, addition of 0.02% of f-MWCNTs improved the damping of the fundamental, second and third natural frequencies by 9.4%, 7.5% and 6.3%, respectively.

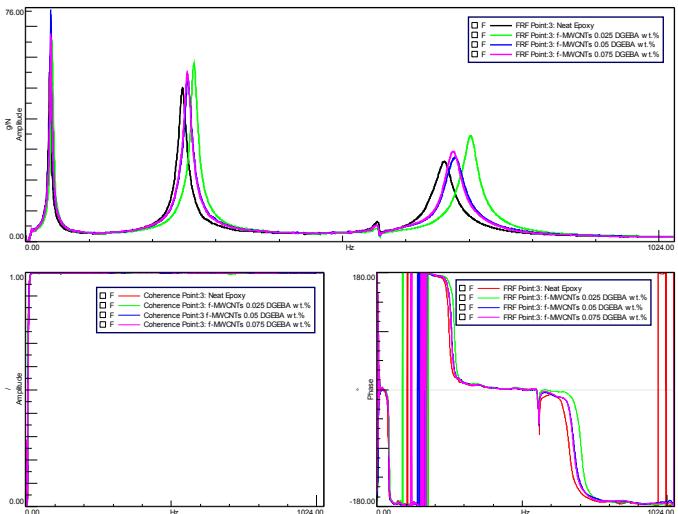

Fig. 5. FRFs, coherence and phase diagrams for neat epoxy and f-MWCNTs (0.025, 0.050 and 0.075 DGEBA wt.%) reinforced composites

The relative effects of pristine vs. functionalized carbon nanotubes on the damping ratios of epoxy-based composite beams were investigated and are depicted in Fig. 6 and 7, respectively. As one can observe from Fig. 6, the damping ratios dropped by 18% till loading of 0.06 wt.% and then improved by adding p-MWCNTs in the composites for the first vibration mode. A 46% improvement in damping ratio of p-MWCNTs/epoxy composite was observed with a loading of 0.37 wt.%. For f-MWCNTs/epoxy composites, a decrease in damping ratio can be observed over the whole range of loadings. While the damping ratios with f-MWCNTs at loadings of 0.02-0.06 wt.% were still higher than those with p-MWCNTs, they did not increase with higher CNT contents for the first mode of vibration.

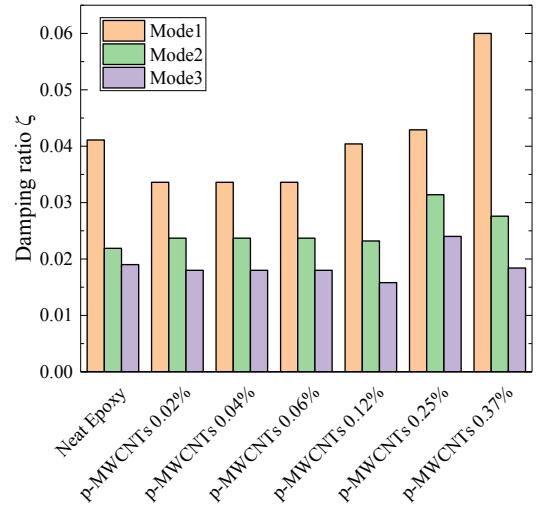

Fig. 6. Damping ratio of p-MWCNTs-reinforced composites with different loadings.

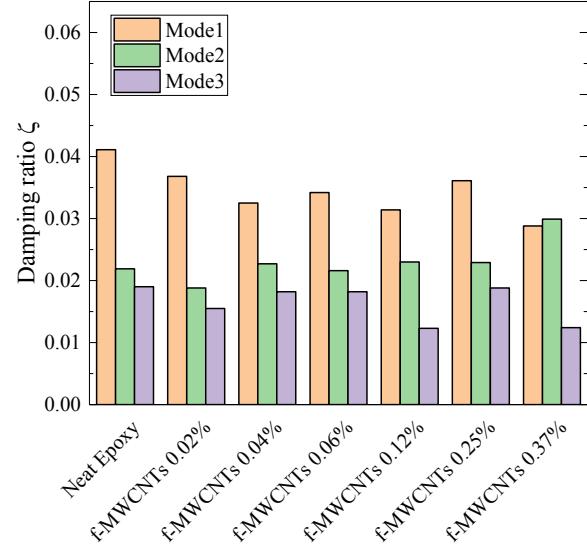

Fig. 7. Damping ratio of f-MWCNTs-reinforced composites with different loadings.

For the second mode of vibration, both pristine and functionalized multiwalled carbon nanotubes improved the damping characteristics of nanocomposite beams. There was

over 40% improvement in damping ratio in p-MWCNTs/epoxy composites at 0.25 wt.% loading. The maximum improvement in damping ratio in f-MWCNTs/epoxy composites was observed at the 0.37 wt.% loading and reached 36.5%. Damping ratio results for the third mode of vibration showed no significant improvements.

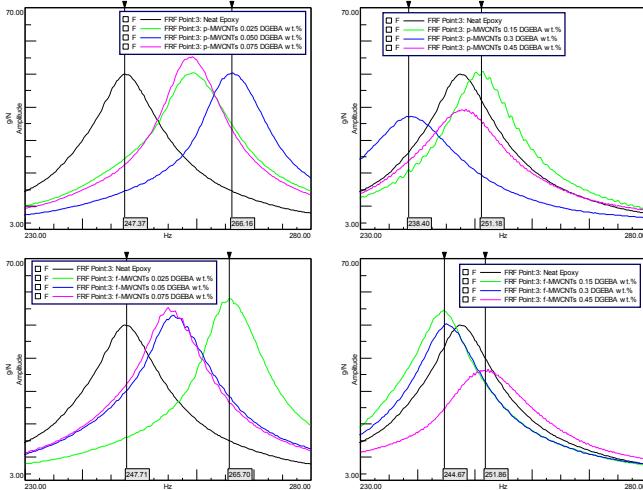

Fig. 9. Magnification of FRFs, coherence and phase diagrams around second resonance peak of MWCNTs/epoxy.

## V. CONCLUSION

The experimental vibration and damping analyses of p-MWCNTs/epoxy and f-MWCNTs/epoxy nanocomposites were completed. Nanocomposite specimens were fabricated for six

different MWCNT loadings (0.02, 0.041, 0.061, 0.123, 0.25 and 0.37 wt%). Microstructural analyses and tensile and bending tests were carried out to examine the effects of p-MWCNTs and f-MWCNTs. The frequency response functions, coherence and phase diagrams of nanocomposites were obtained using a periodic up-chirp forced vibration technique. The damped natural frequencies and damping ratios were obtained for different loadings of MWCNTs. The experimental results indicated that the damped natural frequencies of p-MWCNTs/epoxy and f-MWCNTs/epoxy composites increased by adding CNTs up to 0.12 wt.% and decreased with higher MWCNTs content. Another finding was that the improvement in fundamental natural frequency was more significant compared than that at higher natural frequencies. The forced vibration test also confirmed the beneficial effect of p-MWCNTs in improving the damping ratio of nanocomposites for the first and second vibration modes. However, a decrease in damping ratio was observed in f-MWCNTs/epoxy composites. For instance, a 46% improvement in damping ratio associated with fundamental vibration mode was observed at loadings of 0.37 wt.% in p-MWCNTs/epoxy composites. While the damping ratios with f-MWCNTs at loadings of 0.02-0.06 wt.% were still higher than with p-MWCNTs, they were not increasing at higher CNTs contents for the first mode of vibration.

**Abstract** — This paper describes the piezoresistive properties of a nanocomposite made of polydimethylsiloxane and multi-walled carbon nanotubes that is subjected to high strain rate. We highlight the production process of the composite, the testing protocol, and the results obtained.

**Keywords:** piezoresistance; nanocomposite; high strain rate; polydimethylsiloxane; carbon nanotubes; Kolsky bar

## I. INTRODUCTION

Over the past decade, smart materials have become increasingly popular owing to their intrinsic functional properties that allow for fast, easy, and inexpensive sensing and actuating.

Composites based on nanoscale fillers such as carbon nanotubes (CNTs) are considered the new generation of smart materials. Since their discovery in 1991, CNTs have had a significant impact on the field of material science. They are cylindrical in shape and consist of carbon molecules covalently bonded together to form a tube-shaped lattice, lending them their unique properties — superior electrical and magnetic conductivity, lightness, and strength. Polydimethylsiloxane (PDMS) is the simplest member of the silicone polymer family and is characterized by its attractive mechanical properties and translucency.

Much work has been done on developing highly sensitive strain sensors made from CNT–polymer nanocomposites. This paper investigates the potential of PDMS mixed with CNTs in the development of high strain rate (impact) sensors.

## II. METHODOLOGY

### A. Composite Production Process

The material in question is an elastomeric composite made from PDMS as the matrix and multi-walled carbon nanotubes (MWCNTs) as the phase. The production of this composite was a complex, time-consuming, and dangerous process. First, there is the issue of avoiding exposure, since CNTs are considered hazardous and not enough research has been done on the risks they pose to human health. Second, the dispersion of CNTs in PDMS was difficult to achieve. The reason for that

is the tendency of CNTs to agglomerate over time when mixed in liquids. To prevent these agglomerations, chloroform was used as a solvent to aid the dispersion [1], and the material was sonicated repeatedly throughout the process. Third, the curing time of PDMS at room temperature is unfavorably long at 48 to 72 h. This creates a wide window in which CNTs can agglomerate. To remedy this problem, the PDMS was cured at 110 °C, which reduced curing time to 30 min. Last, to cure the material at high temperature, a custom press-casting heated mold was developed.

The mold was made from two blocks of aluminum cut using computer numerical control (CNC). The bottom part (drag) contained the PDMS, while the top part (cope) had an emboss that forced the PDMS on the surface out of the cast area and into channels on all four sides of the mold that contained the excess material. The cope was hinged to the drag of the mold and closed with a mechanism resembling that of a waffle maker. This design prevents imperfections caused by air pockets and bubbles that would otherwise get trapped during assembly below the cope and inside the cast. Moreover, three through-holes were drilled in the cope below the surface of the cast to house two cartridge heaters and one thermocouple. The heaters were connected to a relay, a thermocouple, and a PID controller in a circuit that controls the temperature inside the mold according to the user's selection.

Figure 1. Heated Press-casting Mold

Figure 2. PDMS/CNT Solution - Chloroform Expulsion

Our primary objective was to study the effect of CNT concentration in PDMS on the electrical resistivity when the material was subjected to high strain rates. Therefore, three different CNT concentrations were studied, ranging from 1wt. % to 2wt. %, with 0.5wt. % increments.

Dispersion is a spatial quality that represents how evenly distributed CNTs are in the PDMS matrix. Manually mixing CNTs in PDMS does not generate enough shear forces to overcome the inter-tube Van der Waals forces and separate the tubes from their aggregations [1]. On the other hand, more advanced techniques such as mechanical stirring and sonication were found to deliver better results in dispersing nanoparticles in solutions. However, the efficiency of these methods is greatly reduced with the use of highly viscous liquids such as PDMS. Therefore, a solvent was used to dissolve the PDMS, thereby reducing its viscosity. Chloroform was chosen for two reasons. One, CNTs were found to disperse well in chloroform compared with their dispersion in other reagents like toluene [1]. Two, chloroform dissolved PDMS without chemically reacting with it, unlike other reagents that might provide better dispersibility. Once the dispersion process was complete, the solution was heated to evaporate the chloroform and expel it from the solution. To speed up the process, a vacuum was introduced to encourage the chloroform's evaporation as shown in Fig. 2. Finally, the solution was cast in the mold to produce a 3 mm × 120 mm × 120 mm sheet of the composite.

The production process<sup>1</sup> of the material is summarized in the following eight steps:

1. Chloroform was mixed with MWCNTs at a ratio of 1/15 g.mL<sup>-1</sup> (MWCNT:CHCl<sub>3</sub>) in a beaker and sonicated for 1 h.
2. Chloroform was mixed with PDMS part A at a ratio of 2/3 g.mL<sup>-1</sup> (PDMS:CHCl<sub>3</sub>).
3. The solutions from steps 1 and 2 were mixed and sonicated for 3 h.
4. The solution from step 3 was heated in an Erlenmeyer flask under vacuum at 62 °C while mechanically stirring at 1200 r.min<sup>-1</sup> for 3 h to expel the chloroform.

<sup>1</sup> Applicable to 1wt. % of CNTs. For 1.5wt. % and 2wt. %, the concentration of CNTs in PDMS was adjusted accordingly.

Figure 3. Sample Shape

Figure 4. Probe Insertion Guide Housing

5. Part B was added to the solution from step 4, and this solution was manually mixed for 10 min.
6. The solution from step 5 was put in a vacuum chamber to remove any air bubbles trapped under the surface.
7. After degassing, the solution was carefully cast in the mold at a controlled temperature of 110 °C for 30 min.
8. The mold was carefully opened, and the sheet casting was removed from it.

To prepare the material for testing, samples were laser cut from the sheets produced using an Epilog Laser Fusion M2 cutter in the shape shown in Fig. 3.

To measure the electrical resistance of the material, a four-wire connection [2] was used to control current through the sample and measure the voltage change along the sample. The distance between the probes was controlled for all samples, since it impacts measured potential significantly. A fixed distance was achieved by the design and fused deposition modelling of a small housing for the samples that guide the insertion of the probes, as shown in Fig. 4.

#### B. Testing

Testing the material's electrical resistance response to high strain rate was performed using a Kolsky (Split-Hopkinson) (Fig. 5). The Kolsky bar was manufactured in house [3] and was used to subject the material to high strain rates. MATLAB was used for system control, and a National Instruments USB-6351 DAQ device was used for data acquisition.

After the probes were inserted in the sample and connected to current and voltage source meters following the four-wire connection, the sample was sandwiched between the incident and transmitted bars of the Kolsky bar, as shown in Fig. 4.

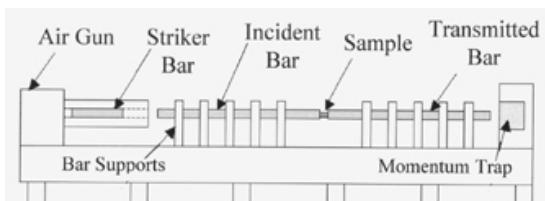

Figure 5. Kolsky (Split-Hopkinson) Bar Schematic

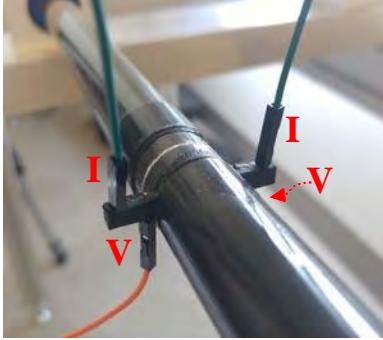

Figure 6. Sample Setup on Kolsky Apparatus

The air-gun pressure was kept constant at 100 psi for all tests to approach reproducibility of results. The DAQ was synced with the trigger through a MATLAB code such that it started collecting data from the strain gauges and the sample the moment the trigger on the Kolsky bar was pulled. The data sampling went on for 5 s from the moment the trigger was pulled.

### III. RESULTS AND OBSERVATIONS

#### A. Composite Production

The sheets of composite produced were checked for quality to ensure samples were as uniform as possible. First, the surface of the sheet was inspected for cavities caused by trapped air. Second, the sheets were cut in different areas, and the cross-section was inspected for cavities as well. Since the material is black, imperfections within each sample were hard to detect nondestructively. However, a method used to test the uniformity of the sample ensured that the initial resistance of the samples was within the same range. In that way, samples with significant imperfections were eliminated.

We faced several challenges during the production process. First, the chloroform had to be completely evaporated from the material before it was cast. Any remaining chloroform would threaten the chemical purity of the composite, leading to incorrect results. Excess chloroform also affects the physical structure of the final composite. If chloroform exists in the material casted, it will quickly evaporate inside the mold because of the high curing temperature. This creates cavities at the surface of the casting and affects its physical structure, as shown in Fig. 7(a).

Achieving good results depended on trial and error. It took three attempts to finally arrive at a reliable process that produced good-quality sheets of PDMS with CNTs. The sheets produced were free from surface and body imperfections according to our visual inspections. Fig. 7(b) shows a successfully produced sample. Samples were laser cut from these sheets for testing.

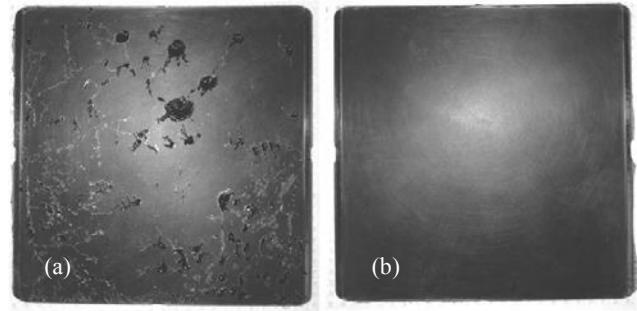

Figure 7. (a) Incomplete Chloroform Evaporation. (b) Complete Chloroform Evaporation.

#### B. Test Results and Observations

Dynamic tests were conducted on five samples for each concentration of CNTs in PDMS. The results obtained were found to be consistent and exhibited similar trends. However, only data from one representative set of samples are presented here.

Fig. 8 shows the voltage measured from the sample during the initial moments of impact. The normalized voltage from the strain gauges on the incident and transmitted bars is also shown and represents the stress waves propagating through the system. Early observation of the CNT–PDMS plot shows a spike in voltage reaching up to 2.5 times the initial voltage. Moreover, the voltage was found to rise in steps that are synced with the propagating stress waves in the system. Furthermore, the sample voltage was observed to lag half a period behind the incident wave and was in phase with the transmitted wave.

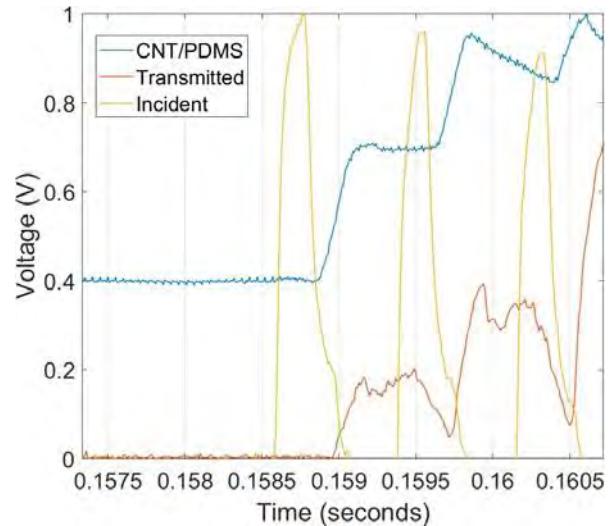

Figure 8. Transmitted and incident voltage output. (1 wt. %sample)

Fig. 9 shows the resistance change within the sample plotted against the strain. The stress-strain curve of the material is also plotted on the graph to emphasize the observed correlation. The change in resistance aligned with the stress/strain curve of the sample, indicating a strong correlation between electrical resistance and applied stress on the material.

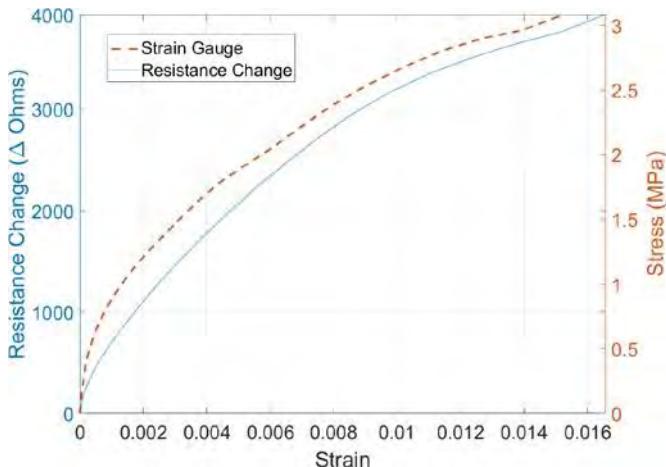

Figure 9. Strain Gauge and Resistance Change vs. Strain at Initial Contact

Fig. 10 shows the change in resistance within samples of different CNT concentration plotted against time. The observed rise in resistance was consistent at all three concentrations. However, we observed that increasing the CNT concentration in samples led to smaller resistance changes within them. The rate at which the resistance of the composite changed decreased when CNT concentration in the PDMS increased.

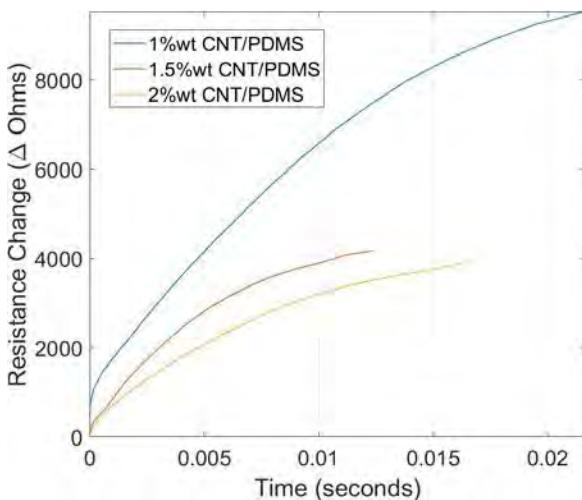

Figure 10. Resistance Change with respect to time for different CNT/PDMS weight percentage.

#### IV. CONCLUSION

The effect of high strain rate on the piezoresistive properties of elastomeric composites shows promise in the potential development of high strain rate sensors. The results show a strong correlation between high strain rate and electrical resistance, indicating piezoresistive behavior in the material.

The elastomeric composite was prepared using Sylgard 184 PDMS and MWCNTs. The material was sonicated to break down the CNT chains and agglomerations. Our results show that chloroform functioned well as a solvent for the purposes of dispersing CNTs in PDMS. A custom press casting mold was developed to efficiently cast sheets of the material that were then laser cut to produce the samples for dynamic testing using the Kolsky bar. During tests, the current through the material was controlled, and the voltage and strain were measured.

The electrical resistance was found to spike upon loading with a lag of half a period relative to the incident wave and in-phase relative to the transmitted wave. The slow recovery of voltage indicates viscoelastic behavior in the material [4]. The magnitude of the peak resistance was found to be 2.5 times the initial resistance, which represents the signal to be detected. The peak value was found to be directly related to the strain rate (as further research will show). By detecting this peak, we hope to determine the strain rate through means of statistical analysis. This research has proven the potential of CNT-impregnated elastomers for the development of impact force sensors. Future work includes further testing on the material to confirm preliminary results and gather enough data to build a robust statistical model. The goal of the model is to generate stress values from the input, the measured electrical resistance across the material.

#### ACKNOWLEDGMENT

The authors gratefully acknowledge the generous financial support of Lassonde School of Engineering (York University) and NSERC–Quanser Chair in Design Engineering.

**Abstract**— This paper presents a methodology for designing hard compaction rollers for an automated fiber placement (AFP) head with a hot gas torch heating system for laying thermoplastic carbon fiber reinforced plastic (CFRP) tapes. Some manufacturing defects and alternative designs are reviewed to highlight the importance of AFP compaction roller conformity and surface adhesion. The formulation of a general parametric description of the design challenge is derived and adequately addresses the problem on a tow-to-tow basis.

**Keywords:** *Automated Fiber Placement; CFRP; compaction roller*

## I. INTRODUCTION

Manufacturers of aircrafts widely use CFRP to produce large parts, such as airfoil covers and fuselages. An example of such is the use of automated fiber placement manufacturing to produce Boeing's 787 Dreamliner's fuselage [3]. AFP is a highly flexible and effective process for manufacturing parts at a high rate of production. However, with parts of increasing geometrical complexity, there are difficulties for a single roller with fixed geometry to provide uniform pressure to compact the tape onto the surface of the part. It is necessary either to have a conformable roller that can adjust its geometry to fit the geometry of the surface of the part, or to have multiple rollers with different geometries that correspond to the geometries at different locations of the part. The objective of this paper is to introduce a methodology for designing hard AFP compaction rollers.

## II. THERMOPLASTICS MANUFACTURING DEFECTS AND LITERATURE SURVEY

The quality of the final product is highly dependent on a number of manufacturing parameters, such as temperature, pressure and lay-up speed (see Fig. 1). Within the context of this study, pressure and consolidation during the manufacturing process are the primary concerns.

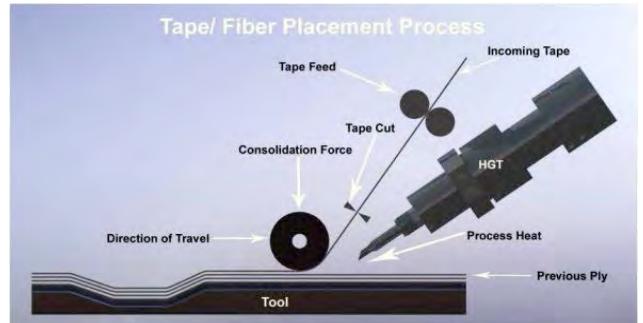

Figure 1. Fiber Placement Illustration (photo courtesy of Automated Dynamics)

During the manufacturing process pressure is applied after temperature is increased. The sustained pressure during the solidification phase of the process prevents the fiber network from springing back [1]. Under adequate pressure, suppressing fiber spring back minimizes voids that exist between individual layers. Pressure also plays a critical role in the development of intimate contact between plies, which in turn is an important parameter for autohesion. In the most severe case, inadequate conformity between the AFP compaction roller and the mandrel's surface can dramatically reduce pressure applied to the CFRP tape and localize the force (see Fig. 2).

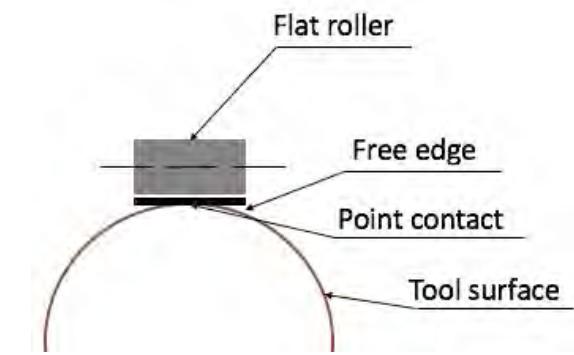

Figure 2. Illustration of lack of roller and mandrel curvature conformity

Denkena, Schmidt, and Weber introduced a modular AFP laying head in 2016, which includes a unique set of height adjustable compaction rollers that are pneumatically controlled, thus increasing the flexibility of the design (see Fig. 3) [2]. The compaction rollers used are made of a flexible material, as it is best suited for thermoset CFRP manufacturing, and heating is done with a laser. Qualitatively, experiments conducted have validated the effectiveness of the compaction unit both on flat and contoured surfaces. For thermoplastic manufacturing that employs a hot gas torch heating element, hard rollers are better suited to perform the task.

NASA's Phase II SBIR program led to the development of a number of innovative conformable compactors [4]. Research published by Lamontia, Gruber, Waibel, Cope, and Hulcher included a study on defects caused by poor compactor to surface conformity as well as the design of a highly conformable compaction system. This study highlights that when compactors lack sufficient conformity with the tool surface, the time/temperature/pressure requirements for high-quality laminates are not fulfilled due to the concentration of forces exerted on high points of the tape [4]. An example of one of the high conformity compactor designs can be seen in Figure 4. This design features 76 heated segments that are covered in shims, which protect the fibers during manufacturing. The compactors were constructed and tested, however the authors did not report the results of those experiments in their study.

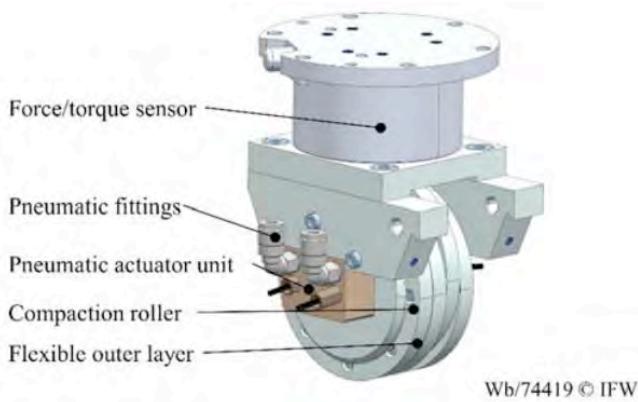

Figure 3. Modular Compaction Unit [2]

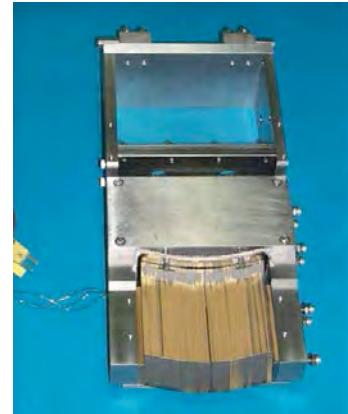

Figure 4. Hot line compactor featuring 76 heated segments [4]

To the best of the author's knowledge there exists very little research describing an approach to designing hard compaction rollers for thermoplastic CFRP manufacturing; this is the motivation behind the study.

### III. METHODOLOGY

A cylindrical mandrel with a radius of  $R_s$  and a compaction roller with a profile radius of  $R_i$  was used to formulate a general equation to describe the adherence of the two components: with  $R_i > R_s$ . A local coordinate system was positioned at the center of the cylinder. However, in Fig. 5 the axes are translated onto the surface of the tape to better describe their directions:  $x$  (normal to the surface),  $y$  (transverse to the layup direction) and  $z$  (in the layup direction).

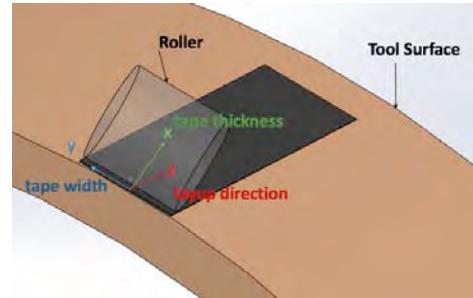

Figure 5. Coordinate System (shifted)

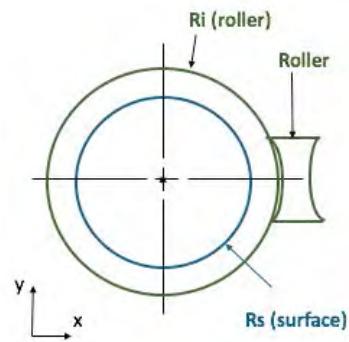

Figure 6. Concentric circles in design space

In the XY plane, the roller's profile and instantaneous curvature at the tool's surface was represented by two concentric circles centered at the origin (see Fig. 6). Compression of the tape during manufacturing can be modeled by translating the circle of smaller curvature,  $R_s$ , by  $\Delta X$ . The value of  $\Delta X$  is such that the tape is at its minimum thickness under compression,  $C$ . The aforementioned variable can be determined experimentally.

$$\Delta X = (R_i - R_s) - C \quad (1)$$

With reference to Fig. 7, a number of variables are needed in order to fully describe the distance of the gap that lies between the roller and the mandrel, at the edge of the tape. These are given in Table 1. The angle  $\theta$  (either for the roller or for the surface) is given by,

$$\theta = \sin^{-1} \frac{w}{2R} \quad (2)$$

The coordinates of the contact point between the roller and the edge of the tape can be described as,

$$\begin{bmatrix} x_i \\ y_i \end{bmatrix} = R_i \begin{bmatrix} \cos(\theta_i) \\ \frac{w}{2 \cdot R_i} \end{bmatrix} \quad (3a)$$

The coordinates of the contact point between the mandrel surface and the edge of the tape are,

$$\begin{bmatrix} x_s \\ y_s \end{bmatrix} = R_s \begin{bmatrix} \cos(\theta_s) \\ \frac{w}{2 \cdot R_s} \end{bmatrix} \quad (3b)$$

As previously mentioned  $R_s$  has to be translated by  $\Delta X$ , the result is a new set of variables ( $x_s'$  and  $y_s'$ ).

$$\begin{bmatrix} x_s' \\ y_s' \end{bmatrix} = \begin{bmatrix} x_s \\ y_s \end{bmatrix} + \begin{bmatrix} \Delta X \\ 0 \end{bmatrix} \quad (4)$$

The gap between the roller and the surface of the mandrel at the edge of the tape is,

$$t = x_i - x_s' \quad (5a)$$

$$t = R_i \cos(\theta_i) - [R_s \cos(\theta_s) + (R_i - R_s - C)] \quad (5b)$$

$$t - C = R_s(1 - \cos\theta_s) - R_i(1 - \cos\theta_i) \quad (6)$$

The quantity ( $t - C$ ) represents the lack of desired compaction. The condition  $t/C = 1$  represents optimal compaction, while  $t/h = 1$  represents no compaction. If an allowable minimum compaction (say  $t/h = \alpha$ ) is specified, then the profile of the roller can be designed such that  $C < t < \alpha \cdot h$ .

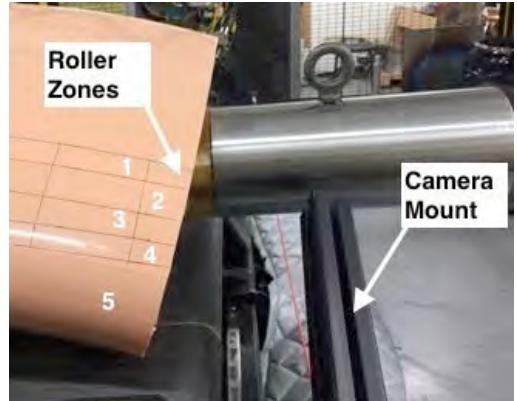

Figure 7. Boundary conditions of roller curvature

#### IV. EXPERIMENTAL INVESTIGATION

The set up used for preliminary experimental investigations is seen in Fig. 7. The mandrel's surface is divided into 5 segments, each with a unique range of surface curvature, and 6 compaction rollers were manufactured. An extruded T slot bar was fixed onto a tripod and the assembly was positioned such that the camera's lens is parallel to the subject being captured.

Images were then processed using ImageJ. Fig. 8 depicts an area of 16,362 pixels which serves as a reference when calculating the percentage of the total area occupied by the gap, if any exists. The aforementioned gap area was calculated by drawing a perimeter encapsulating the gap using ImageJ's polygon tool, see Fig. 9.

The results recorded in table II highlights the successful application of equation 6, since the rollers conform well within their intended range of surface curvatures, e.g. roller 1 conforms to segment 1. In addition, it was observed that even in the least severe case, when the gap area was only 1.5% of the reference area, the gap distance,  $t$ , measured in ImageJ exceeded the thickness of the CFRP tape (0.127mm).

#### V. CONCLUSION

A methodology for calculating an appropriate hard compaction roller profile curvature for a given tool surface curvature, used during thermoplastic AFP processing, has been presented. Equation 6 can be used to guide the design of compaction rollers for geometries of varying curvatures.

Initial experimental investigations validate equation 6 based on the conformity study that was performed in section IV. Future investigations include using the rollers to manufacture a CFRP component on the same mandrel and study manufacturing defects. The manufacturing process will consist of stopping the AFP head when a particular roller no longer adequately conforms to the tool surface and changing it for a more appropriate compaction roller.

**Abstract**—The effect of Minimum Quantity Lubrication (MQL) on performance of Friction Stir Welding (FSW) process for Aluminum Alloy 6061-T651 plates was investigated. MQL was used as a cooling and lubrication medium. Five different levels of rotational speed and three feed speed ranges with and without MQL were tested. The effect of MQL on the mechanical properties of the weld joints was studied throughout means of Ultimate Tensile Strength (UTS) tests. Statistical analyses were run to study the relationship between certain process parameters and response. The results showed that the average UTS of the welds is improved when MQL was applied to most of the process variables. The highest UTS was achieved at spindle speed with 1600 rpm and with feed rate 180 mm/min due to improvement of the grain growth.

## I. INTRODUCTION

Over the past decade, manufacturing companies have been forced to consider the environmental and social effects of their products instead of only focusing on economic benefits. Sustainability implies dealing with more than simply analyzing and modifying the performance of manufacturing processes as related to the environment. Aluminum is promising for the automotive industry because of its high strength/weight ratio, emissions, safety, corrosion resistance, and sustainability [1]. Unfortunately, high thermal and electrical conductivity of aluminum alloys are problematic in fusion and resistance welding [2]. The researchers have investigated relevant aspects, such as FSW method mechanics, metallurgical evolution of the material, the material flow, and bonding conditions. They have

focused on finding effective welding variables for various materials to optimize the performance of the joints [3].

The friction stir welding process (FSW) avoids the usual problems that occur when using conventional welding to join low melting point materials or dissimilar materials. In FSW, metals are welded without attaining the melting temperature of the metals. During the FSW processes, the rotating probe slowly moves into a butt joint line between two rigidly clamped plates or sheet metals as shown in Figure 1.

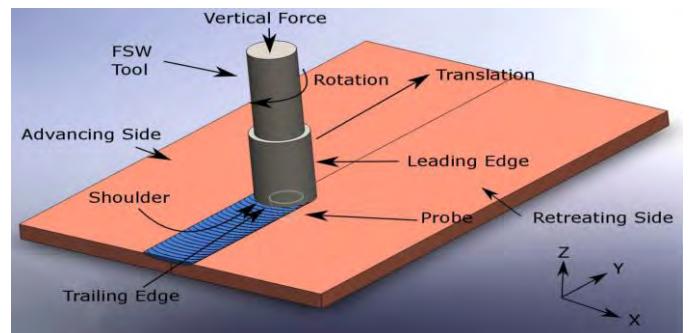

FIGURE. 1: SCHEMATIC ILLUSTRATION OF FRICTION STIR WELDING

FSW processes were first applied on aluminum alloys because of their low melting temperatures, and were found to be an effective technique. Improvement of the strength of common friction stir welded joints is possible through careful control of temperature. In several solid-state welding techniques, external liquid cooling has been used to improve weld performance. Frictional contact between the workpiece and the tool shoulder, while the tool is traveling, will generate heat; usually, the temperature is about 80 to 90% of the melting temperature of the materials [4].

There are several parameters in FSW that can be employed to control the process. These include spindle speed, feed speed, tool geometry, and tilting angle of the tool. Cooling strategies are one of several possible techniques to enhance the properties of the friction stir welding process. Several studies have investigated the effect of cooling strategies on the properties of friction stirring tools and the FSW joints.

As a new and sustainable method of lubrication and cooling, MQL optimizes the use of metalworking fluids [5]. The MQL process replaces regular lubrication methods, resulting in more sustainable manufacturing processes, thus acting as an achievement-oriented technology. This process has been widely verified as a near-dry process with respect to human health, cost, and environmental friendliness. The MQL process uses a small quantity of oil and sprays of compressed air. As a cooling system it is used for many manufacturing processes, but has not previously been used for FSW. Because MQL uses small amounts of highly biodegradable and environmentally friendly oils, it has promise as a sustainable manufacturing process.

The main objective of this research is to study the effect of the MQL scheme on the FSW process and the joints of AA 6061-T651 within appropriate process parameters.

## II. METHODOLOGY

### A. Experimental Design

The present study uses a full factorial experimental design (FFD) to achieve the response measurements. A statistical analysis of variance (ANOVA) test is conducted to determine the corresponding importance value of the input variables. Straightforwardly, the objective of the ANOVA test in this study is to distinguish which process variables are significant, and to determine the contribution of each variable. To compare pairs of treatment means and to find which process variable has a significant effect, the Fisher Least Significant Difference (LSD) method is used with 95% confidence. For analyzing the results, Minitab software was utilized to investigate the statistical analysis. Five different levels of rotational speed and three feed speed ranges are applied in this study, in addition to the coolant lubrication strategies in two levels as shown in Table (1).

TABLE I. : FSW PROCESS CONDITIONS

	1000	1300	1600	1900	2200
<b>Spindle Speed (rpm):</b>					
<b>Feed rate (mm/min):</b>	100	180	260		
<b>Coolant Lubrication Strategies:</b>	Dry	MQL system			

### B. Experimental Setup

The FSW processes in this study will use 3.175 mm plate sample thickness of AA 6061-T651 cut into  $65.5 \times 56.5$  mm workpieces. Table 2 shows the typical mechanical properties of AA 6061-T651.

TABLE 2: THE MECHANICAL PROPERTIES OF AA 6061-T6 [6]

Ultimate Tensile strength (MPa)	Tensile strength (MPa)	Yield strength (MPa)	Elongation (%)
260-310	228-283	193-262	10-11.62

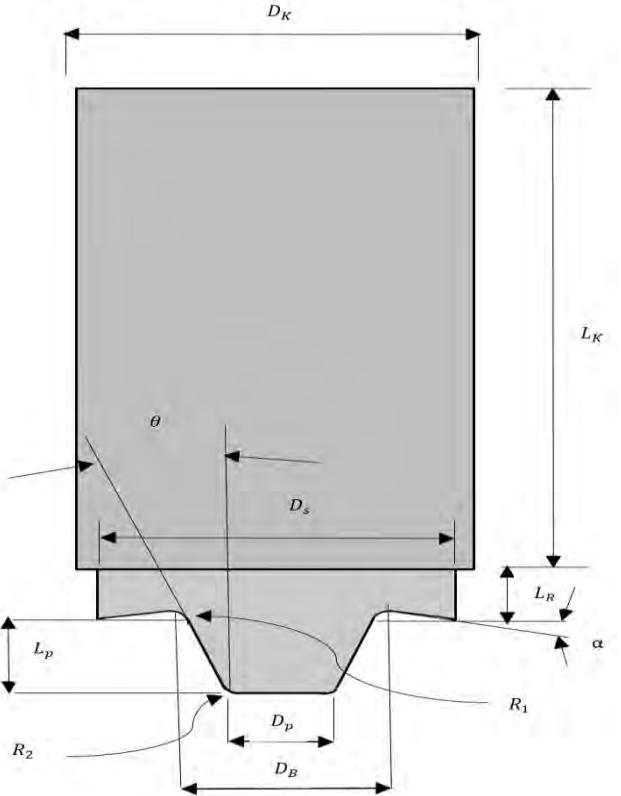

FIGURE (2) DEMONSTRATES THE GEOMETRICAL DIMENSIONS OF THIS TOOL.

FIG. 3: MQL SYSTEM

In this study, the tools are manufactured from A2 tool steel due to its resistance to thermal fatigue, cracking, and high toughness. The pin is a smooth trapezoidal cylinder, containing no threads, tapers, or other welding enhancement designs as shown in Figure (2).

To enhance the FSW process characteristics, the MQL process is applied in this study. Figure (3) explains the micro lubricating MQL system that is used with different variables. This system using a micro-pump which deliver too small amounts of oil. The vegetable oil that will be used is rapeseed oil, and ECOLUBRIC E200.

The specimens are machined from each welded plate subjected to tensile testing with geometry according to ASTM standards, using a dog bone shape in a sample of 32 mm gauge length. Tensile testing is applied to each weld at room temperature and perpendicular to the weld direction using an Instron-type tensile testing machine. Three samples are machined from each welded plate. For each sample prepared, ultimate tensile strength and efficiency are calculated, and the results are averaged.

### III. DATA ANALYSIS

Table (6) shows the ANOVA test for the UTS of the welded metals. This analysis is conducted at a confidence interval of 95%. As the P-value is zero for the spindle speed and the feed rate factors, they have significant effects on UTS results. As shown in the table, the lubricant factor is not independently significant. This might be because it has only two levels, while it is observed that the interaction of the lubricant factor with the spindle speed factor and feed rate factor has a significant effect. This reflects the importance of the types of the lubricant on the spindle speed and feed rate. Additionally, there is a significant effect of the triple interaction between the spindle speed, feed rate, and the lubricant.

TABLE (6): ANOVA TEST RESULTS FOR TENSILE STRENGTH

<b>Source</b>	<b>DF</b>	<b>Adj SS</b>	<b>Adj MS</b>	<b>F-value</b>	<b>P-Value</b>
<b>Spindle Speed</b>	4	110916	27729	601.09	0
<b>Feed Rate</b>	2	9524	4762.1	103.23	0
<b>Lubricant</b>	1	18	17.7	0.38	0.537
<b>Spindle Speed*Feed rate</b>	8	7993	999.1	21.66	0
<b>Spindle Feed</b>	4	3902	975.5	21.15	0
<b>Rate*Lubricant Spindle Speed *Feed</b>	2	2209	1104.4	23.94	0
<b>Rate*Lubricant</b>	8	4609	576.1	12.49	0
<b>Error</b>	90	4152	46.1		
<b>Total</b>	119	143322			

Note: DF: The total Degree of Freedom, Adj SS: Adjusted sums of squares, Adj MS: Adjusted mean squares.

Table (7) shows the Fisher pairwise comparisons of the effect of the spindle speed levels on UTS. The spindle speed with 1600 rpm records the highest UTS, which significantly differs from 1900, 2200, and 1000 rpm respectively; while

there is no significant difference between 1600 and 1300 rpm. Also, the levels of 1300 and 1900 rpm are significantly different from 2200 and 1000 rpm. As tool spindle speed increases more than 1600 rpm, the resulting higher temperature cause to wider Heat Affected Zone, that leading to reduction in tensile strength at the jointed area. Also, the friction produces progressively more intensive stirring and mixing of the metal workpiece from lower to upper surface, thus decreasing the tensile strength. This means that any future study can rely on these levels for optimization or economic concept.

TABLE (7): FISHER TEST RESULTS FOR SPINDLE SPEED OF UTS

<b>Levels (rpm)</b>	<b>N</b>	<b>Mean</b>	<b>Grouping</b>
<b>1600</b>	24	205.19	A
<b>1300</b>	24	196.85	AB
<b>1900</b>	24	187.38	B
<b>2200</b>	24	160.34	C
<b>1000</b>	24	121.46	D

The feed rate factor has recorded the highest effect on the UTS at 180 mm/min as shown in Table (8), which presents the Fisher pairwise comparisons of the feed rate levels on UTS. As Fisher test of the feed rate factor, 180 mm/min has a significant effect on the tensile strength. The heat generated is reduced when the feed rate becomes higher because the interaction time between the material and FSW tool is decreased; that the reduced heat generation might produce the formation of a tunnel defect inside the insufficient metal flow of the bottom region. Thus, when the feed rate is increased, correspondingly, the tensile strength properties also increase to a maximum at 180 mm/min.

TABLE (8): FISHER TEST RESULTS FOR FEED RATES OF UTS

<b>Levels(mm/min)</b>	<b>N</b>	<b>Mean</b>	<b>Grouping</b>
180	40	186.60	P-Value
100	40	170.18	I
260	40	165.94	I

### IV. CONCLUSIONS:

This study investigated the effect of MQL on the welding properties of AA 6061-T651. Statistical analysis is conducted to achieve the influence of controlled factors on the tensile strength. According to the ANOVA results, the following conclusions may be drawn:

1. The controlled parameters, spindle speed and the feed rate, have a significant effect on weld joint strength.
2. The interaction of lubricant factor has a significant effect with the spindle speed factor and feed rate factor, which means that the lubricant depends on the value of these factors.
3. The spindle speed with 1600 rpm records the highest UTS, it might be because of finer grain size produced at this spindle speed.

4. The feed rate factor has recorded the highest effect on the UTS at 180 mm/min.

# Review Paper on Digital Manufacturing & Design

Mukhtiar Singh

Department of Mechanical Engineering,

Lovely Professional University

Jalandhar - Delhi G.T. Road, Phagwara, Punjab 144411

mukhtiarts@gmail.com

**Abstract**—The transformation is happening through digital manufacturing and design (DM&D) – a shift from paper-based processes to digital processes in the manufacturing industry. As technology is having a huge impact on the ways products or services are designed & manufactured. Ever increasing customer demands for newer products with better features is transforming the dynamic of manufacturing towards embracing digital technology. Mass customization of products and services is preferred over mass production. There is an increased pressure upon businesses to serve an individual customer at a competitive cost comparable to the mass production cost, with shortest possible development time and production by focusing on levels of customization, quality and performance along with competitive price and value. With the advancements made in Information Technology, Material Science, Production Technologies and Supply Chain Strategies for the past 50 years' manufacturers are well positioned to challenge the traditional methods the products are designed and manufactured. Digital manufacturing and design encompasses visualization, manufacturing simulation, ergonomic and human factor analyses, holistic view of product and process design, development and product design sensitive to the process constraints and capabilities. The next stages of the new era and next Industrial Revolution termed as INDUSTRY 4.0. This article is all about defining a transformational shift from conventional methods of manufacturing to Digital Manufacturing adopting factors like Digital Thread, Advanced Analysis, Intelligent Machining, Security in Manufacturing, Model based system Engineering and reconfigurability in manufacturing systems etc

**Keywords-** Digital Manufacturing & Design, Digital Thread, Intelligent Machining, Digital Manufacturing Security, Cyber Security, Model Based System Engineering

## I. INTRODUCTION

The manufacturing environment radically changed over the last decades as manufacturing companies strived to improve their performance in a globalized, interconnected and volatile market environment. Manufacturing companies in the 21st century face increasingly frequent and unpredictable market changes driven by global competition, including the rapid introduction of new products and constantly varying product demand. Traditional approaches of dedicated

production lines, although still in use/practice, are becoming irrelevant with changing market requirements such as; increases in product demand, product changes, such as the introduction of a new product in the line, and system failures, such as a machine breakdown, in a cost effective or timely manner. In a highly competitive market and high volume manufacturing, such as automotive, the introduction of automation and information and communication technologies (ICT) on the shop floor, supported by digital manufacturing tools, has led to more flexible production systems which are capable of dealing with the volatile market demands and having a mixed product flow. Digital Manufacturing & Design is a platform for exploring new methods for manufacturing product. Digital manufacturing evolved from manufacturing practices such as design for manufacturing (DFM), flexible manufacturing (FM), lean manufacturing (LM) and computer-integrated manufacturing (CIM) which requires the collaboration across process and product design. The first Industrial Revolution, began in mid-1800s represented the transition from manual production to mechanical production, empowered by outfitting of water and steam power control [1]. The Second Industrial Revolution came at the beginning of the 20<sup>th</sup> century with the advancement of methodologies that empowered large scale manufacturing, including the mechanical production system [2]. The Third Industrial Revolution, otherwise called Digital Revolution, represented the advances made conceivable via robotization as mechanical and simple advances offered approach to computerized gadgets between the 1950s and the 1970s. The Fourth Industrial Revolution which is also called Industry 4.0 is the succeeding stage in the development of manufacturing.

The cyber capabilities resulting from advances in computing combined with physical systems to have enabled a highly intelligent, SMART (Sustainable Manufacturing and Advanced Robotics Technologies) machines that integrates design, and produces robotized manufacturing ecosystem [3]. The Formal definition of Manufacturing is the way towards changing over the crude materials, segments, or parts into completed products that meet a client's desires. Manufacturing is the most tangible part of the product lifecycle because it results in a clear outcome [4].

In recent years, industrial nations around the globe have invested heavily in new technologies, software, and services to advance digital design and manufacturing using cyber-physical systems, data analytics, and high-performance computing for optimum product and process design. In product life cycle stages, design begins in an abstract fashion with conceptual design and concludes with detail design, where final detailed part specifications are created. The subsequent step of the process is to take the product from a design and develop it. This stage includes defining the items that need to be manufactured and how they will be created and assembled. In product design and development process, production prototypes are created and checked to see if they meet performance and cost requirements. As well as long term production capabilities are established [5]. Next stage is support stage where once produced and purchased by the customer, the product must still be supported. The support stage of the lifecycle is where you provide the customer with information to assist in the effective use of the product and maintain the operational performance of the product. Product's lifecycle ends with disposal and recycling. The dispose state of the lifecycle draws on information from the design and build phases to understand the composition and what portions of a product can be recycled into future applications [6]. The dispose stage may also play a crucial role in iterating the design to further develop a product that meets performance expectations and that can be disassembled at the end of life. With the possibilities of many iterations, multiple opportunities for improvement have been identified for traditional design and manufacturing processes over the time. In a product's lifecycle, many iterations may be required before customer approval is received.

There are various challenges associated with traditional paper bases processes as in paper based processes, information sharing can consume valuable time and delay the development process. In traditional processes, there is also a lag during and in- between stages in the lifecycle as necessary approvals are sought [7]. Sometimes, this can even result in losing first-to-market competitive advantage. Another challenge in paper based processes is that maintaining a single source of true information for product and process definitions is very difficult and can limit the capabilities for data analysis and evidence based decision-making. Frequent communication gaps can result when planned changes are made during design and development process, as well as after the production launch. To address all these issues a new approach called digital manufacturing is most appropriate. The concept of digital manufacturing is an integrated suite of tools that work with product definition data to support tool design, manufacturing process design, visualization, modelling and simulation, data analytics, and other analyses necessary to optimize the manufacturing process as this approach uses advanced computing power to optimize the product lifecycle. [8]. Digital manufacturing allows you to more efficiently and commandingly share information in the design process.

The term Digital thread refers to the communication framework that allows a connected data flow and integrated view of the asset's data throughout its lifecycle across traditionally siloed functional perspectives can be used to create a computer based digital twin which is an integrated system of data, models, and analyses that can be used in design, manufacturing, support, and disposal. The concept of digital thread is very useful in designing smart manufacturing which strives to orchestrate and optimize business, digital and physical processes across factories and the entire product value chain. The digital thread also provides a formal framework for controlled interplay of authoritative technical and as-built data with the ability to access, integrate, transform and analyze data from disparate systems throughout the product lifecycle into actionable information. This whole idea is called as the Fourth Industrial Revolution, Industry 4.0 [9].

## II. PRODUCT LIFECYCLE & CHANGE TRANSITIONED

Product lifecycle refers to all the stages of a product concept design to disposal and recovery. Product lifecycle can be seen from different points of view. All in all, item lifecycle covers three primary stages: start of life, including outline and assembling; center of life, including use, administration, and upkeep; at last the end of life, these products are re-collected, arranged, dismantled, re-manufactured, reused, & disposed [10]. Different organization have different motivations to collect product lifecycle data. A couple of them are transparency, business assessment, change, and estimating. Full transparency empowers both the purchasers and producers to settle on better educated choices [11]. Cases of transparency incorporate the arrival of the nourishment data on sustenance items and the arrival of natural effects data on products to customers. With a specific end goal to have transparency, we have to gather and offer information of various parts of an item or venture. Another motivation to collect product lifecycle data is to use data for business evaluation and improvement [12]. Continuous improvement requires continuous evaluation of the business process from different aspects. Continuous evaluations require continuous collection of data to evaluate [13]. By collecting data, the enterprise management is able to forecast valuable information. An example of this is when an enterprise collects the market trends to predict future market demands. Another is when an enterprise collects the energy usage of an industrial machine to predict its failure. As we just learned, the product life-cycle covers three main phases: beginning of life, middle of life, and end of life. The information flow during the beginning of life is quite complete and is collected using different information management systems, such as computer-aided design, or CAD models, computer-aided manufacturing, or CAM systems, and product data management or PDM systems [14]. The information flow becomes less complete after the beginning of life cycle. In fact, the information flow is stopped after product is delivered to a consumer for the majority of today's consumer products such as household

appliances and vehicles. This is because after products are delivered to consumers, the ownership of product is no longer with companies and is transferred to customers, therefore, it is not easy for companies to track product usage data generated by consumers. As a result, decision makers involved in each phase of a product lifecycle make decision based on an incomplete and inaccurate product lifecycle data from other phases, which in many cases result into inefficient decisions. Product lifecycle data can be categorized under static data and dynamic data [15]. Static data is mainly generated at the beginning of life phase and rarely changes during the lifetime of the product. Examples of static data are bill of materials, material content, take back information, disassembly instruction, return policies, and recycling information. Static data is fairly complete and can be collected through existing data management systems. The dynamic information incorporates mainly the information created during usage phase. Cases of progression information which utilize designs, natural conditions, and adjusting activities [16]. Dynamic information is regularly lost and is hard to acquire during product lifecycle. Product lifecycle have numerous applications. Assume that organizations can track and follow product utilization information produced by buyers & consumers [17]. Companies could gain substantial business advantages if they use product usage data to improve their products and optimize relevant operations [18]. For example, lifecycle acquisition can be used to enable product-related services. Product lifecycle data is valuable and can be used to facilitate the service delivery such as maintenance, repair, and after-sales services. It is particularly important in the aviation industry. In aviation industry, capital equipment, and products have long service lives and complex configurations [19]. The productivity of the business is not just from the offers of capital gear and flying machines, yet from keeping up them for an expected 30 or more-year life expectancy. Along these lines, upkeep and repair organizations mean to limit support cost and turnaround time to boost income. Because of the many-sided quality of the framework, robotized data recovery and item structure data can help organizations effortlessly recognize their potential disappointments and acquire the data essentially for part repair and tooling plan. Gathering item lifecycle information is a spine for an incorporated enterprise.

Data standards are very useful to establish a relationship between two different datasets to create information or connect machines from different manufacturers. They specify a consistent data format so that the data can be shared and transformed into usable information. Some examples are, STEP and IGES, are data standards for sharing product design data like geometry [20]. MT Connect is a standard that supports the capture and sharing of information from machining equipment. Mil Standard 31000A and A SME 1441 define ways to share product model information using a technical data package to support the product life cycle.

### III. DIGITAL THREAD

From the initial concept, products evolve through a regular sequence of plan, design, build, support, and dispose. During each of these stages, a colossal measure of information is produced. Although traditionally, much of it has not been captured, it can be processed into very valuable information that can impact the product life cycle in many different ways. A name's been given to describe all of the data generated in every part of a product's life cycle- the digital thread. The digital thread concept seamlessly integrates information through the value chain from requirements gathering through feasibility reviews, design, manufacturing, testing, and on to final sustainment and disposal phases. This means specialists, throughout the process, can work on the product, and process definitions simultaneously to inform decisions, through the life of a system or product. While promising, adoption of the digital thread was initially limited, but has continued to gain momentum. Like any paradigm shift, the digital thread approach is potentially disruptive, especially to organizations that do not have in house information technology resources [21]. For example, the information technology foundation for the digital thread has typically been viewed as overhead, simply a cost of doing business that needs to be shortened.

The digital thread paradigm views the IT infrastructure as an investment that will generate a return in increased effectiveness and responsiveness. A second challenge, facing the digital thread, is the transitioning profile of manufacturing jobs from skilled to smart or information workers that combine their expertise with physical systems, and the ability to work with the data generated in the production process [22]. This change will more tightly link production staff with the design process. Giving them more opportunities to impact the design of a product that they create. A third challenge facing the digital thread implementation is natural. How do we keep the information secure? Traditional processes used physical documents that could be controlled and locked up. There's a natural resistance to putting valuable intellectual property in digital form, especially as retailers seemingly report intrusions on a regular basis. Information security is a key component of the digital thread, and as we all see, is incorporated from the beginning [23]. Sharing data and information between different functions and systems of the product life cycle can add significant value to the entire development process. Some examples are, faster product launches, clearer communication between suppliers and manufacturers, resulting in fewer errors, reduced rework and scrap. Reduced inventory in the supply chain. Reduced unit product cost which increases profit margin. And even the expansion to additional markets. All around, the techniques by which products are composed and fabricated are progressing at a quick pace just directly in front of us. Traditionally processes, checked and controlled by people, are presently being controlled and observed by brilliant sensors and actuators in this new era of manufacturing [24].

Intelligence of a system can be perceived as the capability of the system to achieve a goal or to sustain desired behavior in business of uncertain conditions. In context of manufacturing, intelligent machining is a criterion in which machine tools can identify their own states and the environment in which they are operating, and can execute start, control, and terminate machine activities [25]. In other words, intelligent machines are self-worth and can make decisions related to assembling processes. The intelligent machining worldview is empowered to the coordination of keen sensors and controls. Advances in sensor technologies and automated data systems, provide new opportunities for real time collection of valuable measurements that can be converted into actionable data to make smart decisions [26].

The data acquisition and management module is comprised of the data aggregator component, a data post processor, and a data buffer component. The data aggregator component collects time synchronized raw data from external sensors. Since the data generated from different sensors can be in different formats, they need to be transformed into single format to enable it to be processed into information. Data aggregators allow for this interoperability [27]. Empty connect, is an example of industry standard data aggregation agent that allows for data aggregation. Data processor processes the collected data into suitable data formats that can be used by machine learning algorithms to make smarter decisions. Whereas, data buffer allows for data buffering so that the unwanted data can be erased at this point. The data buffer stores only relevant data that could be used by machine learning algorithms to generate actionable intelligence. Data buffers act where in between the data processing and machine learning algorithms and allows for efficient storage [28]. The data dividend machine learning and knowledge discovery module, uses the processed monitoring data to construct a data dividend prediction model for the target machine. The prediction model is used in conjunction with the data from past experiences to monitor and control the machining tool.

#### IV. ADVANCED MANUFACTURING ENTERPRISE

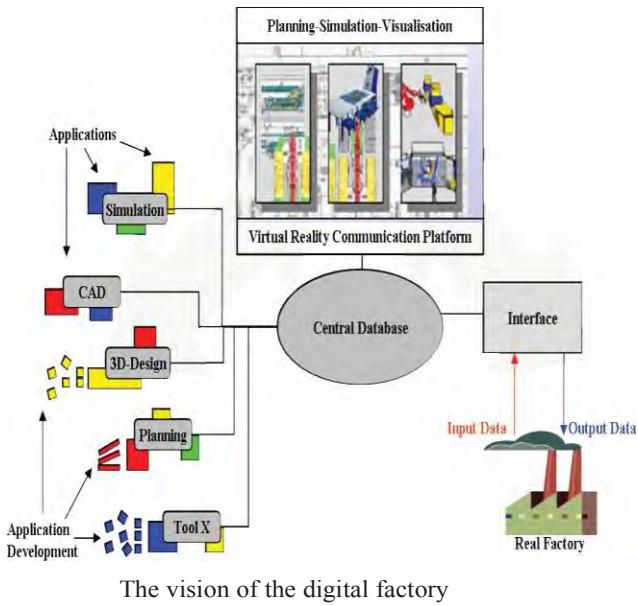

According to the National Institute of Standards and Technology, advanced manufacturing is an entity that makes extensive use of computer, high precision and data innovation incorporated with a superior workforce in a creation framework equipped for outfitting a heterogeneous mixture of products in little or huge volumes with both the productivity of large scale manufacturing and the adaptability of custom assembling so as to react quickly to client demands. Anderson Economy Group has defined advanced manufacturing as, operations that create advanced products, use innovative techniques in their manufacturing, and are inventing new processes and technologies for future manufacturing [29]. Advanced Manufacturing is not quite recently the work of robots

and cutting-edge forms yet in addition incorporates the assembling of imaginative items and utilization of innovative standards. Components of cutting edge producing are arranged under two primary classes, tangible and intangible components. Tangible elements of manufacturing systems include manufacturing processes, industrial control systems, industrial robotics, assembly systems, material transportation systems and storage systems. Intangible elements of assembling frameworks incorporate all arranging and administration part of the assembling firm, cases of cutting edge innovations incorporate Nano-fabricating, semiconductor, additive manufacturing and bio-producing.

#### V. DIGITAL MANUFACTURING SECURITY

Digital manufacturing via the digital thread requires the consideration of security in all domains including network, desktop, hardware, and software applications. Security is, in fact, an integral part of the overall digital manufacturing design since it involves various valuable intellectual property resources, which we call IP throughout this course [30]. And should not be confused with IP, an acronym used in computer networks to mean Internet protocols. These IP resources are mostly information such as hardware designs, machine control instructions, payroll transactions, or business deals. The leak of IP information can cause huge loss to your company. And therefore, IP needs primary attention while designing system security. Threats to IP, come from various sources that includes business competitors and state affiliated actors. The biggest threats to IP is the insider threat. Since insiders are the people with legitimate access to important information and hence, such threats are hard to detect. Therefore, in DMD security, we need different levels of security to provide restricted access to the information. Such access control will allow only certain authorities in the organization to access the IP information. Recent developments in digital manufacturing may be categorized into two major groups. The developments of the first group have followed a bottom-up approach considering digital manufacturing, and extending its concepts, within a wider framework e.g. the digital factory or enterprise. The developments of the second group have followed a top- down approach considering the technologies in support of individual aspects of digital manufacturing, e.g. e-collaboration and simulation. The digital factory includes models, methods, and tools for the sustainable support of factory planning and factory operations. It includes processes based on linked digital models connected with the product model. At a theoretical level, several researchers have contributed to the definition of the digital factory vision and suggested how this vision could be implemented in reality. From a technological point of view, new frameworks for distributed digital manufacturing have appeared on the scene. Recent developments focus on a new generation of decentralized factory control algorithms known as ‘agent based’. A software agent, first, is a self-directed object, second, has its own value systems and a means of communicating with other such objects, and, third, continuously acts on

its own initiative. A system of such agents, called a multi-agent system, consists of a group of identical or complementary agents that act together. Agent-based systems encompassing real-time and decentralized manufacturing decision-making capabilities have been reported.

## VI. MODEL BASED SYSTEM ENGINEERING

The INCOSE systems engineering handbook points to three meaningful definitions of systems engineering [31]. A complete definition - Systems Engineering is an integrative approach which intends to empower the recognition of acknowledged systems. It focuses on characterizing client needs and required outputs, in the development cycle. Documenting stipulations and then proceeding with design composites and system demonstration while considering the complete problem [32]. Operations, cost and schedule, performance, training and support, test, manufacturing and disposal [33]. It accommodates all the disciplines and specialty groups into a team effort framing a structure advancement process that proceeds from idea, to production, to operation. It additionally considers both the business and industrial needs of all clients with the goal providing a quality product that meets the consumer needs.

Systems engineering is a reiterative process of top down synthesis, reinforcement, and operation of a real-world system that satisfies, in near optimal manner, the full range of requirements for the system. From an operational perspective, System engineering is a development engineering that scrutinize on the design and operation of the entire framework as particular from the parts.

### A. System Engineering & Lifecycle

A system progresses through its life cycle as the result of actions. Performed and managed by people in organizations, using processes for execution of their actions. The life cycle stages used the standard are concept, development, creation, usage, support and retirement. Different models have emerged for managing the processes within and across life cycle stages [34]. The first life cycle model for systems engineering that is the waterfall model. The waterfall model is a specified, sequential process that follows a predetermined sequence. Waterfall is easily converted into schedules with deliverables, where the process flows downwards through all the stages that are required, concept, development, production, utilization, support and retirement. By its nature, in waterfall there is an embedded assumption that requirements are well understood and not likely to change during the execution of a project. The second approach is actually a class of methods. Incremental and iterative methods. Incremental and iterative methods have proven to be successful for small, simpler systems or elements of a system due to their focus on flexibility and judicious risk taking.

### B. Model-Based Definition

According to INCOSE, model-based systems engineering, also known as MBSE, is the formalized application of modeling to support system requirements, design, investigation, confirmation, and approval exercises starting in the reasonable outline stage and proceeding through advancement and later life cycle stages. Model-based systems engineering is still in a dynamic state of development and is a vast topic to fully address. As a result, this course is offering a broad perspective with connections throughout the course that give you the opportunity to learn more about a topic of interest. A key component of model-based systems engineering is the model-based definition, or MBD. Model-based definition embodies the concept of moving away from paper-based documentation and drawings to digital, 3D CAD representation, manufacturing data, and performance models. An example of the dynamic state of MBSE, the definition of MBD is still evolving and converging. Standards, like ASME Y 14.41, ISO 16792, and MIL-STD-31000, can provide guidance on how to annotate drawings. But multiple perspectives exist in regards to what makes up a model. The framework to use a model-based system a framework is required provides the guiding structure to implement analysis throughout the lifecycle of the product. An analysis framework connects a variety of simulation tools -- for example, Ansys, Nastran, MATLAB, and tools built in-house-in such a way that outputs of one analysis provide the input for subsequent analyses without human intervention. The Model-Based Systems Engineering (MBSE) framework is Siemens offering HEEDs. HEEDs provide a means of computationally exploring possible design alternatives in search of specific performance goals.

## VII. Cloud-based Design and Manufacturing

Cloud-based design and manufacturing (CBDM) refers to a service-oriented networked product development model in which service consumers are able to configure products or services and reconfigure manufacturing systems through Infrastructure-as-a-Service (IaaS), Platform-as-a-Service (PaaS), Hardware-as-a-Service (HaaS), and Software-as-a-Service (SaaS) [35]. In the IaaS model, cloud service providers offer on-demand access to computing resources such as virtual machines and cloud storage. In the PaaS model, cloud service providers deliver computing platforms such as social collaboration platforms, programming and execution environments for cloud computing. In the HaaS model, cloud service providers and consumers are enabled to rent and lease manufacturing equipment such as milling machines and 3D printers. In the SaaS model, cloud service consumers are enabled to run computationally expensive application software such as AutoCAD remotely without installing and running the software on their local computers [36]. Cloud-Based Design (CBD) refers to a networked design model that leverages cloud computing, service-oriented architecture (SOA), Web 2.0 (e.g., social network sites), and semantic web technologies to support cloud-based engineering design services in distributed and collaborative environments. Cloud-Based Manufacturing (CBM) refers to a networked manufacturing model that exploits on-demand access to a shared collection of diversified and distributed manufacturing resources to form temporary, reconfigurable production lines which enhance efficiency, reduce product lifecycle costs, and allow for optimal resource allocation in response to variable-demand customer generated tasking

## VIII. CONCLUSIONS

Digital Manufacturing & Design creates a product at speed beyond human imagination. The DMD domain is inspired by a detailed thread of product, handled information and data, which brings about significant protected innovation. Industries can reduce their paper based processes to digital process which at last will lead in increase in productivity. When development of product was made initially in 8 to 9 months now had been reduced to 20 to 30 days and this is digital manufacturing. DMC will become a platform used by millions of people daily. Users can easily add their own manufacturing recipes and examine their works in their own web browsers. The digital thread is networked at several functions and levels in order to enhance efficiency and effectiveness.

DMD reduces the effects on the supply chain by transparently sharing efficiency information, whether man, machine, materials, or methods, throughout the supply chain. Increasing supply chain confidence between tiers, reducing excess inventory that's contained within the supply chain, and allowing for realizing more efficient and agile supply chain models. Data analytics ideas have taken into account the development of new assembling ideal models including the smart manufacturing, social assembling and cloud based

manufacturing. Digital manufacturing incorporates technologies for the virtual representation of factories, buildings, resources, machine systems equipment, labor staff and their skills, as well as for the closer integration of product and process development through modelling and simulation Closing the gap between the product definition and the actual manufacturing production activities within the enterprise, fully transforming tacit manufacturing knowledge into tangible, and, finally, digital knowledge, optimizing data management, and developing standard models are some key priorities.

**Abstract**—A novel three-dimensional finite strain visco-hyperelastic constitutive model is proposed to capture the strain rate dependency of rubber-like materials. The overall material behavior is defined by cumulative description of hyperelasticity and non-linear viscoelasticity. The hyperelastic part is based on exponential logarithmic Hart-Smith strain energy function and the viscous part comprises of a fading integral which links the current stresses to the applied strain history. The derived analytical framework is verified with respect to experimental data. The potential of the proposed model has been constituted by an excellent fit between proposed model and considered test data.

**Keywords**—Rubber-like materials, Strain rate, Visco-hyperelasticity, Constitutive modeling

## I. INTRODUCTION

Rubber-like materials undergo large deformations at relatively low stresses and recover their initial shape upon removal of the load. This exceptional ability makes them suitable and without a doubt irreplaceable materials in vital engineering applications. This uncommon behavior is caused by the underlying coiled long chain polymer molecules. These chains straighten when the material is stretched and recoil upon removal of the load. This substantial aspect contributes towards their extraordinary mechanical behavior and makes rubbers a strain rate dependent material. This rate dependency is associated with the rearrangement of the molecular chains [1].

Rubber viscoelasticity can be described by two distinct theories: a) Linear viscoelasticity b) Non-linear viscoelasticity. To summaries, linear viscoelasticity models are constituted by considering parallel and/or series arrangements of elastic springs and linear viscous dash-pots. These rheological analogies are superimposed by Boltzman's principle and the relaxation function is approximated with a prony series formulation[2], [3], [4]. Whereas, the non-linear viscoelastic constitutive relations are formulated by employing generalized fading history integral function [5], [6]. In this approach, an approximation of matrix stress functional defines the strain history on stresses.

In order to prescribe time dependent response of the elastomers, quasi-linear viscoelastic frame work requires to be represented by 4-6 term prony series approximations. As a result, large number of material constants are needed to be determined [7], [8], [9]. In contrast, the number of material constants can be reduced by articulating nonlinear viscoelasticity. Moreover, numerical implementation of such formulations is a straightforward procedure and the material parameter identification is comparatively less time consuming task. For that reason, a novel power-exponential strain history functional has been proposed in the nonlinear finite strain visco-hyperelastic framework to capture rate dependency in various types of elastomers. For the purpose of validation, derived constitutive relations are compared with the literature based high strain rate experimental data for polyurea [10].

## II. CONSTITUTIVE MODEL DEVELOPMENT

### A. Hyperelasticity

Hyperelastic constitutive laws are derived from strain energy density  $W$ . It expresses the stored elastic strain energy in material per unit reference volume as a function of the principle strain or stretch invariants.

$$W = f(I_1, I_2, I_3), \quad (1)$$

Where  $I_1$ ,  $I_2$  and  $I_3$  are the invariants of left Cauchy-Green tensor ( $B = FF^T$ ) defined as:

$$\begin{aligned} I_1 &= \text{tr}(B) = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 \\ I_2 &= (\text{tr}B)^2 - \text{tr}B^2 = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2 \\ I_3 &= J = \sqrt{\det(F)} = \sqrt{(\lambda_1^2\lambda_2^2\lambda_3^2)} \end{aligned} \quad (2)$$

Cauchy stress in an incompressible hyperelastic continua is given by[11]:

$$\sigma^e = -p^e I + 2 \left[ \left( \frac{\partial W}{\partial I_1} + I_1 \frac{\partial W}{\partial I_2} \right) B - \frac{\partial W}{\partial I_2} B^2 \right] \quad (3)$$

where where  $p^e$  is a hydrostatic pressure term which needs to be determined from boundary conditions and  $I$  is an identity

tensor. Time independent behavior of elastomers is characterized using Hart-Smith strain energy [12] as it provides distinctive advantages in modeling finite strain hyperelastic materials due to its exponential form[13], [14], [15], [16].

$$W_{HS} = C_1 \int \exp(C_3(I_1 - 3)^2) dI_1 + 3C_2 \ln \frac{I_2}{3} \quad (4)$$

Here  $C_1, C_2$  and  $C_3$  are model parameters and need to be determined from experiments.

Let us consider an in-compressible {i.e.  $J = 1$  in eq.(3)} material deformation under uniaxial extension mode. If the stretch in the loading direction is denoted by  $\lambda$  then the deformation gradient  $F$  for this loading becomes:

$$F = \begin{bmatrix} \lambda & 0 & 0 \\ 0 & \lambda^{-0.5} & 0 \\ 0 & 0 & \lambda^{-0.5} \end{bmatrix} \quad (5)$$

Consequently the invariants are depicted as:

$$I_1 = \lambda^2 + 2\lambda^{-1}, I_2 = \lambda^{-2} + 2\lambda \quad (6)$$

From eq. (3) and (4), we arrived to uniaxial stress-stretch relation as:

$$\sigma_{11}^e = -p^e + 2\lambda^2 \left( \frac{I_1 C_2}{I_2} + C_1 \exp^{C_3(I_1 - 3)^2} - \frac{C_2 \lambda^2}{I_2} \right) \quad (7)$$

Then after, the hydrostatic pressure term  $p^e$  is calculated by applying uniaxial loading condition  $\sigma_{22}^e = \sigma_{33}^e = 0$

$$\sigma_{22}^e = 0 = -p^e + \frac{2}{\lambda} \left( \frac{I_1 C_2}{I_2} + C_1 \exp^{C_3(I_1 - 3)^2} - \frac{C_2}{\lambda I_2} \right) \quad (8)$$

Finally, by substituting the expression for  $p^e$  into eq(7); the we derived incompressible uniaxial hart-smith stress-strain law as:

$$\sigma_{11}^e = 2(\lambda^2 - \lambda^{-1}) \left[ \frac{I_1 C_2}{I_2} + C_1 \exp^{C_3(I_1 - 3)^2} - \frac{(\lambda^2 + \lambda^{-1}) C_2}{\lambda I_2} \right] \quad (9)$$

### B. Viscoelasticity

The generalized constitutive relation for non-linear incompressible viscoelastic material behavior is given by[17]:

$$\sigma^v = -p_v I + F(t) \cdot \prod_{\tau=-\infty}^t \{C(\tau)\} \cdot F(t)^t \quad (10)$$

where  $\sigma^v$  is time dependent cauchy stress tensor,  $p$  is the hydro-static pressure term also called Lagrange Multiplier and  $\prod$  is a strain history function given by:

$$\prod_{\tau=-\infty}^t \{C(\tau)\} = \int_{-\infty}^t \Phi(I_1, I_2) m(t - \tau) E(\dot{\tau}) d\tau \quad (11)$$

In equation (11),  $\Phi(I_1, I_2)$  is the function depending on invariants of strain tensor  $C$  and the strain rate  $E(\tau)$  is defined as:

$$\dot{E} = \frac{1}{2} (\dot{F}^T F + F^T \dot{F}) \quad (12)$$

$m(t)$  is a relaxation function which is represented by a series of exponential series functions as

$$m(t) = \sum_{i=1}^N \exp \left( -\frac{t - \tau}{\theta_i} \right) \quad (13)$$

where  $\theta_i$  is the relaxation time. Several researchers have assigned  $N$  values greater than/equal to 2 in their work[18]. In order to reduce the number of material constants with single relaxation time scheme i.e.  $N = 1$ , we are proposing a novel suitable representation of the function  $\Phi(I_1, I_2)$  as:

$$\Phi(I_1, I_2) = E(\dot{\tau})^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \quad (14)$$

The starting point for the time integration is at the instant when loading commences. It is assumed that the effect of deformation history for  $\tau < 0$  on the stress at time  $t > 0$  is negligible. Thus, the period of deformation history which is considered to effect the stress response and hence the limits of integration in the second term on the right-hand side of Eq.11 becomes  $[0, t]$  rather than  $[-\infty, t]$ .

Substituting Eqs. 14 and 13 with  $N=1$  into Eq. 11 results in the following proposed integral approximation for  $\prod$

$$\prod = \int_0^t \dot{E}^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \exp \left( -\frac{t - \tau}{\theta_1} \right) \dot{E} d\tau \quad (15)$$

Substitution of eq.(15) into eq.(10) yields a finite strain viscoelastic model for incompressible materials as

$$\sigma^v = -p_v I + F \cdot \left[ \int_0^t \dot{E}^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \exp \left( -\frac{t - \tau}{\theta_1} \right) E(\dot{\tau}) d\tau \right] \cdot F^t \quad (16)$$

### C. Visco-hyperelasticity

Visco-hyperelastic behavior is generally introduced by aggregating hyperelasticity and viscocity i.e.  $\sigma = \sigma^e + \sigma^v$  [18], [19].

$$\sigma = -p I + 2 \left[ \left( \frac{\partial W}{\partial I_1} + I_1 \frac{\partial W}{\partial I_2} \right) B - \frac{\partial W}{\partial I_2} B^2 \right] + F \cdot \left[ \int_0^t \dot{E}^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \cdot \exp \left( -\frac{t - \tau}{\theta_1} \right) E(\dot{\tau}) d\tau \right] \cdot F^t \quad (17)$$

where  $\sigma$  is the total stress and  $p$  is the total hydrostatic pressure incorporating static and viscoelastic components. Inserting  $\dot{E}_{11} = \lambda \dot{\lambda}$  into eq.(17) concludes the uniaxial stress as:

$$\sigma_{11} = -p^v + \sigma_{11}^e + \lambda^3 \int_0^t (\lambda \dot{\lambda})^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \cdot \exp \left( -\frac{t - \tau}{\theta_1} \right) \dot{\lambda} d\tau \quad (18)$$

By applying uniaxial loading condition that  $\sigma_{11} = 0$  into eq.(18),  $p^v$  is formulated as:

$$p^v = -\frac{\lambda^{-1}}{2} \left[ \int_0^t \lambda^{-2} (\lambda \dot{\lambda})^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \cdot \exp\left(-\frac{t-\tau}{\theta_1}\right) \dot{\lambda} d\tau \right] \quad (19)$$

Replacing  $p^v$  in eq(18), we derived the uniaxial stress-deformation expression as:

$$\begin{aligned} \sigma_{11} &= \sigma_{11}^e + \lambda^3 \int_0^t (\lambda \dot{\lambda})^{A_1} \cdot A_2 \cdot \exp(I_2 - 3)^{A_3} \cdot \\ &\exp\left(-\frac{t-\tau}{\theta_1}\right) \dot{\lambda} d\tau + -\frac{\lambda^{-1}}{2} \left[ \int_0^t \lambda^{-2} (\lambda \dot{\lambda})^{A_1} \cdot A_2 \cdot \right. \\ &\left. \exp(I_2 - 3)^{A_3} \cdot \exp\left(-\frac{t-\tau}{\theta_1}\right) \dot{\lambda} d\tau \right] \end{aligned} \quad (20)$$

### III. VERIFICATION OF PROPOSED MODEL

We have considered experimental data reported by Roland et. al [10] for verifying derived analytical results. They have performed uniaxial tensile test on polyurea from moderate to high strain rates using drop weight apparatus. The hyperelastic

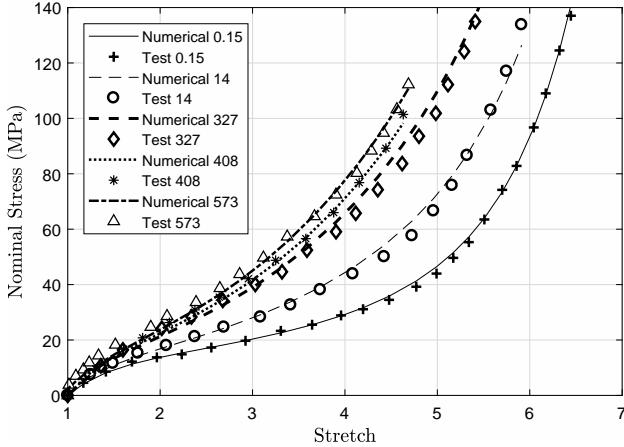

Fig. 1: Comparison of Roland et. al [10] data with proposed model

Hart-Smith material parameters are determined with respect to quasi-static (in this case  $0.15 \text{ S}^{-1}$ ) experimental data. The detailed procedure for parameter identification is described in [13]. Where as the material parameters for the viscoelastic part has been derived by considering test data for the strain rates of  $14 \text{ S}^{-1}$  and  $573 \text{ S}^{-1}$ . These required material constants have been optimized using non-linear least square function "Fmincon" in MATLAB (see Table I). Fig. (??) demonstrates an excellent agreement between the proposed model results and the experimental data. Notably, the model is adequate to predict the material response for the rates of  $327 \text{ S}^{-1}$  and  $408 \text{ S}^{-1}$  accurately even though the relevant experimental data have not been considered for the material parameters identification.

TABLE I: Optimized material parameters

Hyperelastic model			Viscoelastic model			
$C_1$	$C_2$	$C_3$	$\theta_1$	$A_1$	$A_2$	$A_3$
0.4474	12.79	8.1E-4	5.4E-3	-0.7355	259.89	0.05

### IV. CONCLUSION AND FUTURE WORK

To summarize, a novel visco-hyperelastic material law has been proposed to capture rate dependency in elastomers by adopting generalized non-linear viscoelasticity. Analytical stress-strain relations are derived for uniaxial tension mode. An excellent agreement between numerical results and experimental data reported by Roland et. al [10] has been obtained. Also, the predictive capability of the model has been demonstrated. Following the promising findings, the conducted work will be extended by considering broader spectrum of experimental data. The developed model will be implemented in commercial finite element code via user defined subroutine to analyze complex geometries and loadings.

### V. ACKNOWLEDGMENT

The authors would like to acknowledge Dr.Taisiya Sigaeva for her assistance in the implementation of hyperelasticity. The grants provided by Lassonde School of Engineering and NSERC Quanser Chair in Design Engineering are thankfully acknowledged.

**Abstract**—In this paper we review different definitions of Modal Participation Factor (MPF) available in the literature and propose a simple classification and unified concept for their application with particular focus in aerospace engineering. A case study is presented to aid the reader understand under what conditions each definition of MPF applies, its physical interpretation and which definitions have the potential to act as response tracking mechanisms during design optimization.

**Keywords:** *modal participation factor, modal contribution factors, dynamic analysis, mode tracking*

## I. INTRODUCTION

In practice, complex structures must be analyzed under a large set of dynamic operating conditions to ensure that the design will meet prescribed functional requirement.

During design optimization, a relatively small number of such operating conditions are selected as critical and are used to minimize or maximize the objective function. However, the dynamic response is strongly dependent on the physical characteristics of the structure and thus the use of a deterministic set of critical operating conditions may lead to unexpected behaviors. To monitor inexpensively the behavior of the design space during optimization, a response tracking mechanism based on MPFs could lead to large computational savings and improve the optimization process by considering the variations of the response of the design space as the design evolves.

MPFs have been used in the past as response tracking mechanisms in several engineering disciplines. For instance, Keong et al. [1] tracked a targeted mode during the design optimization of a head suspension assembly by defining a participation factor that resembled the most to the mode of interest. In the field of civil engineering, MPFs have been widely used to approximate the dynamic response of buildings without performing any dynamic analysis [2-13]; this procedure was later on applied in aerospace for the case of a cantilever wing model [14].

The concept of MPF, however, seems to be ambiguous. A simple search of the words “modal participation factor” in the open literature quickly reveals that several variants of this

concept exist. For instance, in electrical engineering [15-18] the term MPF refers to the product between the left and the right eigenvectors; other researchers [19-22] used simple definitions for MPF such as the same term to refer to the components of the eigenvector matrix. On the other hand, [23-28] defined different convenient mathematical forms as modal participation factor suitable to their specific applications.

This significant variation in the definitions of MPFs is also conveys into a wide range of applications. For instance, Wallrapp & Wiedemann [29] computed a quasi-static modal solution and a corresponding participation factor to assess the importance of each mode retained in the solution; Chung-Band and Young Bahng [30] utilized a participation factor based on modal strain energy to identify dominant modes; Van Lagenhove & Brughmans [31] reviewed three kinds of MPFs as methods to identify the best location for sensors to correlate a Finite Element Model (FEM) with experimental results. Similarly, other researchers [32, 33] used different definitions of MPFs to correlate experimental with numerical results.

In this paper, we propose a unified concept and a simple classification of the different mathematical definitions of modal participation factors found in the literature. A case study is presented to aid the reader to understand under what conditions each definition applies, its physical interpretation and which definitions have the potential to act as response tracking mechanisms during design optimization.

## II. MODAL CONTRIBUTION FACTORS

The complex behavior of a dynamic structure can be decomposed into a set of simple harmonic motions  $q_i(t)$ , also known as modal responses, linearly coupled with amplitude ratios. This transformation is achieved by finding the so-called natural frequencies,  $\omega_r$  and mode shapes,  $\Phi_r$  that satisfy the characteristic equation (i.e., the undamped free vibration problem) and applying the following variable change:

$$u(t) = \Phi q(t) \quad (1)$$

Where  $u(t)$  is the nodal vector of physical displacements, and  $\Phi$  is the matrix of eigenvectors. Expanding (1) in a summation form we obtain:

$$u_n(t) = \phi_{n,i}q_i(t) + \dots + \phi_{n,i}q_i(t) \quad (2)$$

From (2), the **modal contribution** can be defined as the quantity of movement that each mode contributes to the total nodal response [34-37]. In other words, it is the product between the modal response  $q_i(t)$  and the amplitude ratio  $\phi_{n,i}$ , denoted here with the Greek letter gamma ( $\gamma$ ).

$$\gamma_{n,i}(t) = \phi_{n,i}q_i(t) \quad (3)$$

All definitions of modal participation factors aim to rank the relative importance of  $\gamma_{n,i}$ , nevertheless, these definitions can be subdivided in two classes. The first class (Class I) is derived from the equations of motion and it's commonly known as static modal participation factors (SMPF). SMPFs have the potential to be used as a reanalysis tool since they predict the magnitude of  $q_i$  [42-51]. The second class (Class II) is intended solely to assess the relative importance of a mode within the solution of a system response.

We should make emphasis on the term “relative importance of a mode”, since the interpretation of the results obtained from the second class of participation factors is dependent on its mathematical definition, as discussed below in section IV.

### III. CLASS I

The amplitude of a modal response can be expressed as the product of a constant called modal participation factor  $\Gamma_i$  and a time dependent term  $D_i(t)$  [7,14,36,37].

$$q_i(t) = \Gamma_i D_i(t) \quad (4)$$

Though in general the time history of the response may be of interest, it is the value of the maximum displacement that will be used to designing or optimizing a structure. The maximum value of the response  $u^0$  is directly proportional to the maximum dynamic response  $D^0$ .

$$u^0 = \Phi \Gamma D^0 \quad (5)$$

Where  $u^0$  is the vector of maximum nodal displacements,  $D^0$  is the dynamic amplification vector and  $\Gamma$  is the diagonal matrix of modal participation factors. To find appropriate expressions for  $\Gamma$  and  $D^0$  we resort to the definition of the SMPF.

We begin by decomposing the vector of external forces into two components: a time invariant vector  $f$  and a time dependent expression  $p(t)$ .

$$F(t) = fp(t) \quad (6)$$

The vector  $f$  can be expanded into a matrix of static forces  $f^s$  acting at node  $j$  in the mode  $i$ ; where the sum of the columns of  $f^s$  is equal to the magnitude of the  $j$ -th component of the vector  $f$  [14, 37].

$$f_{j,i}^{st} = \Gamma_{i,i} \phi_{j,i} \quad \begin{cases} \text{for } i=1,2,\dots, N \\ \text{for } j=1,2,\dots, n \end{cases} \quad (7)$$

where:

$$\Gamma = \text{diag}(\Phi^T f) \quad (8)$$

When the eigenvectors are mass normalized, the vector of total static displacement can be found by the use of Hooke's law:

$$u_j^{st} = \sum_{i=1}^N \frac{\Gamma_{i,i}}{\omega_i^2} \phi_{j,i} \quad \text{for } i=1,2,\dots, N \quad (9)$$

The vector of total static displacement can then be related to the vector of total dynamic displacements by introducing (9) into (2).

$$u_j^0 = u_j^{st} \omega_i^2 D_i^0 \quad (10)$$

Depending on the form of the excitation force  $p(t)$ , a particular method can be selected to find an analytical solution for  $D^0$ , as explained below.

#### A. Steady-state

From [36], a dynamic amplification factor  $R_i$  is defined as the ratio between the amplitude of the dynamic response  $D_i^0$  and the amplitude of the static response  $D_i^{st}$ .

$$R_i = \frac{D_i^0}{D_i^{st}} \quad (11)$$

Where the amplitude of the static response can be found by neglecting the contribution of the acceleration and the velocity terms in the well-known mass-normalized modal equations of motion.

$$D_i^{st} = \frac{1}{\omega_i^2} \quad (12)$$

And the dynamic amplification factor for an undamped single degree of freedom (SDOF) system is given by (13), when the unitary periodic function  $p(t)$  is equal to 1.

$$R_i = \frac{1}{(\omega_i^2 - \omega_0^2)} \quad (13)$$

By introducing (11-13) into (10) we find an inexpensive expression that allows to estimate the maximum amplitude of the nodal physical displacements during steady-state vibration.

$$u^0 = u^{st} R \quad (14)$$

To compare the output of this method with respect to others, a steady-state modal participation fraction  $L_i^{st}$  is defined in (15). This fractional number allows to compare the relative amplitudes of the modal responses  $q_i$  for a given design and loading condition.

$$L_i^{st} = \frac{|\Gamma_i D_i^0|}{\sum_i^N |\Gamma_i D_i^0|} = \frac{|\Gamma_i / (\omega_i^2 (\omega_i^2 - \omega_0^2))|}{\sum_i^N |\Gamma_i / (\omega_i^2 (\omega_i^2 - \omega_0^2))|} \quad (15)$$

#### B. Transient

The steady participation factors neglect the contribution of the transient components of the time domain solution. When the global maximum is of particular interest, we aim to estimate the maximum dynamic amplitude response.

$$D_i^{\max} = \max(D(t)) \quad (16)$$

The transient participation fraction  $L_i^{ts}$  can then be defined similarly to the steady participation fraction as the ratio between the maximum amplitude of the harmonic solution and the sum of the maximum amplitude of all the modes retained.

$$L_i^{ts} = \frac{|\Gamma_i D_i^{\max}|}{\sum_i^N |\Gamma_i D_i^{\max}|} \quad (17)$$

#### C. Internal loads Participation Factor

For point loads, the element internal force is computed as the product of the element stiffness matrix and the corresponding

displacement vector of the nodes that conform the element in the global coordinate system.

When the element and global coordinate systems do not coincide a rotation matrix,  $C^T$ , is necessary to ensure that the internal forces computed,  $N_e$ , are expressed in the element coordinate system.

$$N_e(t) = C^T K_e U_e(t) \quad (18)$$

Where  $K_e$  and  $U_e(t)$  are the element stiffness matrix and the vector of nodal displacements in the global coordinate system, respectively.

We can expand (18) into its modal components as:

$$N_e(t) = C^T K_e \Phi_e q(t) = C^T K_e \Phi_e \Gamma D(t) \quad (19)$$

The magnitude of  $\Gamma D(t)$ , determines the dominance of a mode in the solution, whereas the product  $\Sigma_e = C^T K_e \Phi_e$  determines the impact of such mode in the r component of the element load where  $r \in \{1:6\}$ . A participation factor can then be defined as:

$$L_{r,i}^{\text{load}} = \frac{|\Sigma_{e_r,i} \Gamma_i D_i|}{\sum_{i=1}^N |\Sigma_{e_r,i} \Gamma_i D_i|} \quad (20)$$

#### IV. CLASS II

The following definitions intend to assess inexpensively the relative importance of a mode and to ensure that a sufficient number of eigenvalues are retained to recover the solution in the physical domain. The most widely used definition is that of the modal mass participation factor, in practice modes with negligible modal effective mass are removed from the equations of motion, since its participation to the overall response is small [20,38].

However other definitions have been proposed, for instance, Wilson [25] used a mode participation factor similar to (8) to estimate which modes should be retained in a subsequent mode superposition analysis. Carlblom et al. [26] presented four criteria to select important modes during the dynamic analysis of rail vehicles, and recently, Kammer, et.al. [39] proposed a new definition to select important elastic modes in free-free systems. In the following subsections we present most common definitions found in literature relevant to structural analysis.

##### A. Modal Mass Participation Factor

The modal effective mass was initially derived for a single degree of freedom system subject to an enforced motion through the base. The reaction force at the base  $F_{\text{base}}$  due to the enforced acceleration  $\ddot{U}_o$  in the frequency domain is given by:

$$F_{\text{base}}(\omega) = m \left[ 1 + \left( \frac{\omega}{\omega_n} \right)^2 H \left( \frac{\omega}{\omega_n} \right) \right] \ddot{U}_o(\omega) \quad (21)$$

In this context the effective mass of the system is  $m$  and it is directly proportional to the reaction force at the base. Thus, a large modal effective mass indicates a large inertial force.

The above analysis has been generalized to unconstrained multi-degree of freedom systems (MDOF) through a Craig-Bampton transformation matrix [9, 38], and the resulting

equation is (22), where  $M$  is the mass matrix. This equation, relates the rigid-body (or unconstrained) modes  $\Phi^r$  with the elastic modes  $\Phi^e$ .

$$\Gamma^{\text{mm}T} = \Phi^r T M \Phi^e \quad (22)$$

We can prove that the product of the modal mass participation factors  $\Gamma^{\text{mm}}$  divided by the modal mass  $M_q$  is identical to the mass matrix of unconstrained degrees of freedom. This, expressed in component form is the so called modal effective mass  $M^{\text{eff}}$ .

$$M_{p,i}^{\text{eff}} = \frac{\Gamma_{p,i}^{\text{mm}T} \Gamma_{i,p}^{\text{mm}}}{M_{i,q}} \quad (23)$$

Where the subscript p indicates the number of unconstrained elastic degrees of freedom (DoF) and i is the number of modes retained in the analysis.

Though the definition of the modal effective mass has been derived using a free-free MDOF system, an important point should be kept in mind: the modal characteristics of the elastic degrees of freedom must be computed with respect to a boundary DoF, which should be constrained for the analysis [6, 8, 38]. Otherwise, the results extracted using the method described above are ill-founded and the participation of the elastic DoF's will tend to be zero.

Finally, for comparison purposes with other methods we can define an effective modal mass fraction  $L_{p,i}^{\text{mm}}$  as the ratio between the effective modal mass and the total mass of the system:

$$L_{p,i}^{\text{mm}} = \frac{M_{p,i}^{\text{eff}}}{\sum_{j=1}^n M_j} \quad (24)$$

##### B. Free-Free Participation Factor

Recently [39], presented a new definition to estimate the relative importance of each mode for a free-free system, based on the concept of Effective Interface Mass (EIM), commonly used in the dynamic analysis of subsystems that will be attached to larger assemblies.

The equations of motion for a dynamic free-free system in matrix form are described as:

$$\ddot{q}(t) + \omega_i^2 q(t) = \Phi^T f_p(t) \quad (25)$$

Using equation (1) to recover the physical displacements from (25) and solving for the physical acceleration, we obtain:

$$\ddot{u}(t) = \Phi \ddot{q}(t) = \Phi \Phi^T f_p(t) - \Phi \omega_i^2 q(t) \quad (26)$$

In (26), the modes that are strongly excited by the external force vector are, in consequence, expected to contribute strongly to the physical acceleration at the nodes. Thus, we can define a free-free modal participation factor  $\Gamma_i^{\text{free}}$  as the trace of the product between two eigenvectors.

$$\Gamma_i^{\text{free}} = \text{tr}(\Phi_i \Phi_i^T) \quad (27)$$

Since our interest lies in evaluating the relative importance of the elastic modes, the free-free participation factor  $L_i^{\text{free}}$  should be compared against the elastic degrees of freedom only.

$$\Gamma^{\text{elas}} = \text{tr}(\Phi^{\text{elas}} \Phi^{\text{elas}T}) \quad (28)$$

Thus, the free effective mass is defined as the fraction between the free-free modal participation factors and the trace of the product of the matrix of elastic eigenvectors.

$$L_i^{\text{free}} = \frac{\Gamma_i^{\text{free}}}{\Gamma_{\text{elas}}} \quad (29)$$

### C. Modal Strain Energy Participation Factor

Several authors [40-41] have proposed the use of the element modal strain energy  $MSE_{ei}$  as assessment criteria. The element modal strain energy is evaluated at each element stiffness submatrix  $K_e$  in the global coordinate system.

$$MSE_{ei} = \frac{1}{2} \Phi_{e,i}^T K_e \Phi_{e,i} \quad (30)$$

Furthermore, the authors in [40] defined a modal strain participation fraction as the ratio between the strain energy and the kinetic energy of the system in free vibration.

$$L_{ei}^{\text{MSE}} = \frac{\Phi_i^T K_e \Phi_i}{\Phi_i^T M \Phi_i \omega_i^2} \quad (31)$$

A large modal strain fraction at the element  $e$ , at the  $i$ -th mode indicates that the element is a major load carrying component for such mode. Thus, any structural modifications in that element will produce significant changes in the modal characteristics of the structure and vice versa.

## V. CASE STUDY

A simple 5-degree of freedom model was created to assess the performance of each of the methods described above. As shown in figure (1), the model consists of a five DOFs cantilever beam. Each beam element has a stiffness of 8700 [N/m] and a 5% modal critical damping is also considered.

The model is excited by a force  $p$  of magnitude 100 N applied at the 5<sup>th</sup> node with a periodic function and an excitation frequency of 5 rad/s as shown in (32). This analysis can be seen as a simplified aircraft wing under windmilling incident.

The modal equation of motion is solved in the time domain using Runge-Kutta's numerical method [52] and the result is presented in figure 2.

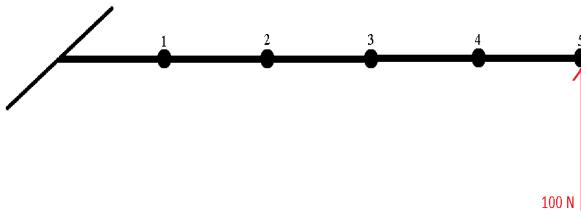

Figure 1. Case study: cantilever beam

$$p(t) = \sin(\omega t) \quad (32)$$

The modal steady-state  $L_i^{\text{st}}$ , transition  $L_i^{\text{ts}}$ , modal effective mass  $L_i^{\text{mm}}$  and free-free  $L_i^{\text{ff}}$  participation fractions are compute using equations (15), (17), (24) and (29), respectively, and the results are shown in figure 3. This figure gives an idea of the difference in magnitude obtained with each method, however the results should be interpreted independently.

Both, the steady-state  $L_i^{\text{st}}$  and the transition  $L_i^{\text{ts}}$  participation fractions are estimates of the amplitude of the modal response, therefore the percentage of participation is well in agreement with figure 2: the amplitude of the first mode is very large in comparison to that of the fifth mode for the given excitation frequency.

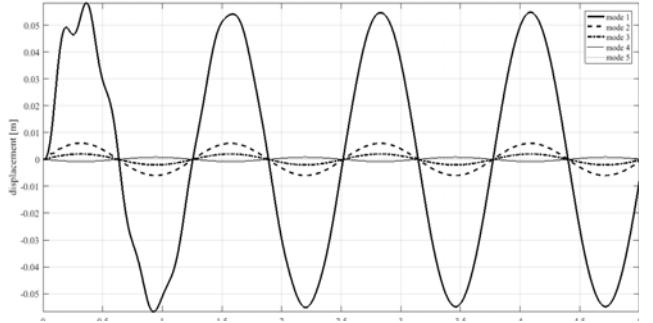

Figure 2. Modal response.

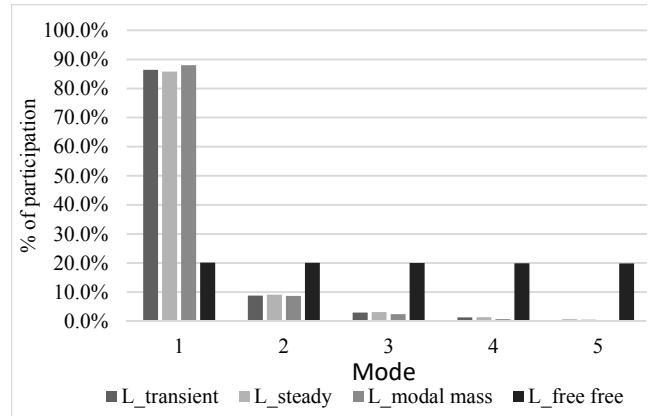

Figure 3. Modal participation factors.

The modal effective mass participation factor is also in agreement with figure 2, a large modal effective mass indicates that a particular mode has a large modal inertial component, and thus it is easier to excite.

The estimated free-free participation fractions are mostly in disagreement with the rest of the participation fractions computed, since its magnitude reveals that the participation of all modes is almost identical. Note that the definition of  $L_i^{\text{ff}}$  is simply the trace of the modal residues, i.e. how the node  $i$ -th responds to an excitation applied at the  $j$ -th node.

Using both, the steady-state and transition modal response participation factors, the contribution of each mode to the internal load was estimated using equation (20). The modal strain energy was also computed using equation (31). In order to compare the three sets of results, the values of each matrix were normalized with respect to the component with the largest magnitude and the results are displayed in figure 4.

Take for example figure 6 (d), according to the modal strain energy, it appears that the second mode becomes more relevant to the response of element 4, thus, any structural modification

that could impact the behavior of the second mode would also have a major impact in the magnitude of the load experienced by element 4. However, the results obtained using equation (32) are in disagreement with those of the modal strain energy, which indicates that the internal load is dominated by the first elastic mode.

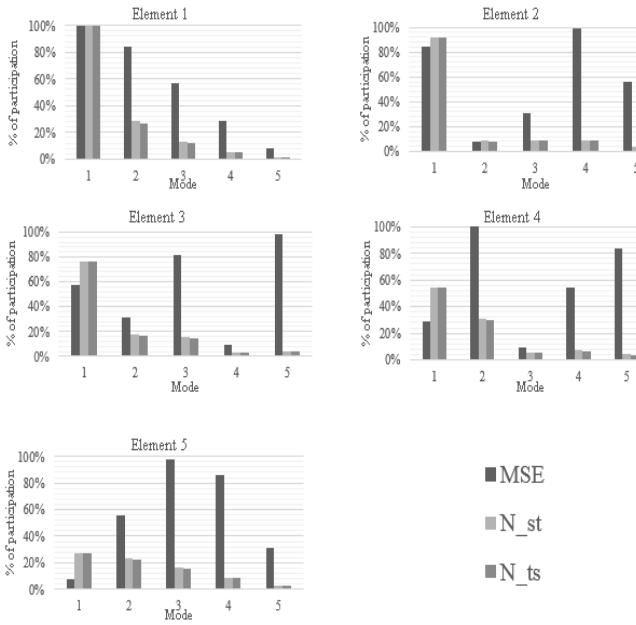

Figure 4. Internal load modal participation factors.

Using the steady and the transient modal response participation factors, the peak in plane shear force was recovered using equation (19) with (15) and (17), respectively. Table I shows a comparison and percentage error between the recovered load and the actual peak load computed using MSC NASTRAN [53].

TABLE I. PEAK SHEAR FORCE PER ELEMENT

Peak shear force per element					
Element	Actual Peak Load	Load $\Gamma_i D_i^{st}$	%error	Load $\Gamma_i D_i^{ts}$	%error
1	55.8422	51.9211	7.02%	60.3657	8.10%
2	55.2437	51.7904	6.25%	47.0600	-14.81%
3	54.1775	51.5293	4.89%	52.3115	-3.44%
4	52.6880	51.1385	2.94%	67.5420	28.19%
5	50.8545	50.6189	0.46%	37.18662	-26.88%

The percentage error of the steady-state modal response participation factors  $L_i^{st}$  is due to the omission of the transient terms. Since the peak load occurs during the transition period, the load recovered corresponds in fact to the actual steady-state in-plane shear force.

On the other hand, error of the peak load recovered using the transient modal response participation factor  $L_i^{ts}$  was found to be significantly larger. This is due to an implicit assumption in (16): the peak of all the modal responses are in phase, thus the method tends to either over or underestimate the value of the peak load.

## VI. CONCLUSIONS

The first class of modal response participation factors have the potential to be used as reanalysis tools. When the excitation force is periodic and the interest lies in solving for the steady-state response, the  $L_i^{st}$  fraction provides accurate results.

The second class of modal response participation factors are independent of the excitation and depend solely on the mass and stiffness distribution, in this sense, this type of factors should not be used as a measure of the relative amplitude of the modal responses. Instead, their application should be restricted, for example, in the case of the modal effective mass fraction, to determine the number of modes to be retained in the analysis (except when the model has an enforced acceleration through the base [2, 3]). Such methodology can serve as an inexpensive response tracking mechanism in complex structures during design optimization.

The modal strain energy, on the other hand, is an inexpensive expression that relates the mass and stiffness distribution of the structure to its modal characteristics. This expression can be useful to visualize and correlate how modifying the physical properties at element level can impact the behavior of a specific mode.

**Abstract**— Modeling of hypervelocity impact (HVI) on materials and structures is often associated with high computational expenses, especially when inhomogeneous materials are involved. To reduce computational cost, complex materials are often represented in modeling as homogeneous substances with the effective properties similar to those of the real materials. Although this approach has been successfully used in modeling of HVI on different materials with complex architecture, there are applications where it may not be applicable due to significant influence of materials' meso-scale features on resulting HVI damage. Two of such applications are considered in this study, and include simulation of HVI on sandwich panels with metallic foamcores, and composites fabricated by filament winding. In the former case, adequate modeling of the multi-shock action of the foam ligaments on hypervelocity fragment cloud propagating through the foam core requires an explicit representation of the foam geometry in numerical model. In the latter case, the meso-scale modeling is required due to experimentally observed dependence of HVI damage of the composite on the particular filament winding pattern used in its fabrication. The study presents numerical models developed for both of these applications and compares numerical results with obtained experimental data.

*Hypervelocity impact, orbital debris, advanced materials*

## I. INTRODUCTION (HEADING I)

Models for the simulation of impact behavior of different inhomogeneous materials have been described in the literature and implemented in commercial software packages, such as Autodyn, LS-Dyna etc. These models are often based on the homogenization of advanced materials with complex micro- and meso-structure, and their representation in the modeling as a macroscopically homogeneous media with effective properties equivalent to those of the real materials. Although computationally efficient, this approach may be too simplistic for some materials with meso-scale inhomogeneities. This paper considers two problems, where simulation of damage of inhomogeneous materials required meso-scale representation of

the materials' architecture. These examples are modeling of hypervelocity impact on a foam-core sandwich panel and simulation of HVI-induced damage in CFRP composites fabricated by filament winding.

Open-cell foam-core sandwich panels are considered by many researchers as a promising alternative to honeycomb-core panels in MMOD protection applications. For instance, in an experimental study presented by NASA [1], foam-core sandwich panels (FCSPs) with 25–30% lower areal density than HCSPs demonstrated better ballistic performance. In [2], it was determined that, depending on impact conditions, double-layer foam shields provided from 3 to 15% improvement in critical projectile diameter as compared to double-layer honeycomb shields of similar weight. The performance improvement in case of using the foams was not explained only as a result of the simple absence of cells that “channel” the fragment cloud. Rather, the radial expansion of fragment cloud and repeated impact of fragments on individual foam cell ligaments induced further fragmentation, melt, and vaporization of fragments [3].

Figure 1. Open-cell aluminum foam (left) and a fragment of a foam-core sandwich panel (right)

Material models implemented in commercial hydrocodes and recommended for simulation of impact on foams are represented, for example, by the LS-DYNA's \*MAT\_057 (\*MAT\_LOW\_DENSITY\_FOAM), \*MAT\_063 (\*MAT\_CRUSHABLE\_FOAM), and a set of equations of state for porous materials in AUTODYN (Crushable foam EOS, Compaction EOS, P-Alpha EOS). These and other available material models treat the foams as homogeneous materials and, therefore, a priori unable to represent multi-

shock interactions of foam ligaments with fragments of debris cloud propagating through the foam.

Composite fabricated by filament winding is another example of a material with the meso-scale inhomogeneity. This feature results from multiple interweavings of filament bands forming a filament-wound composite part. In space, these materials can be used in spacecraft propellant tanks (so-called composite overwrapped pressure vessels) and remote manipulator systems (e.g., Canadarm). Behavior of composites under HVI has been studied experimentally and numerically by many researchers, e.g. [4, 5]. However, most of the reported work was confined to the standard laminated composites and homogenization-based simulation techniques, whereas less attention has been paid to the filament-wound materials.

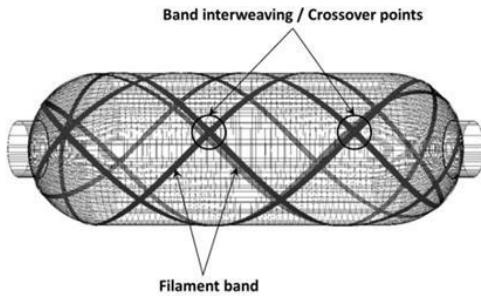

Figure 2. Filament winding

In filament winding, the carriage unit of a winding machine moves back and forth relative to the rotating mandrel and lays down on it the resin-impregnated fibers (towpreg) at a specific angle. Fibers are placed onto a mandrel in the form of filament bands, each containing few thousands of fibers. Fig. 2 illustrates the initial stages of filament winding. At each circuit (one back and forth pass of the carriage unit along a mandrel), filament bands are laid on a mandrel at “+” (forward motion) and “-” (back motion) angle. Each circuit results in crossovers between filament bands of “+” and “-” angle. The presence of crossovers is intrinsic to filament winding and forms its well recognizable patterns. The choice of a particular winding pattern is often up to a manufacturing engineer, as different patterns can be easily programmed using software supplied with the filament winding equipment (Fig. 3).

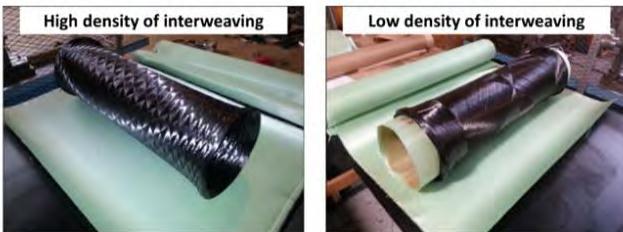

Figure 3. CFRP weaves of different winding patterns

Also, filament-wound composites contain two types of voids: voids internal to filament bands, and voids at the filament bands' crossover regions (Fig. 4). Voids of the latter type represent additional meso-scale feature of filament-wound composites. It is believed that they may result in stress concentration at crossovers leading to formation of cracks and preliminary disintegration of the filament wound composite when subjected to static or impact loading.

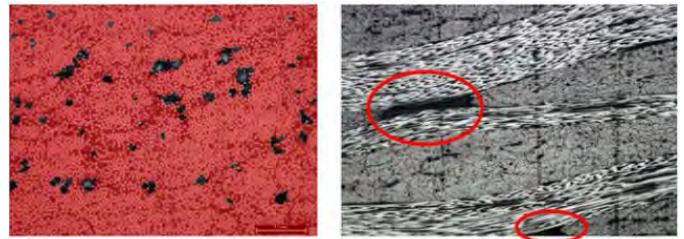

Figure 4. Voids in the filament-wound composite: intra-band voids (left) and voids at the crossovers (right)

## II. MODELING OF OPEN-CELL FOAM

A mesoscale approach to the modeling of open-cell foam geometry must be used in the HVI simulations to represent multi-shock interactions of the foam ligaments and hypervelocity fragment cloud propagating through the foam. The original structure that forms metallic foam is a three-dimensional array of bubbles having a maximum volume for the minimal surface area and surface energy. During the fabrication process, membranes of the bubbles are being removed, leaving an interconnected network of solid struts. A common approach to geometric modeling of open-cell foams is based on Wearie–Phelan idealization [6]. It represents a structure consisting of equal-volume bubbles of two different shapes: namely, the 14-sided tetrakaidecahedron (Fig. 5a) and the 12-sided dodecahedron (Fig. 5b). It is believed that Wearie–Phelan packing provides a minimal surface area for a given volume of cells/bubbles. The periodic domain (translation unit) of the Wearie–Phelan tessellation is shown in Fig. 5c.

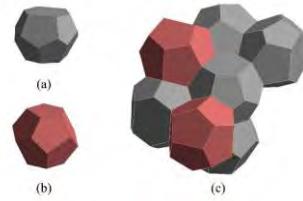

Figure 5. Wearie–Phelan packing

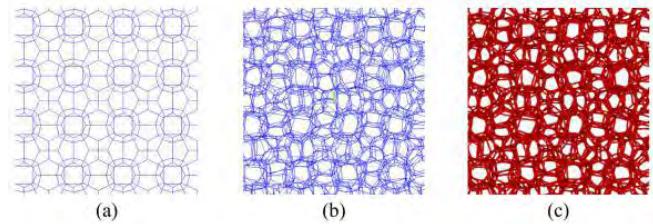

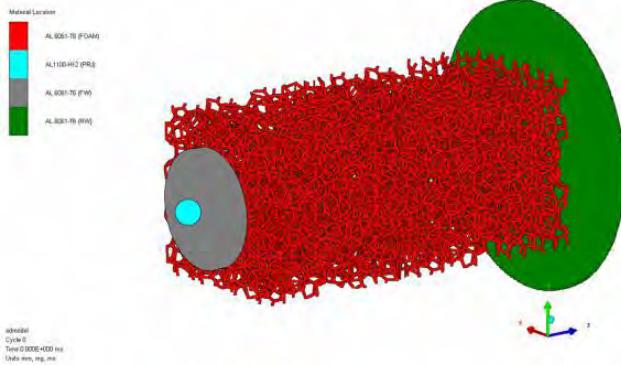

Figure 6. Mesoscale geometric modeling of aluminum foam: from structured frame to randomized solid model

It should be noted that the use of Wearie–Phelan idealization suggests a regular array of bubbles; however, real foams are random structures. To increase the realism of the modeling, therefore, a foam randomization mechanism is implemented. The overall algorithm for the geometric modeling can be described as follows: 1) generation of the representative volume element of aluminum foam with the specified dimensions based on Wearie–Phelan idealization [at

this stage, the geometric model consists of multiple lines connected with each other at nodal points (see Fig. 6a); 2) randomization of the foam using node perturbation (see Fig. 6b); and 3) development of a solid geometric model using the randomized line-based geometry (see Fig. 6c).

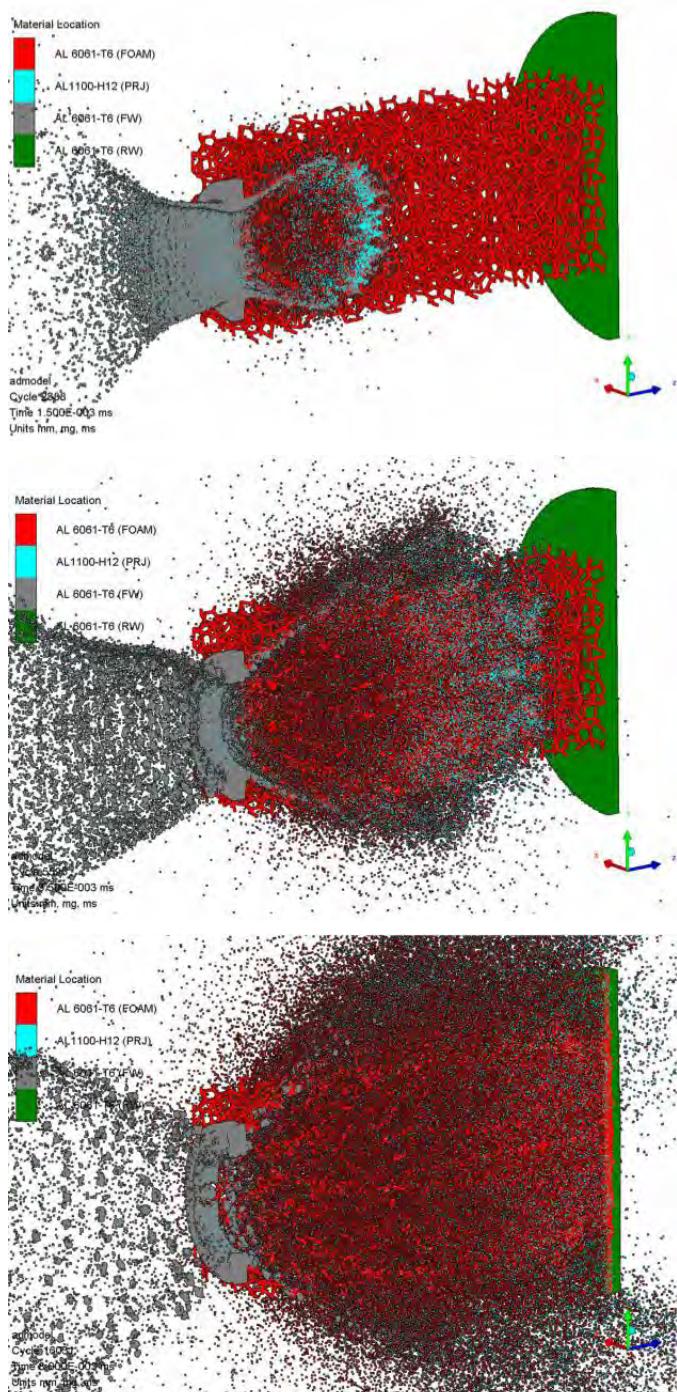

The foam modeling algorithm has been implemented in the form of a script written in ANSYS Parametric Design Language. The SPH model of the foam-core sandwich panel is depicted in Fig. 7. It consists of approximately two million SPH particles. To represent thin ligaments of aluminum foam with a satisfactory accuracy, a smoothing length of 0.015mm has been used. The model exploited the idea of quarter-symmetry. Although aluminum foam has a random structure and is not exactly symmetrical relative to any cutting plane, isotropy of its effective properties allows for such an assumption. The foam in the model is present only in the central region of the panel, where the most energetic fragments with the greatest damage potential will propagate. Additional lateral extension of the foam model was found to be impractical, as it was associated with high computational expenses.

*Figure 7. Numerical model of the open cell foam-core sandwich panel*

Results of the conducted simulation are presented in Fig. 8, which demonstrates three consequent moments of time when the debris cloud propagates through the aluminum foam. It can be seen in the figure that multi-shock action of the foam effectively breaks up fragments of the projectile and the front bumper, converting them into a cloud of small, disperse particles. No perforation of the rear wall was detected during the numerical experiment.

In view of the novelty of the foam modeling approach (i.e., its mesoscale representation in HVI analysis), the numerical prediction was verified by means of a physical experiment. The experiment was carried out using a two-stage light gas gun at the HIT Dynamics, Ltd., impact testing facility (Canada). The tested panel consisted of two Al6061-T6 facesheets and 16-mm-thick 3% 40 ppi aluminum foam from ERG Aerospace. It should be noted that the tested panel had a slightly lower facesheet thickness (0.4 mm instead of 0.5 mm, as used in the numerical tests).

*Figure 8. Results for the foam-core sandwich panel: a)  $t = 1.5 \mu\text{s}$ ; b)  $t = 3.5 \mu\text{s}$ ; and c)  $t = 8.5 \mu\text{s}$*

The panel was impacted by a 1 mm aluminum projectile at 6.965 km / s, and the resulting damage to the panel is shown in Fig. 9. Rear-wall damage was represented by discoloration and barely noticeable bulging. No perforation of the rear wall was detected, which supported the results of the numerical simulation.

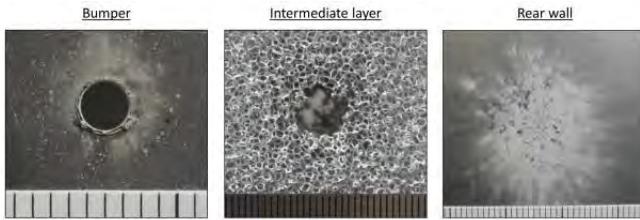

Figure 9. Experimental results for the foam-core sandwich panel

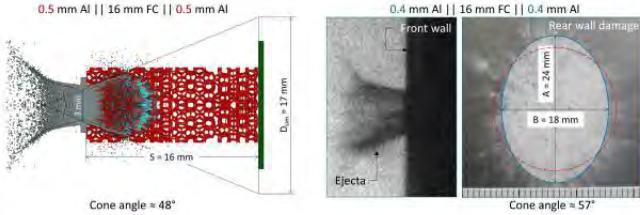

Figure 10. Shapes of ejecta clouds and cone angle measurements

Also, debris expansion angles (also referred to as “cone angles”) were procured for both cases. For the model, this angle could be measured directly, as shown in Fig. 10, and this was found to be equal to 48 deg. To measure the experimental value of this angle, it was assumed that the debris cloud expanded within a cone, with one base having the diameter of the perforation hole in the front facesheet (~3 mm) and the second base with the diameter of the damaged region on the rear wall. As the damaged area on the rear facesheet had a slightly elliptical shape (possibly because of the randomness of the foam; see Fig. 10), the corresponding cone base was represented in the calculations by a circle with the same area as the ellipse (indicated by the dashed line in Fig. 10). With this approximation, the debris expansion angle in the experiment was equal to 57 deg. The observed 9 deg difference was most likely the result of the different facesheet thicknesses of the modeled panel (0.5 mm) and the panel used in the experiment (0.4 mm). The model, therefore, was deemed to provide a good approximation of the physical phenomenon.

### III. MODELING OF FILAMENT-WOUND COMPOSITES

Numerical techniques for the modeling of composite behavior under hypervelocity impact loading have been described in the literature [5, 7] and implemented in commercial software packages. These techniques are designed for the standard laminated composites. They are based on the homogenization of a composite laminate, which is represented in the modeling as a macroscopically homogeneous orthotropic media with effective properties equivalent to those of the real material.

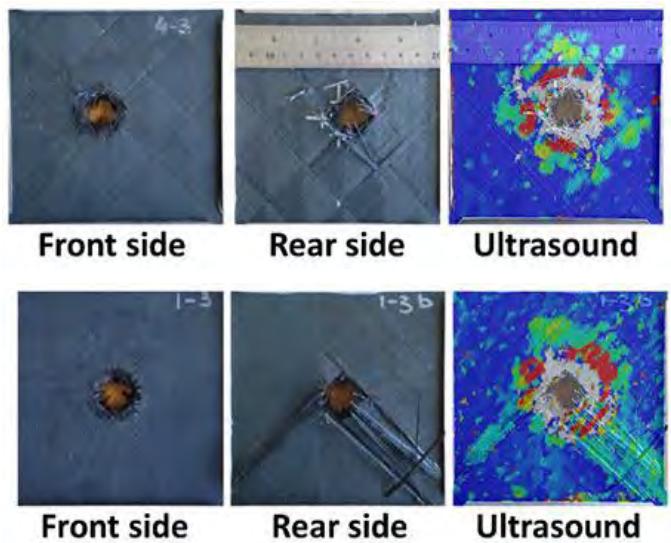

Figure 11. HVI damage to a HDI composite (top) and a LDI composite material (bottom)  
[impact conditions: 7 km/s; 4.76 mm aluminum projectile; 0.8 mm-thick aluminum bumper in front of the composite]

Conducted physical experiments revealed dependence of HVI damage of filament-wound composites on the particular winding pattern used in fabrication, as shown in Fig. 11. In the case of pattern with the high density of interweaving (HDI) of filament bands, a specimen inspection revealed a “containment” of the impact damage within the region restricted by 2x2 weave units adjacent to the perforated hole. In case of low density of interweaving (LDI), the specimen damage propagates outwards along the direction of the fibers, especially in the bottom left and bottom right directions. Correspondingly, the homogenization-based techniques are inapplicable to this class of materials. Instead, in this study, a meso-scale modeling approach was used to represent the material structure in HVI simulations.

The meso-scale representation of the composite materials included explicit modeling of fiber-reinforced filament bands with ultrathin resin-rich regions between them. The following assumptions regarding the behavior of the materials of filament bands and resin-rich regions were made:

1. The material of a filament band is homogeneous, orthotropic, and linearly elastic until failure. The intra-band failure is assumed to be brittle, which is the case for most CFRP systems.
2. The material of the resin-rich regions is homogeneous, isotropic, and linearly elastic until failure. The linear elasticity assumption fits well for the thermoset-resin composites, as thermosets typically do not undergo a significant amount of plastic deformation prior to an initiation of failure.
3. Assumingly, the inter-band damage of the composite, such as delamination, is completely confined to the resin-rich region. The behavior in the resin-rich regions after a failure initiation is determined by such macro-scale parameters as fracture toughness, which allows for the consideration of both adhesive and cohesive types of inter-band fracture.

4. Fracture toughness of thermoset-resin composites does not reveal strain-rate dependence, which is supported by several investigations by previous researchers [8 - 9].

As materials of filament bands and resin rich-regions are assumed to be linearly elastic until failure, their strength models only require the input of elastic constants. Pressure – volume response was modeled using nonlinear EOS for composite filament bands, and the Gruneisen EOS for isotropic resin-rich layers. Failure within the filament bands and resin reach layers was modeled using a continuum damage mechanics model available in AUTODYN.

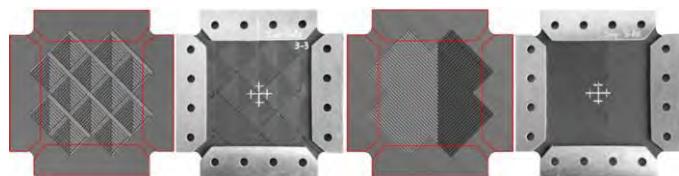

Figure 12. Geometrical modeling of HDI (left) and LDI (right) composites

The modeling approach employed in this study is based on simultaneous utilization of both SPH and FEM in each numerical simulation. The SPH method was used to represent the behavior of parts that exhibited fragmentation, namely aluminum projectile projectiles and bumpers. At the same time, composite panels with a meso-scale representation of filament winding patterns, which contained multiple interfaces between filament bands and resin-rich regions, were modeled using FEM in the Lagrangian formulation combined with the erosion mechanism. The use of erosion helped to avoid excessive mesh distortions and tangling at high deformations.

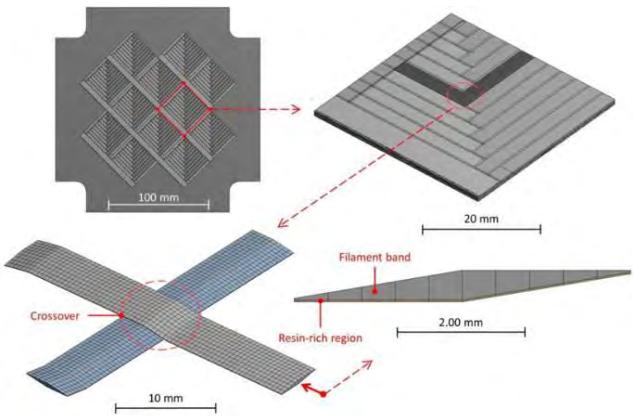

Figure 13. Meso-scale modeling of the filament-wound composite

The detailed meso-scale representation of filament winding was used only in the region of interest to minimize the computational cost. Around that region, the composite was represented by a homogeneous orthotropic material with effective properties equivalent to those of the real material. The geometrical models of the HDI and LDI panels compared with the real specimens are represented in Fig. 12.

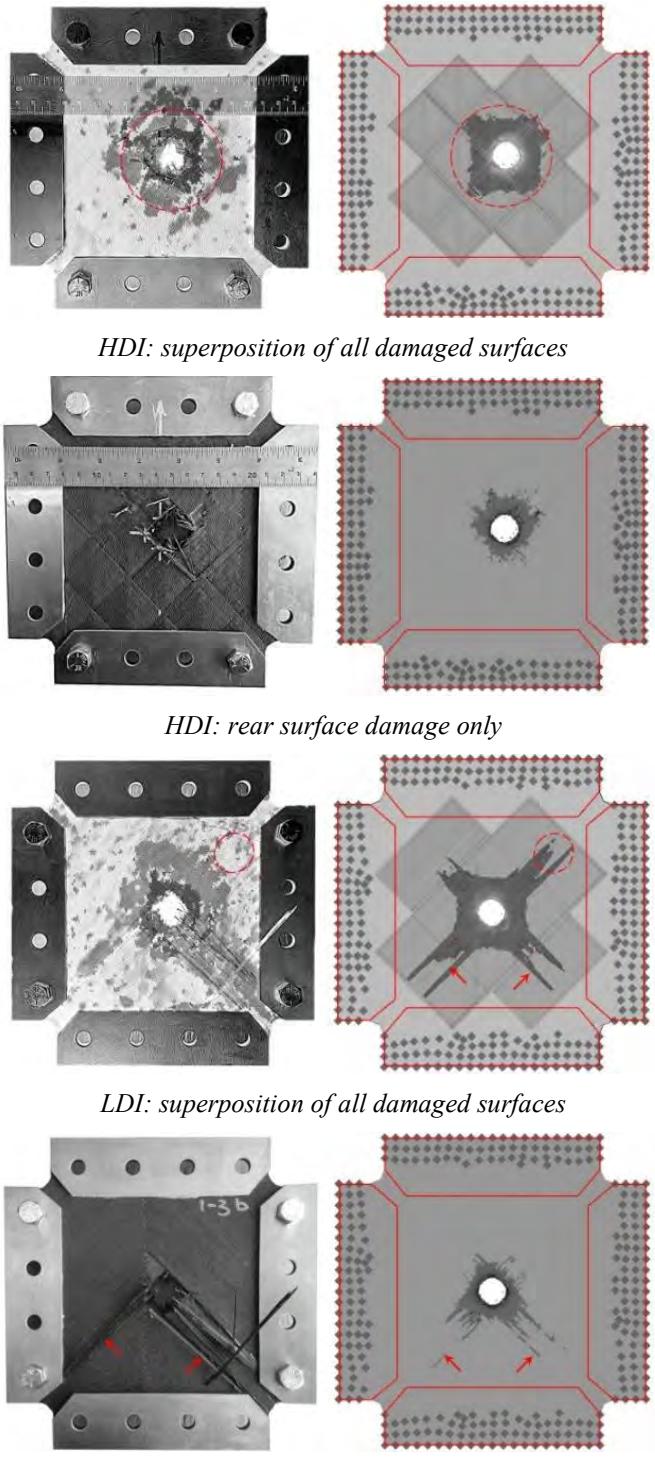

Figure 14. Composite damage: comparison of experimental results and numerical predictions

Fig. 13 represents the main features of the numerical models, including: a macro-scale appearance of the specimen model; a translational unit of the filament winding pattern model; a pair of interweaving filament bands; and a cross-section of a filament band with an adjacent resin-rich region.

Voids at crossover points were represented explicitly in the meso-scale model.

Fig. 14 represents comparison of experimental and modeling results in terms of the damage to composite panels. It reveals the following:

- Simulations tend to somewhat underpredict the damaged area as compared to the damage detected by C-Scan. The exact reason for the underprediction is unknown, but may be attributed to the presence of a strain-rate dependence of the composite fracture toughness that was ignored in the modeling.
- For the HDI specimen, the simulation predicts a “containment” of the HVI damage within the region restricted by 2x2 HDI units adjacent to the perforated hole, which is the same damage pattern observed in the experiment.
- For the LDI specimen, the simulation predicts further propagation of the damage outwards along the fiber direction, which is also consistent with the experimental results. It should be noted, however, that the simulation also predicts the propagation of damage in the top-right corner of the specimen (encircled in Fig. 14) that was not observed on the C-Scan image.
- Damage patterns on the rear surface predicted by simulations for both HDI and LDI specimens are qualitatively in very good agreement with the experiment, as shown in Fig. 14.

#### IV. CONCLUSIONS

For the foam-core sandwich panels, the meso-scale representation of the foam geometry is essential in HVI simulations, as it accounts for multi-shock interactions of the foam ligaments and hypervelocity fragment cloud propagating through the foam. The modelling approach considered in this study can be used in simulations estimating ballistic limit of foam core sandwich panels under hypervelocity impact.

Hypervelocity impact damage of a filament-wound composite is significantly dependent on the filament winding pattern used in its fabrication. In the presence of the winding pattern dependence, adequate simulation of HVI damage requires the utilization of a relatively high level of detail in representing a filament-wound composite. In this regard, the introduced meso-scale modeling approach was found to be suitable for capturing the main features of the HVI damage in the composites with different winding patterns. This approach can be used in the design of spacecraft filament-wound components, in order to determine the critical level of damage that is sustained due to orbital debris impacts.

# Design, Fabrication, and Calibration of a MEMS based Sensing Rosette for Quantifying the Influence of Strain Engineering on the Piezoresistive Coefficients

Amr A. Balbola and Waled A. Moussa

Mechanical Engineering  
University of Alberta  
Edmonton, Canada  
amr.balbola@ualberta.ca

**Abstract**— Strain has been used extensively in enhancing the electron mobility for high speed and low power transistors. As stretching the silicon atoms away beyond their normal atomic space has a significant influence on the carrier mobility. In this paper, to study the effect of strained silicon on piezoresistivity, the strained silicon will be integrated into a ten element sensing rosette, that utilizes the unique properties of crystalline silicon over the (111) plane to fully extract the six stress components in fully temperature compensated manner. Two chips were designed and fabricated, where the pre-strain state was induced onto the silicon substrate during microfabrication. In the first design, a highly compressive film (stressor layer) was utilized to globally produce a tensile strain at the front side of the substrate where the sensing elements were fabricated. While in the second design, the stressor layer was patterned in a way allowing for inducing both local tensile and compressive transverse uniaxial pre-strain onto the substrate. In another word, stressor strip with intrinsic compressive stress will cause a tensile pre-strain underneath it and compressive stress on both sides. This allows for applying different local strain using the same stressor rather than using nitride capping for tensile or silicon germanium for compressive as used on strained based transistors. To evaluate the effect of the pre-strain on the piezoresistive coefficients, uniaxial, thermal, and hydrostatic loading will be utilized to calibrate both designs.

**Keywords-component;** Strain Engineering; MEMS; Piezoresistivity, local stressor, biaxial pre-strain, uniaxial pre-strain, intrinsic stress.

## I. INTRODUCTION

STRAIN ENGINEERING is a cutting edge technology that is being employed mainly to enhance the performance of many CMOS devices [1] as shown in Figure 1. To continue Moore's

law without scaling, strain technology has been utilized in many high volume production, such as Intel [2], [3], IBM [4], Freescale [5], and Texas Instruments [6]. For decades, thermal mismatches [7], lattice mismatches [8], and non-equilibrium deposition [9] have been utilized extensively in producing pre-strain state globally and locally. For instance, stress accompanying with silicide and nitride layers were used on integrating strain with the CMOS devices as pictured in Figure 1. Since 1992, biaxial [10] [11] [12], uniaxial [13] [14], and three dimensional stress [15] were induced onto different transistors to allow for higher performance and speed without going smaller. Many techniques have been employed to apply different controlled strain, such as silicide [16], nitride capping [17], dual stress linear [18], shallow trenches isolation [15], stress memorization technique [13], and selective epitaxial Si-Ge/Si-C layer [3] [19] [20].

As mobility is directly related to the piezoresistive coefficients, these coefficients were utilized to evaluate the influence of strained silicon on the electron and hole mobility. Accordingly, strain engineering has high influence on the piezoresistive coefficients. Hence, strain would have a tremendous impact on the piezoresistive based sensing rosette. For instance, strain engineering could improve the sensitivity of piezoresistive based stress sensors by 30 percent [21]. In this work, a biaxial and transverse strain will be produced and integrated with a piezoresistive sensing rosette, which will allow for quantifying the effect of strain on the piezoresistive coefficients. Tensile and compressive transverse local strains are applied using the same stressing layer rather than using nitride capping for tensile or silicon germanium for compressive strain [2], [3]. Unlike other type of stress, transverse uniaxial stress has the same effect on both electron and hole mobility [16].

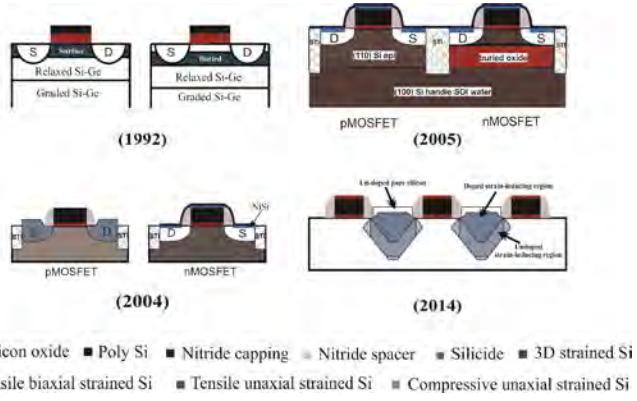

Figure 1. MOSFET structure changes in the past 30 years [2]

## II. STRESSOR DESIGN

A ten-elements sensing rosette, which was developed by the author's group, was utilized to study both global biaxial and local uniaxial strain. This chip was fabricated on (111) silicon to develop a set of independent linear equations that yield the six stress components with full-temperature compensation [22], [23]. The strained silicon technology has been integrated during microfabrication via deposition of highly compressive plasma enhanced chemical vapor deposition (PECVD) nitride film that bends the substrate as plotted in Figure 2. This will produce a tensile biaxial strain at the top side of the substrate, where the sensing rosette is located. Considering that the in-plane stresses are equal on all directions and the (111) plane has isotropic elastic properties [24], the biaxial elastic modulus can be utilized to calculate the pre-stain. A compressive nitride film stress of 600 MPa was measured via the wafer curvature, however the finite element analysis for the stress distribution shows large stress losses up to 70% between the film and substrate.

The same stressing layer was patterned in a way allowing for producing uniaxial local strain onto the silicon substrate as shown in Figure 3. Both tensile and compressive strains were applied using the same layer. Also the shallow trenches technique was used to maximize the strain produced at the piezoresistors' area. The shallow trenches were etched on both sides of the piezoresistors using reactive ion etching. The effect of the stressors and the trenches was numerically studied extensively via ANSYS finite element software package. The result shows that nitride stressor would generate uniaxial tensile and compressive transverse stress around 50 MPa. The simulation indicates a dominant influence of film thickness on the stress transmitted to the silicon, which can reach up to 150 and -200 for tensile and compressive stress respectively, as presented in Figure 4. While the shallow trenches introduce more strain up to 200 and -250 MPa for tensile and compressive stress respectively.

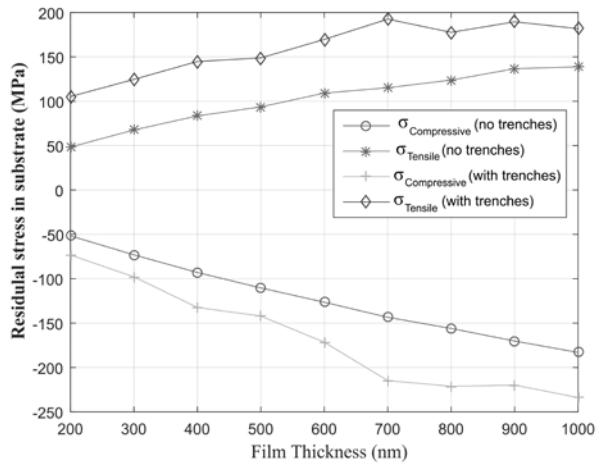

Figure 4. Stress transferred to the silicon versus the film thickness

## III. MICROFABRICATION

Two different designs have been fabricated in the nanoFAB and the MEMS/NEMS Advanced Design Laboratory (ADL) at the University of Alberta. In the first design, a biaxial tensile pre-strain was induced at the front side of the substrate. While both tensile and compressive uniaxial stresses were integrated in the second chip. Both recipes were fabricated on a p-type (111) prime silicon wafers which were initially cleaned using piranha and buffered-oxide etches (BOE). The main fabrication steps are creating the piezoresistive sensing elements and applying the pre-stress state as represented in Figure 5. A highly compressive layer of PECVD silicon nitride was locally deposited to induce tensile and compressive strain onto the sensing elements rather than straining the whole wafer. Finally, prior to the metallization, an additional predeposition diffusion step was carried out to create n+ region at the contact vias to obtain ohmic contact behavior between Al and Si. The fabricated chips were experimentally characterized to assess the piezoresistors functionality. The concentration profile was measured using a time-of-flight secondary ion mass spectrometry (ToF-SIMS). Photomicrographs of both designs are shown in Figure 6 and Figure 7.

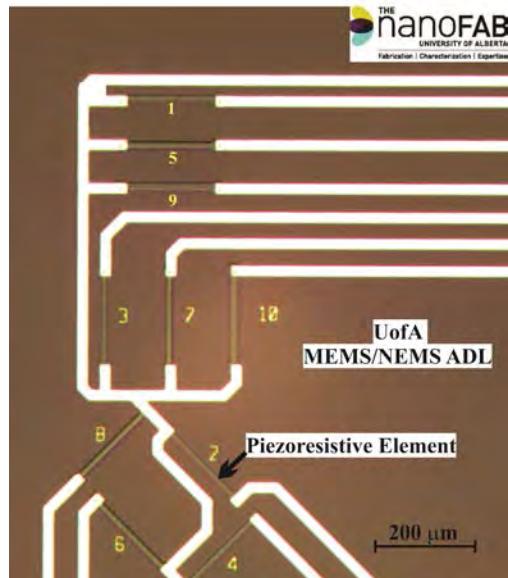

Figure 6. Photomicrograph of the microfabrication biaxial strained based sensing rosette

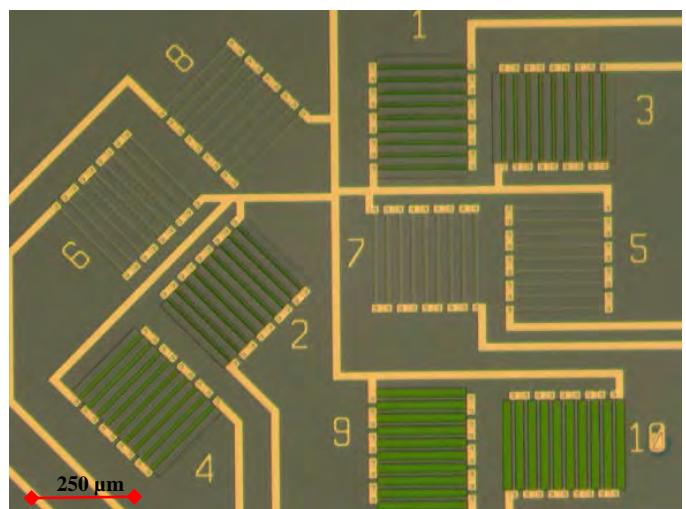

Figure 7. Photomicrograph of the microfabrication uniaxial strained based sensing rosette

#### IV. CALIBRATION

A full calibration of the piezoresistive coefficients over (111) ( $B_1, B_2, B_3$ ) were carried out to quantify the influence of strained silicon on piezoresistive coefficients. The typical calibration results would be used to calculate the piezoresistive coefficients. This test was carried out using a four-point bending (4PB) setup, environmental chamber, and hydrostatic test [21]. Applying known uniaxial stress on the current fabricated sensing chip will give  $B_1$  and  $B_2$  directly, while hydrostatic load will measure  $B_3$ . This calibration setup does not require packaging of the sensing die, where the calibration die is a part of a rectangular beam cut from the wafer, and is connected to a zero-insertion force (ZIF) connector using aluminum traces as shown in Figure 8. These aluminum traces are connected to voltmeter to provide six bias voltages which are enough for fully calibrating the piezoresistive coefficients. The resistance changes from the  $0^\circ$  sensing elements ( $R_1, R_5$ , and  $R_9$ ) are used to determine the  $B_1$  parameters, while  $B_2$  was calibrated via the sensing elements oriented at  $90^\circ$  ( $R_3, R_7$ , and  $R_{10}$ ) as shown in (1). Unlike the  $B_1$  and  $B_2$ ,  $B_3$  can be calculated from  $0^\circ$  or  $90^\circ$  sensing elements using the hydrostatic test.

$$B_1 = \frac{\partial}{\partial \sigma} \left( \frac{\Delta R_\varphi}{R_0} \right) \quad \text{and} \quad B_2 = \frac{\partial}{\partial \sigma} \left( \frac{\Delta R_{90}}{R_0} \right) \quad (1)$$

The test procedure started with measuring the nominal resistance of the six piezoresistors at no load. Then the load was increased incrementally and measured. At each load increment, the resistances were measured again to calculate the change in resistance. Figures 9-11 show the typical results came from the calibration, where the slopes represent the  $B_1, B_2$  and  $B_3$ .

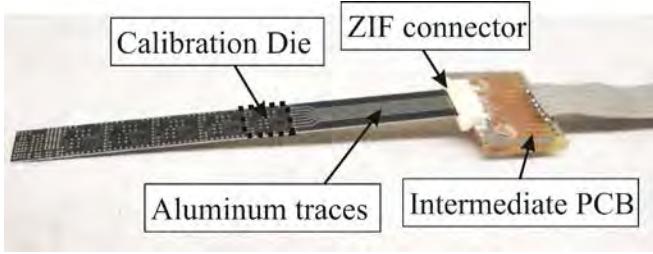

Figure 8. The silicon beam that used in calibration

#### V. CONCLUSION

In the frame of employing strain engineering on enhancing the performance of a MEMS 3D stress sensor, a strained based piezoresistive sensing rosette was developed for studying the effect of strain on the piezoresistive coefficients. The intrinsic stress accompanied with PECVD silicon nitride was utilized to induce a pre-strain into the silicon substrate during microfabrication. Both biaxial global and uniaxial transverse local strain was produced using the same stressing layer. A full study including design, fabrication, and calibration was

carried out to build a chip that can be used to quantify the strain effect.

**Abstract**—In this paper, the transient heat conduction in a layered composite with an insulated interface crack parallel to the boundaries is investigated by using the dual phase lag (DPL) model. Fourier and Laplace transforms are applied and the mixed boundary value problem for the cracked structure under temperature impact is reduced to solving a singular integral equation. The temperature field in time domain is obtained and the intensity factor of temperature gradient is defined. Numerical studies show that overshoot phenomenon may occur due to the combined effect of the insulated crack and application of the DPL heat conduction model. The thermal conductivity and the phase lag parameters have strong influence on the dynamic intensity factor of temperature gradients. The results obtained by the dual phase lag model can be reduced to that by the hyperbolic model and that by the parabolic model.

**Keywords-** transient heat conduction; dual-phase lag model; non-Fourier heat conduction; Singular integral equation

## I. INTRODUCTION

High-rate heat transfer has become a major concern in modern industries and accurate heat conduction analysis is of great importance for the material and structural integrity. For applications involving high power density, extremely short times or cryogenic temperatures, the classical parabolic heat diffusion theory as stipulated by Fourier's law of heat conduction becomes ineffective [1]. A unified heat conduction model that accounts for spatial and temporal effects in macro- and micro-scale heat transfer in a one temperature formulation has been proposed and was experimentally supported [2], namely the dual-phase-lag (DPL) model.

Inherent defects in materials such as dislocations and cracks may disturb the temperature distribution when thermal loading is applied to the material, and singularities may be developed in the neighborhood of discontinuities. Heat conduction problems of cracked materials using the classical Fourier heat conduction model have been investigated by some researchers [3, 4]. Some investigations on crack problems in thermo-elastic materials have been made using the hyperbolic heat conduction model. Transient temperature field

around a thermally insulated crack in a substrate bonded to a coating has been obtained by Chen and Hu [5] using the hyperbolic heat conduction model; and based on the same theory, Hu and Chen [6] obtained the transient temperature and thermal stress distributions around a partially insulated crack in a thermo-elastic strip. The problem of a finite crack in a material layer under the theory of non-Fourier heat conduction has been investigated by Wang and Han [7]. By applying the DPL model to a cracked half-plane under transient thermal loading, the dynamic temperature field around a partially insulated crack has been obtained [8].

To the author's knowledge, the transient interface crack problem in a layered composite under thermal loading by applying the dual phase lag model has not yet been reported in the literature. In this paper, we analyze the transient temperature field around an insulated interface crack in a layered composite under temperature impact using the dual phase lag model. The effect of the parameters of the dual phase lag model and the geometric size of the cracked body on the temperature disturbance field are investigated.

## II. PROBLEM DESCRIPTION

Consider a thermo-elastic, double-layered structure containing an interface crack of length  $2c$  parallel to the boundaries of the structure, as shown in Fig. 1. The thicknesses of the upper and lower layers are  $h_1$  and  $h_2$ , respectively. The layered structure is initially at the uniform temperature of zero, and is suddenly heated to a temperature,  $T_1$  and  $T_2$  on the upper and the lower boundaries, respectively, and  $H(t)$  denotes the Heaviside step function. The crack surfaces are assumed to be thermally insulated, which indicates that the thermal transfer across the crack faces vanishes.

In order to account the effects of finite heat propagation and micro-structural interaction, the Fourier's law of heat conduction is modified to the DPL model [2],

$$q + \tau_q \frac{\partial q}{\partial t} + \frac{\tau_q^2}{2} \frac{\partial^2 q}{\partial t^2} = -k \cdot \left( \nabla T + \tau_T \frac{\partial}{\partial t} \nabla T \right). \quad (1)$$

where  $q$  is the heat flux,  $T$  is the temperature,  $k$  is the thermal conductivity of the material,  $\nabla$  is the spatial gradient operator,  $t$  is the physical time at which observation on heat transport is made,  $\tau_q$  and  $\tau_T$  are the phase lags of the heat flux and temperature gradient, respectively, which are two intrinsic thermal properties of the material. The heat flux precedes the temperature gradient for  $\tau_q < \tau_T$ , and the temperature gradient precedes the heat flux for  $\tau_q > \tau_T$ .

Conservation of the local energy with vanishing heat source applies [9]:

$$-\nabla q = \rho C_p \cdot \frac{\partial T}{\partial t} \quad (2)$$

where  $\rho$  and  $C_p$  are the mass density and the specific heat capacity, respectively.

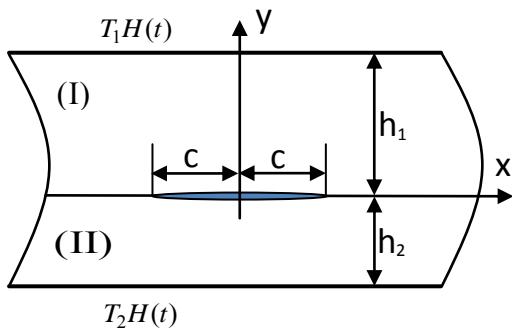

Figure 1. Geometry of cracked double-layered structure under transient thermal impact on the upper and lower surfaces

Incorporating (1) with (2) leads to the heat conduction equations in the following form

$$\nabla^2 T^{(1)} + R_1 \frac{\partial}{\partial t} (\nabla^2 T^{(1)}) = a^2 \left[ \frac{\partial T^{(1)}}{\partial t} + \frac{\partial^2 T^{(1)}}{\partial t^2} + \frac{1}{2} \frac{\partial^3 T^{(1)}}{\partial t^3} \right]. \quad (3)$$

$$\nabla^2 T^{(2)} + R_2 \frac{\partial}{\partial t} (\nabla^2 T^{(2)}) = \frac{a^2}{r_\alpha} \left[ \frac{\partial T^{(2)}}{\partial t} + r_\tau \frac{\partial^2 T^{(2)}}{\partial t^2} + \frac{r_\tau^2}{2} \frac{\partial^3 T^{(2)}}{\partial t^3} \right]. \quad (4)$$

$$R_1 = \tau_T^{(I)}/\tau_q^{(I)}, \quad R_2 = \tau_T^{(II)}/\tau_q^{(I)} \\ r_\alpha = \alpha^{(II)}/\alpha^{(I)}, \quad r_\tau = \tau_q^{(II)}/\tau_q^{(I)}. \quad (5)$$

where  $a = c/L$  is a characteristic length parameter of the material, the superscript “(1), (2)” represent the variables in the upper layer and the lower layer, respectively. It is noted that the following dimensionless variables have been used for simplicity:

$$T^{(1)} = T^{(I)}/T_1, \quad T^{(2)} = T^{(II)}/T_1, \quad L = \sqrt{\alpha^{(I)} \tau_q^{(I)}} \quad (6)$$

and the time have been normalized as  $t/\tau_q^{(I)}$ .

The heat conduction equations are subjected to the following boundary and initial conditions in the dimensionless form as

$$T^{(1)}(x, h_1, t) = 1, \quad (|x| < \infty, t > 0). \quad (7)$$

$$T^{(2)}(x, -h_2, t) = T_2/T_1, \quad (|x| < \infty, t > 0). \quad (8)$$

$$q^{(1)}(x, 0^+, t) = q^{(2)}(x, 0^-, t), \quad (|x| \geq c). \quad (9)$$

$$T^{(1)}(x, 0^+, t) = T^{(2)}(x, 0^-, t), \quad (|x| \geq c). \quad (10)$$

$$\frac{\partial T^{(1)}(x, 0^+, t)}{\partial y} = \frac{\partial T^{(2)}(x, 0^-, t)}{\partial y} = 0, \quad (|x| < c). \quad (11)$$

$$T^{(j)} = 0, \quad \frac{\partial T^{(j)}}{\partial t} = 0, \quad \frac{\partial^2 T^{(j)}}{\partial t^2} = 0, \quad (t = 0, j = 1, 2). \quad (12)$$

### III. METHOD OF THE PROBLEM

Application of Laplace transforms to (3, 4) leads to:

$$T^*(x, y, p) = \int_0^\infty T(x, y, t) \exp(-pt) dt \quad (13)$$

$$T(x, y, t) = \frac{1}{2\pi i} \int_{Br} T^*(x, y, p) \exp(pt) dp$$

where the superscript “\*” denotes the quantities in the Laplace domain and  $Br$  stands for the Bromwich path of integration.

By considering the initial conditions and boundary conditions, we can obtain the appropriate temperature field in the Laplace domain by using Fourier transforms as

$$T^{*(1)}(x, y, p) = \int_{-\infty}^{\infty} \left[ D_1(\xi, p) \exp(my) + D_2(\xi, p) \exp(-my) \right] \exp(-ix\xi) d\xi \\ + W_1(y, p) \quad (0 \leq y \leq h_1) \quad (14)$$

$$T^{*(2)}(x, y, p) = \int_{-\infty}^{\infty} \left[ E_1(\xi, p) \exp(ny) + E_2(\xi, p) \exp(-ny) \right] \exp(-ix\xi) d\xi \\ + W_2(y, p) \quad (-h_2 \leq y \leq 0) \quad (15)$$

where  $D_j(\xi, p)$ ,  $E_j(\xi, p)$  ( $j = 1, 2$ ) are unknowns to be determined and  $m$ ,  $n$ ,  $W_1(y, p)$ ,  $W_2(y, p)$  are known functions.

Introduce the temperature density function as

$$\phi(x, p) = \frac{\partial T^{*(1)}(x, 0^+, p)}{\partial x} - \frac{\partial T^{*(2)}(x, 0^-, p)}{\partial x}. \quad (16)$$

It is clear from the boundary conditions (10) that

$$\int_{-c}^c \phi(t, p) dt = 0. \quad (17)$$

The satisfaction of the mixed boundary value problem on the crack face plane leads to the singular integral equation for  $\phi(x, p)$  as follows

$$\int_{-c}^c \phi(t, p) \left[ \frac{1}{t-x} + H(x, t, p) \right] dt = 2\pi u(b_2 - b_1). \quad (18)$$

where  $H(x, t, p)$  is the kernel function and its expression is omitted here.

The solution of the singular integral equation (18) under the single-valuedness condition (17) may be expressed as [10]:

$$\phi(cx, p) = \Phi(x, p) / \sqrt{1-x^2}. \quad (19)$$

where  $\Phi(x, p)$  is bounded and continuous on the interval  $[-1, 1]$ . From the properties of symmetry and the condition (17), it is seen that  $\Phi(x, p)$  is an odd function of  $x$ , i.e.,  $\Phi(-x, p) = -\Phi(x, p)$ .

By using the numerical method of Erdogan [10], Singular integral equations (17) and (18) can be solved at discrete points as

$$\sum_{k=1}^N \frac{1}{N} \Phi(t_k, p) \left[ \frac{1}{t_k - x_r} + H(x_r, t_k, p) \right] = 2u(b_2 - b_1), \\ (r = 1, 2, \dots, N-1) \quad (20-1)$$

$$\sum_{k=1}^N \frac{\pi}{N} \Phi(t_k, p) = 0. \quad (20-2)$$

$$t_k = \cos[(2k-1)\pi/2N], \quad (k = 1, 2, \dots, N). \quad (20-3)$$

$$x_r = \cos(r\pi/N), \quad (r = 1, 2, \dots, N-1) \quad (20-4)$$

Once the function  $\Phi(t, p)$  is obtained, the function  $D_2(\xi, p)$  can be obtained by applying the Chebyshev quadrature for integration as

$$D_2(\xi, p) \approx -\frac{1}{2\pi\xi G(\xi, p)} \sum_{m=1}^N w_m \Phi(x_m, p) \sin(x_m \xi) \quad (21-1)$$

$$x_m = \cos\left(\frac{2m-1}{2N}\pi\right), \quad (m = 1, 2, \dots, N) \quad (21-2)$$

$$w_m = \pi/N \quad (21-3)$$

The functions  $D_1(\xi, p)$ ,  $E_j(\xi, p)$  ( $j = 1, 2$ ) can be expressed in terms of  $D_2(\xi, p)$  as

$$D_1(\xi, p) = -D_2(\xi, p) \exp(-2mh_1) \\ E_1(\xi, p) = -\frac{mK_1(p)[1 + \exp(-2mh_1)]}{nK_2(p)[1 + \exp(-2nh_2)]} D_2(\xi, p). \quad (22) \\ E_2(\xi, p) = \frac{mK_1(p)[1 + \exp(-2mh_1)]}{nK_2(p)[1 + \exp(2nh_2)]} D_2(\xi, p)$$

#### IV. TEMPERATURE FIELD

The substitution of (21, 22) into (14, 15) can give the temperature in the Laplace domain, and the temperature in time domain can be obtained by applying the Laplace inverse transform.

Of particular interest are the temperature gradients in the cracked media under thermal loadings. A temperature gradient

is a physical quantity that describes in which direction and at how much rate the temperature changes the most rapidly around a particular location. The temperature gradients in the Laplace domain can be obtained as

The singular temperature gradients near the right crack tip in the Laplace domain can be obtained as

$$T_{,y}^{*(1)}(r, \theta, p) = -\frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \cos\left(\frac{\theta}{2}\right). \quad (23-1)$$

$$T_{,y}^{*(2)}(r, \theta, p) = -\frac{K_1(p)}{K_2(p)} \frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \cos\left(\frac{\theta}{2}\right). \quad (23-2)$$

$$T_{,x}^{*(1)}(r, \theta, p) = \frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \sin\left(\frac{\theta}{2}\right). \quad (24-1)$$

$$T_{,x}^{*(2)}(r, \theta, p) = \frac{K_1(p)}{K_2(p)} \frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \sin\left(\frac{\theta}{2}\right). \quad (24-2)$$

The temperature gradients near the crack tip in the radial direction in the Laplace domain can be obtained as

$$T_{,r}^{*(1)}(r, \theta, p) = -\frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \sin\left(\frac{\theta}{2}\right). \quad (25-1)$$

$$T_{,r}^{*(2)}(r, \theta, p) = -\frac{K_1(p)}{K_2(p)} \frac{\Phi(1, p)\sqrt{c}}{2\sqrt{2r}} \sin\left(\frac{\theta}{2}\right). \quad (25-2)$$

where the subscript “,  $j$ ” ( $j = x, y, r$ ) denote the temperature gradient in  $x$ ,  $y$  and radial direction, respectively;  $(r, \theta)$  are the polar coordinates measured from the crack tip defined by

$$r^2 = (x-c)^2 + y^2, \quad \tan(\theta) = y/(x-c). \quad (26)$$

In front of the crack tip at  $\theta = -\pi$ , the temperature gradient reaches the maximum value and the intensity factor of the temperature gradient (IFTG) near the crack tip can be defined as [11],

$$K_T^{*(1)}(p) = \lim_{r \rightarrow 0} 2\sqrt{r} T_{,r}^{*(1)}(r, \theta, p) \Big|_{\theta=-\pi} = \frac{\Phi(1, p)\sqrt{c}}{\sqrt{2}} \quad (27)$$

$$K_T^{*(2)}(p) = \lim_{r \rightarrow 0} 2\sqrt{r} T_{,r}^{*(2)}(r, \theta, p) \Big|_{\theta=-\pi} = \frac{K_1(p)}{K_2(p)} \frac{\Phi(1, p)\sqrt{c}}{\sqrt{2}} \quad (28)$$

and the radial intensity factor of the temperature gradient (RIFTG) near the crack tip can be defined as

$$K_r^{*(1)}(\theta, p) = \lim_{r \rightarrow 0} 2\sqrt{r} T_{,r}^{*(1)}(r, \theta, p) = -\frac{\Phi(1, p)\sqrt{c}}{\sqrt{2}} \sin\left(\frac{\theta}{2}\right). \quad (29)$$

$$K_r^{*(2)}(\theta, p) = \lim_{r \rightarrow 0} 2\sqrt{r} T_{,r}^{*(2)}(r, \theta, p) = -\frac{K_1(p)}{K_2(p)} \frac{\Phi(1, p)\sqrt{c}}{\sqrt{2}} \sin\left(\frac{\theta}{2}\right) \quad (30)$$

By applying the inverse Laplace transform, the near crack-tip temperature gradients in time domain can be obtained as

$$T_{,y}^{(1)}(r, \theta, t) = -\frac{K_T^{(1)}(t)}{2\sqrt{r}} \cos\left(\frac{\theta}{2}\right). \quad (31-1)$$

$$T_{,y}^{(2)}(r, \theta, t) = -\frac{K_T^{(2)}(t)}{2\sqrt{r}} \cos\left(\frac{\theta}{2}\right). \quad (31-2)$$

$$T_{,x}^{(1)}(r, \theta, t) = \frac{K_T^{(1)}(t)}{2\sqrt{r}} \sin\left(\frac{\theta}{2}\right). \quad (32-1)$$

$$T_{,x}^{(2)}(r, \theta, t) = \frac{K_T^{(2)}(t)}{2\sqrt{r}} \sin\left(\frac{\theta}{2}\right). \quad (32-2)$$

$$T_{,r}^{(1)}(r, \theta, t) = -\frac{K_T^{(1)}(t)}{2\sqrt{r}} \sin\left(\frac{\theta}{2}\right). \quad (33-1)$$

$$T_{,r}^{(2)}(r, \theta, t) = -\frac{K_T^{(2)}(t)}{2\sqrt{r}} \sin\left(\frac{\theta}{2}\right). \quad (33-2)$$

where the intensity factor of temperature gradient (IFTG) in the time domain,  $K_T^{(j)}(t)$  ( $j=1,2$ ) is given as

$$K_T^{(1)}(t) = \frac{\sqrt{c}}{2\sqrt{2\pi i}} \int_{Br} \Phi(1, p) \exp(pt) dp. \quad (34-1)$$

$$K_T^{(1)}(t) = \frac{\sqrt{c}}{2\sqrt{2\pi i}} \int_{Br} \frac{K_1(p)}{K_2(p)} \Phi(1, p) \exp(pt) dp. \quad (34-2)$$

and the radial intensity factor of temperature gradient (RIFTG) near the crack tip in time domain is

$$\begin{aligned} K_r^{(1)}(\theta, t) &= -\frac{\sqrt{c}}{2\sqrt{2\pi i}} \int_{Br} \Phi(1, p) \sin\left(\frac{\theta}{2}\right) \exp(pt) dp \\ &= -K_T^{(1)}(t) \sin\left(\frac{\theta}{2}\right) \end{aligned} \quad (35-1)$$

$$K_r^{(2)}(\theta, t) = -K_T^{(2)}(t) \sin\left(\frac{\theta}{2}\right). \quad (35-2)$$

It can be seen from (33) that the dynamic temperature gradients possess a  $r^{-1/2}$  singularity near the crack tip, which is in agreement with the corresponding static thermal crack problem [3, 11]. The dynamic effect is merely introduced by the IFTGs, which are time-dependent as shown in (34, 35). It can be observed that the maximum temperature gradient appears at the angle  $\theta = \mu\pi$ , which corresponds to the lower and the upper crack surfaces near the crack tip; this conclusion is in agreement of the physical intuition that abrupt temperature changes occur near the crack tip. The effect of the geometric size  $h_1$  and  $h_2$  on the radial intensity factor of temperature gradient (RIFTG) is through the function  $\Phi(1, p)$ , and the geometric size does not affect the angular function of the temperature gradient.

## V. NUMERICAL RESULTS AND DISCUSSION

The temperature field in the time domain can be obtained by applying the numerical inversion of Laplace transform, as detailed in Miller and Guy [12]. The geometric size of the composite is chosen as  $h_1/c=1$ ,  $h_2/c=2$ ,  $L=1$ , without loss of generality.

The temperature distribution in the cracked layers is shown in Figs. 2 and Figs. 3 for the cases of  $k_1/k_2=0.5$  and

$k_1/k_2=2$ , respectively. Other related material parameters of the two layers are assumed to be  $\tau_q^{(1)}=\tau_q^{(2)}=10^{-9}s$ ,  $\tau_T^{(1)}=2.0\times10^{-9}s$ ,  $\tau_T^{(2)}=0.5\times10^{-9}s$ . The normalized temperature applied on the boundaries of the layers are assumed to be  $T_1=1$ ,  $T_2=2$ .

For the case of  $k_1/k_2=0.5$ , the disturbance of the thermally insulated crack on the temperature field can be observed from the iso-temperature lines in Fig. 2, and there is a temperature jump across the crack faces. The interference of the insulated crack results in the higher temperature in the inner region of the heat conduction medium than that on the boundary, this is called temperature overshooting phenomenon, as shown in Fig. 2, which corresponds to the normalized time  $t=2.0$ . This temperature overshooting phenomenon is of great importance in thermal engineering applications such as safety design of the electronic or mechanical devices under severe thermal loadings [13]. Fig. 3 display the temperature distribution in the cracked layers for the case of  $k_1/k_2=2$ , temperature overshooting phenomenon is observed and there is a temperature gap across the crack. Comparing to Fig. 2, it can be seen that the temperature intensification around the crack varies as the thermal conductivity parameters changes.

Of much interest is the temperature distribution on the crack faces as the insulated crack interrupt the temperature in the cracked composite. The temperature on the crack faces and crack face extended lines is shown in Fig. 4 for different time points. It is observed that there is temperature jump across the insulated crack on the interface of the bonded layers, while outside the crack region the temperature on the interface is continuous. As the time changes, the temperature on crack faces and the extended lines changes accordingly. It can be seen that the temperature on part of the upper face may exceed the temperature on the boundary.

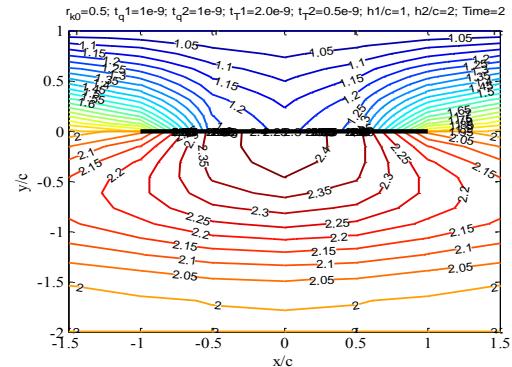

Figure 2. Temperature distribution in cracked layers when  $k_1/k_2=0.5$  at  $t=2.0$ .

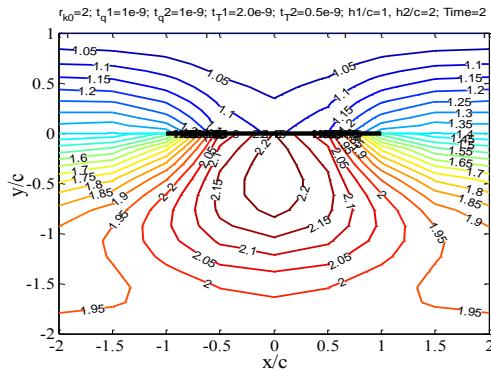

Figure 3. Temperature distribution in cracked layers when  $k_1/k_2 = 2$  at  $t = 2.0$ .

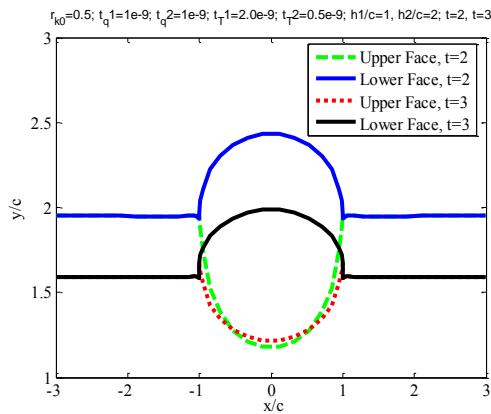

Figure 4. Temperature distribution on crack faces and extended lines when  $k_1/k_2 = 0.5$ .

## VI. CONCLUSIONS

The transient temperature distribution in a layered composite with an interface crack under temperature impact loading has been studied using the dual phase lag model. The crack lies parallel to the boundary and is assumed to be thermally insulated. Fourier and Laplace transforms are applied to solve the temperature field, and the mixed boundary problem is reduced to solving a singular integral equation. An asymptotic analysis and inverse Laplace transform are applied to obtain the temperature field in the time domain and the intensity factor of temperature gradient is defined. Numerical studies show that overshoot phenomenon may occur due to the combined effect of the insulated crack and application of the DPL heat conduction model. The thermal conductivity and the phase lag parameters have strong influence on the dynamic intensity factor of temperature gradients.

**Abstract**—Turbulent flow inside the urban roughness sublayer, despite its complexities, plays a crucial role in the microclimate of the built environment. The parameterization of flow in the urban roughness sublayer provides a better understanding of turbulent exchange process leading to accurate weather forecasting. This study focused on developing relationships between turbulent quantities, including momentum and heat fluxes, and mean quantities such as mean wind speeds. Field data, including wind directions, wind speeds, and thermal stability conditions, were collected from an urban canopy in Guelph, Ontario, Canada during the summer 2017. Comparative data was obtained from a nearby rural station. A systematic scaling analysis was performed to identify a range of quantities highly related to turbulent fluxes. All combinations of quantities leading to dimensionless groups were evaluated. Linear and nonlinear correlation coefficients between different groups of variables identified when mean and turbulent quantities were related. Significant improvement in correlation coefficients was observed using high order polynomial regression, revealing the challenge of developing a robust model for predicting nonlinear behavior of turbulence. This study also used artificial neural networks (ANNs) to find nonlinear relationships between turbulent and mean quantities. As used here, an ANN is a multivariable function which attempts to approach the exact value of turbulent flux based on independent variables, properly chosen from dimensionless groups. Results showed that these approaches can successfully relate most, but not all, turbulent quantities to mean quantities.

## I. INTRODUCTION

Flow interactions between near-surface regions and the atmosphere in built-up areas cause spatial and temporal flow complexity leading to phenomena such as channeling flow, secondary vortices, complex three-dimensional patterns and turbulence. Within the lower level of the urban atmosphere, which is the region from the surface up to the top of the atmospheric roughness sublayer, net transport of energy and

pollutants is greatly influenced by the turbulent flow. Therefore, a general understanding of turbulent exchange processes in the lower urban atmosphere can give insight into underlying flow features. Numerous studies have investigated flow characteristics in mesoscale models that characterize large spatial and temporal scales. Three-dimensional effects, which are significant up to two or more times building heights, and the methods used for approximating the atmospheric roughness sublayer, can considerably change modeled flow and dispersion processes. Another important feature of flow is the formation of shear layers at roof level, which oscillate at dominant frequencies due to instabilities. Turbulence transport into the canopy is driven by these shear layers and turbulence characteristics vary by any change in the upwind conditions. More flow complexity arises in canopies with unequal building heights. Side separation layers, jetting flow from the windward face of downstream buildings, and channeling flow in a finite street length, can all cause additional difficulties when investigating in-canyon flows in these environments [1-4]. Analytical and numerical studies focused on the UCL are not developed enough to capture all of the important features of flow in these regions. It has been suggested that empirical relationships can be developed for the variables of interest. Turbulent exchange processes are usually investigated by measuring momentum and heat fluxes. Similarity theory is used to parameterize variables and guide the design of experiments to record the most desirable information [5]. Successful use of similarity theory requires guessing relevant variables that can be determined from measureable parameters, and ensuring these are relevant to predicting the unknown variables of interest. Numerous studies have employed Monin-Obukhov similarity theory to estimate wind, temperature, and turbulence statistics profiles as functions of friction velocity and length scales [6]. Additionally, accurate and reliable measurements of meteorological quantities, which can be obtained from field measurements or approximated from wind tunnel studies, are required to relate turbulent fluxes to other known quantities in the flow such as mean velocity or temperature. There have been many attempts to parametrize and describe turbulent transport in rough but horizontally homogenous environments. However, turbulence characteristics are still not well understood in

horizontally inhomogeneous urban areas and further investigations are required. The pioneering efforts of Roth and Oke [7], followed by many others, have shown how to parametrize turbulent fluxes in horizontally inhomogeneous built areas. Most of these studies attempted to find or modify correlations between turbulent quantities and Monin-Obukhov length over the canopy. It has been found that there can be strong nonlinear relationships between different quantities within the canyon [8].

## II. OBJECTIVE

This study investigated the relationships among different turbulent and mean quantities within and above an urban canyon under all wind directions, wind speeds, and thermal stability conditions. Scaling analyses were completed to identify relationships between variables. The study used measured microclimate data collected around an urban canyon in Guelph, Ontario, Canada during the summer 2018. The canyon has an aspect ratio of unity and is located on the University of Guelph campus. Strong nonlinear relationships between turbulent and mean quantities were observed. These were investigated by fitting high order polynomial equations to the data set. Artificial neural networks (ANNs) were also employed to find how turbulent fluxes can be related to groups of known variables to allow investigation of non-linear relationships. The approach presented here can be extended to turbulent flow in other canopies with different morphologies and climates.

## III. OBSERVATION SITE

Data was collected from an urban microclimate field campaign held at the University of Guelph, Guelph, Ontario, Canada from 13th to 25th of August 2017 (Fig. 1). Meteorological conditions, including fluctuating velocity,

surface and atmospheric temperature values, were measured within the urban canyon and on the roof-top of the building situated at the southwest canyon wall, using RM Young 81000 three-dimensional sonic anemometers recording at 4 and 32 Hz. Data was also collected from the Guelph Turfgrass Institute, an open-field station representative of rural conditions located 1.9 km northeast of the canyon site [9]. Since local wind direction can significantly affect turbulence quantities and flow patterns within and above the urban canopy, the field data were collected and analyzed under all wind directions and thermal stability conditions.

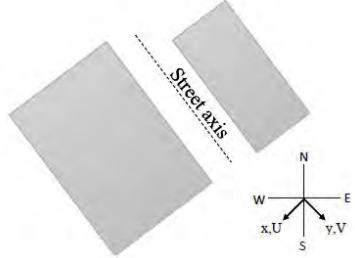

Figure 1: Top view of urban site

## IV. METHODOLOGY

Most variables will be considered to have mean and fluctuating components:  $X = \bar{X} + x$  where  $x$  is the turbulent fluctuating component and the overbar notation signifies a 30-minute time average of a variable. Lowercases are used to express variances and fluxes, e.g.  $\bar{u}^2$  represents velocity variance in the x direction. Subscripts  $R$ ,  $S$  and  $t$  denote roof-level, street-level, and rural area measurements. ANNs, which can discover nonlinear relationships between various parameters, were employed to relate turbulent quantities

to mean variables or those that can be measured conveniently. Properly scaled mean quantities form the input layers and turbulent fluxes are predicted at the output layer. Multilayer feedforward backpropagation network was used to find relationships between inputs and outputs while minimizing errors. The backpropagation algorithm is an iterative procedure that tries to modify weights based upon errors determined for all layers. Problems such as overfitting may arise in training a network, resulting in a poor generalization [10]. To avoid this, a simple optimization procedure was used to find a suitable network architecture containing an optimum number of hidden layers and neurons. It was speculated that in cases where the underlying relationships between variables are relatively simple, linear regression can outperform neural networks for relating turbulent and mean quantities. Therefore, it was necessary to understand the strength of linear or nonlinear correlations between different quantities before seeking complex relationships. Before creating a neural network, a systematic dimensional analysis was performed. All possible dimensionless groups containing two or three variables were built. Then, this analysis was used to distinguish between existing linear and nonlinear relationships. Moreover, high order polynomial functions were fit to the measured data to understand the severity of nonlinear relationships. This procedure provided us with a selection of quantities with known strong linear or nonlinear relationships.

## V. RESULTS AND DISCUSSION

### A. Two-variable Dimensionless Groups

A systematic dimensional analysis identified all of the relevant two-variable dimensionless groups in table I. Those groups with linear correlation coefficients higher than 0.2 between turbulent fluxes and other quantities are shown. Some strong linear correlations were found at street level that were mostly related to other turbulent quantities such as variances along the street axis,  $\bar{v}^2_s$ . Significant linear correlation coefficients between different turbulent fluxes at street level, e.g.  $\bar{u}\bar{w}_s$  and  $\bar{v}\bar{w}_s$ , provide an opportunity to find turbulent fluxes of interest by knowing the value of other fluxes, which may be accessible to determine. Among all momentum and heat fluxes, those with components in the vertical direction, i.e.  $\bar{u}\bar{w}$  and  $\bar{w}\bar{t}$ , play important roles in the correct representation of the urban boundary layer. It is evident that there is a significant correlation between the momentum flux in the vertical direction,  $\bar{u}\bar{w}_s$ , and other mean quantities including  $\bar{U}_s^2$  and  $\bar{W}_s^2$ . Unlike at street level, the roof level turbulent fluxes did not exhibit high linear correlations with other variables. It is worth noting that there are still some linear relationships between vertical momentum fluxes,  $\bar{v}\bar{w}_R$  and  $\bar{u}\bar{w}_R$ , and mean quantities with correlation coefficients of 0.4 to 0.6. In comparison with flow within the canyon, wind speed and wind direction at roof-level are more likely to follow the flow patterns in the rural area. Linear correlations between rural wind speed,  $\bar{S}_t^2$ , and momentum fluxes at roof level are shown in table I. Some other important correlations were also found, including relationships between  $\bar{u}\bar{w}_R$ ,  $\bar{u}\bar{w}_R$  and  $\bar{v}\bar{w}_R$ , and squared mean velocity components within the canyon,  $\bar{V}_s^2$  and  $\bar{U}_s^2$ . It is revealed that turbulent quantities at street level can be determined indirectly through mean quantities at the roof level and the rural site. Among all

two-variable dimensionless groups, heat fluxes at roof-level only correlated with other heat fluxes at roof and street level. Higher order polynomial fits were also used to attempt to correlate the measured data for each two-variable dimensionless group. An example of the corresponding correlation coefficients is shown in Fig. 3. Comparing the value of correlation coefficients of linear and higher order polynomial functions, particularly groups containing  $\bar{U}_R^2$ ,  $\bar{U}_s^2$  and  $\bar{W}_s^2$ , shows the existence of strong nonlinear relationships. For example, using a second order polynomial function to relate  $\bar{u}\bar{w}_R$  to  $\bar{U}_R^2$  increases the correlation coefficient by 178 percent. Fig. 4 shows how using the second order polynomial can improve the prediction of the relationship between  $\bar{u}\bar{w}_R$  and  $\bar{U}_R^2$ . However, there was no significant change in correlation coefficients for groups containing  $\bar{V}_s^2$  or  $\bar{V}_R^2$ . Likewise, using nonlinear functions for other vertical turbulent fluxes did not produce noticeable changes in correlation coefficient (not shown here). It can be concluded that nonlinear regression can significantly improve relationships between turbulent and some mean quantities. This highlights the importance of developing a proper nonlinear function which can describe nonlinear behavior of turbulent fluxes.

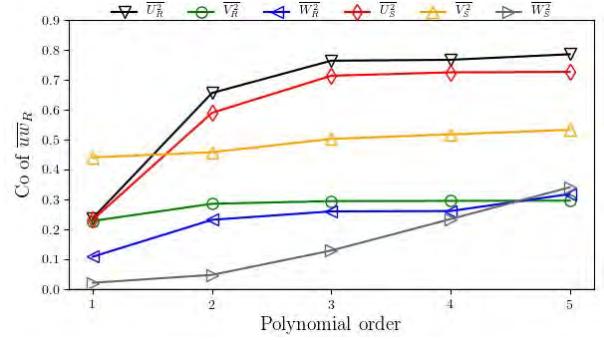

Figure 3: Correlation coefficient (Co) for different order polynomial regressions of the momentum flux

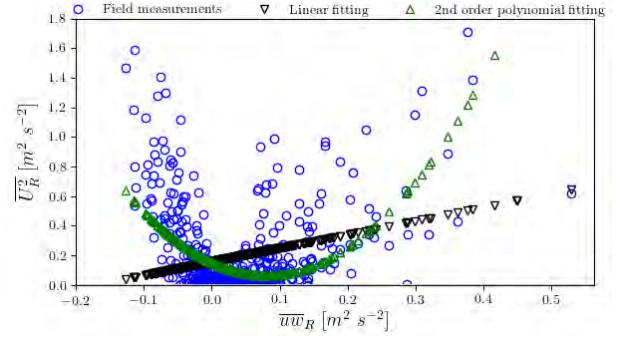

Figure 4: Comparison of linear and high order polynomial regression of momentum of flux

### B. Three-variable Dimensionless Group

The same algorithm used above was also applied to three-variable dimensionless groups. Fig. 5 shows how higher order polynomial regressions can modify correlation coefficients. Vertical heat flux at roof level,  $\bar{w}\bar{t}_R$ , had a strong nonlinear relationship with temperature differences between surface and adjacent atmosphere multiplied by vertical velocity (solid line). There are poor linear and nonlinear relationships between other heat flux (horizontal heat fluxes are not shown) and mean

quantities. In this figure,  $\bar{T}_{srR}$  and  $\bar{T}_{srs}$  represents surface temperature at roof and street levels.

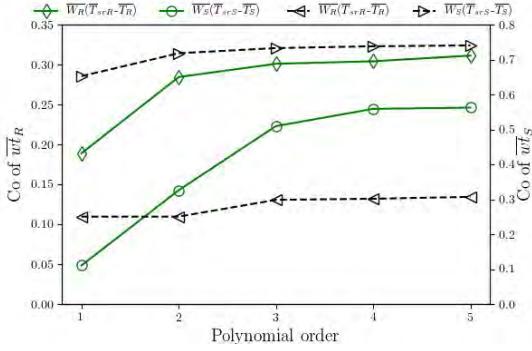

Figure 5: Correlation coefficient (Co) for different polynomial regressions of vertical heat flux; primary axis (solid lines) and secondary axis (dash lines)

### C. Developing a Multivariable Function

The scaling studies provided insight into what mean quantities can be related to turbulent quantities. The unsteady and, to some extent, unpredictable nature of turbulent flows, particularly within a canyon, make turbulence modeling difficult and it seems unreliable to try to predict most features of turbulence using only one quantity. It has been suggested that multivariable functions can limit duplicity of solutions for a turbulence problem [11]. Thus, multivariable functions were developed using ANNs. Among all two and three-variable groups, those which exhibited high linear correlation coefficients between turbulent and mean quantities were chosen as candidates in the search for multivariable functions. The capability of an ANN to restrict and predict turbulent fluxes was evaluated by performing statistical

analysis. Two metrics fractional bias (FB) and normalized mean square error (NMSE) were employed [12]. NMSE represents the overall scatter between observed and predicted quantities while FB quantifies the overall under- or over-estimation of measured quantities. Tables II and III show how efficiently and precisely ANNs can predict vertical turbulent fluxes. FB and NMSE were calculated for single-variable functions obtained from linear regressions of each individual group of variables, and multivariable functions generated by ANN containing each group as an independent variable. Friction velocity,  $u_{*s} =$

$(\bar{u}w_s^2 + \bar{w}w_s^2)^{1/4}$ , played an important role in scaling mean quantities leading to proper prediction of the turbulent fluxes. In comparison with linear regressions for the same case, an ANN often reduced NMSE by one order of magnitude. An ANN with input variables of  $u_{*s}\sqrt{\bar{t}^2_s}$ ,  $\bar{s}_R\sqrt{\bar{t}^2_s}$ ,  $\bar{s}_t\sqrt{\bar{t}^2_s}$  showed 68 to 98 percent improvement in prediction of vertical heat flux at street level,  $\bar{w}t_s$  compared to linear correlations. Employing ANNs also provided an opportunity to directly relate turbulent fluxes to horizontal rural velocity,  $s_t$ , with an acceptable accuracy.

Notable improvements also occurred in ANN predictions of  $\bar{uw}_S$  and  $\bar{uw}_R$  with  $f(u_{*S}^2, \bar{W}_S u_{*S}, \bar{U}_S u_{*S})$  and  $f(u_{*R}^2, \bar{U}_R u_{*R}, \bar{U}_S u_{*R})$  as multivariable functions, respectively. On the other hand, FB deteriorated when an ANN was used to predict fluxes, but the results were still considered acceptable, meeting the range of acceptance criteria [13]. Figs. 6 and 7 compare predictions of hourly time series of turbulent fluxes using ANN and field measurements. These figures are based on case studies 3 and 9, as referred to in Tables II and III, which represented significant improvement in prediction of relevant turbulent fluxes. Field data were collected at all wind speeds and directions, so no clear trend was expected for hourly flux time series. The level of agreement between observations and the ANN predictions is remarkable. This suggests that a well-trained ANN, such as built herein, can ingest the inherently chaotic flow behavior within and above the canopy. However, ANNs failed to predict other turbulent fluxes, such as  $\bar{wv}_S$  and  $\bar{wt}_R$ , using mean quantities. Additionally, as depicted in Tables II and III, linear regressions in cases 1 and 5 outperformed nonlinear multivariable functions.

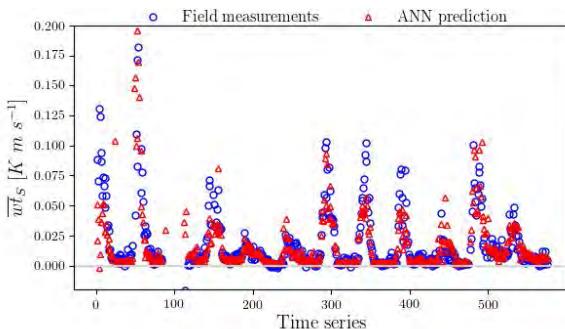

Figure 6: Comparison of ANN results with measurement data of vertical heat flux within the canyon

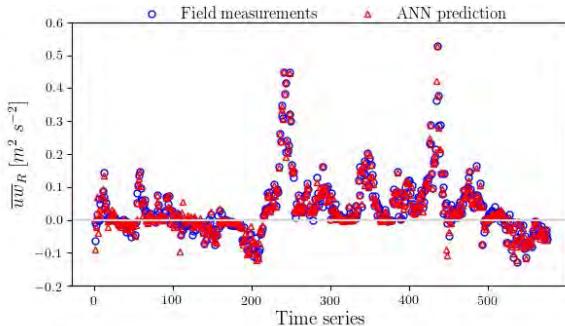

Figure 7: Comparison of ANN results with measurement data of vertical momentum flux at roof-level

## VI. CONCLUSIONS

Systematic scaling analysis was performed to find relationships between turbulent and mean quantities within and above the urban canopy. Field data was collected under all wind directions, wind speeds, and thermal stability conditions from a street canyon within an urban canopy, and also a rural area, in Guelph, Ontario, Canada. Several approaches were used to establish relationships between turbulent and mean quantities. The significance of nonlinear behavior and relationships between quantities was evaluated by creating dimensionless groups of variables containing two or three quantities. High linear correlations for vertical momentum flux at both roof and

street levels were found with mean wind speeds. This linear behavior is much more profound at street-level. Applying higher order polynomial functions to the field data revealed some strong nonlinear relationships. It was observed that using nonlinear functions can improve correlation coefficients significantly, for example, enhancing correlation coefficient by 178 percent for the relationship between  $\bar{uw}_R$  and  $\bar{U}_R^2$ . Similar results were found for the vertical heat flux. Additionally, it was found that artificial neural networks (ANNs) can be generated to predict such strong nonlinear relationships. The predictive capability of ANNs was evaluated for the current dataset by comparing NMSE and FB calculated by ANN and linear regressions. It was found that a well-trained ANN accurately predicted vertical momentum and heat fluxes within and above the canyon. However, in some cases linear regression outperformed ANN predictions. The different approaches are complementary to one another, and can be used in combination to further develop robust optimization algorithms for predicting turbulence quantities from mean meteorological values.

## VII. ACKNOWLEDGEMENTS

The lead author acknowledges the financial support of the NSERC Discovery Grant program. All authors thank the following individuals who helped with the urban microclimate field campaign: Denis Clement, Steve Nyman, Chris Duiker, Manuela Racki, Jeffrey Dafoe, Joanne Ryks, Ryan Smith, Stephen Stajkowski, and Baharam Gharabaghi.

**Abstract** — In this study, the concept of multi-directional functionally graded cellular material (FGCM) is introduced. FGCMs consist of two spatially-varying engineered phases: solid and void. Different parameters, such as relative density, cell topology, cell orientation, and cell elongation, can be tailored in multiple directions to optimize their mechanical performance. We implement a homogenization technique to evaluate the structural response of plates made by advanced cellular solids. The homogenized effective properties are used in a third-order shear deformation theory (TSDT) formulation. The governing differential equations are solved by a finite element method to predict the mechanical response of FGCM plates. The numerical results reveal that it is possible to increase the buckling load as much as 115% and decrease the maximum deflection about 60% by using an FGC structure.

**Keywords -** *Architected advanced materials, Functionally graded cellular materials, Homogenization, FDM 3D printing*

## I. INTRODUCTION

Over the last 50 years, several investigations revealed that cellular materials may replace fully dense solids in many different applications [1, 2]. Opposed to conventional materials which gain their properties merely from their material composition, cellular solids gain their properties mainly from their underlying architectures [3]. Several investigations have been performed to study the mechanical behavior of cellular materials. The majority of these early investigations on the mechanical properties of advanced porous materials was summarized by Gibson and Ashby in their textbook on “Cellular Solids, Structures and Properties” [1]. Furthermore, application of cellular materials as mechanical elements was first introduced in the design of structural sandwich panels in 1969 when periodic honeycomb sheets were used as the core of sandwich panels [4]. These studies and many others [5-9], shed some light on the properties and possible applications of cellular materials.

The characteristic properties of the representative cell (relative density and void (pore) topology), were uniform across the lightweight structure in all the initial studies mentioned above. However, recent technical developments in advanced manufacturing techniques, like additive manufacturing [10] and powder metallurgy [11], lead to new opportunities to design and manufacture architected cellular structures, in which the geometrical features and material composition of their constituent unit cells can vary in a specified direction. The cellular structures in which the cell’ relative density and topology vary across the lightweight structures with a pre-defined distribution function are called “Functionally Graded Cellular (FGC)” structures. This idea is inspired by natural and biological materials such as bamboo, plants and Humboldt beak.

A few studies are available in the literature implementing the idea of graded cellular properties in the structural mechanical design. One of the earliest research in the field of FGC structures was performed to apply the idea of graded honeycomb structures to obtain a Poisson-curving structure; i.e. a structure which experiences a significant change in its thickness as a result of a prescribed curvature [12]. Afterwards, a finite element based micromechanical model was proposed to predict the fracture toughness of FGC foams [13]. Moreover, FGC structures were shown to be suitable for practical applications such as orthopedic hip implants [14] and cores of aero-engine fan blade [15].

In the present article, we perform a comprehensive study on the architected multi-directional FGCMs with a focus on architected cellular plates. The cell topology is modelled by a superellipse function [16], and the effective properties are obtained by using standard mechanics homogenization [17]. A generalized power-law function is proposed to model the variation of cell characteristics in multiple directions. The governing equations for the structural analysis of FGC plates are obtained by using Reddy’s third-order shear deformation theory [18], and solved by a finite element model. The advantages of FGC structures over regular cellular structures are illustrated

through various examples and the effect of different distribution functions are investigated.

## II. MODELLING OF FUNCTIONALLY GRADED CELLULAR PLATES

### A. Formulation of Cell Geometry

In this work, an FGC plate with length  $L_{tot}$ , width  $W_{tot}$ , and thickness  $T_{tot}$  is considered in the  $xy$ -plane as shown in Fig. 1. The plate consists of  $N_x$  cells in  $x$ -direction,  $N_y$  cells in  $y$ -direction, and  $N_z$  cells in  $z$ -direction, where  $(x, y, z)$  refer to the global Cartesian coordinate system also shown in Fig. 1.

The properties of cellular materials depend on their relative density and void topology. Here, a focus is made on extruded two-dimensional square cells in which the void topology of each cell is introduced according to the following superellipse function [16]:

$$\begin{bmatrix} \tilde{x} \\ \tilde{y} \end{bmatrix} = \begin{bmatrix} r_x \cos^n \theta \\ r_y \sin^n \theta \end{bmatrix} R(\theta) \quad (1)$$

where  $0 \leq \theta \leq 2\pi$ ,  $\tilde{x}$  and  $\tilde{y}$  are the local coordinate system whose origin is at the center of the unit cell. Three parameters  $(r_x, r_y, n)$  have been introduced to control and optimize the void size and topology. Equation (1) simplifies to a circular cell with radius  $r_0$  for the case of  $n = 1$  and  $r_x = r_y = r_0$ . Moreover,  $R(\theta) = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}$  is the rotation matrix enabling to rotate the void topology within each cell. To allow a systematic study for the effect of void topology and void orientation on the mechanical responses of FGC structures, four independent parameters are considered: shape parameter ( $n$ ), aspect ratio ( $A.R. = \frac{r_y}{r_x}$ ), relative density ( $\rho_{rel}$ ), and orientation angle ( $\theta$ ). In this study, these four parameters are assumed to vary in the range of  $[0.01, 3]$ ,  $[1, 3]$ ,  $[0.01, 1]$  and  $[0, \pi]$ , respectively. Fig. 2 presents the effect of  $n$  and  $A.R.$  on the void topology of periodic cellular materials. It should be mentioned that cell topologies for which the void geometry intersect with cell boundaries has been marked as “Geometrically Inadmissible” in Fig. 2.

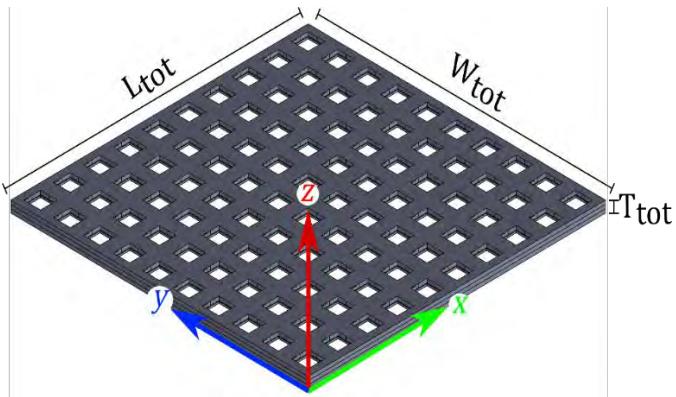

Fig. 1- Homogenous cellular plate

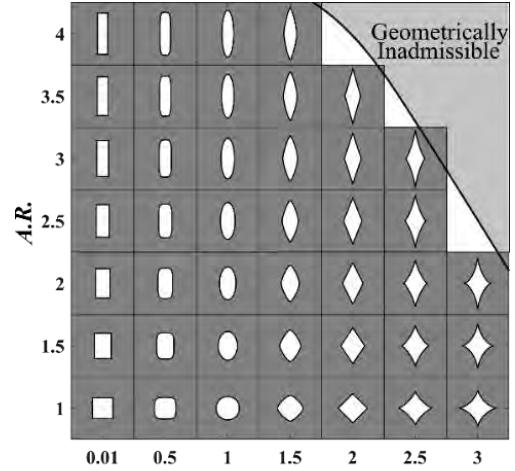

Fig. 2- Achievable cell topologies by a 2D superellipse function as a function of the shape parameter ( $n$ ) for  $\rho_{rel} = 0.9$  and different aspect ratios (A.R.)

### B. Formulation of Cell Topology Variation in FGCMs

A general power-law function is introduced here to represent any property distribution throughout the length, width and thickness of the material as:

$$P(\bar{x}, \bar{y}, \bar{z}) = P_1 + (P_0 - P_1) \left(1 - \frac{\bar{x}}{\bar{x}_{0P}}\right)^{mx_p} \left(1 - \frac{\bar{y}}{\bar{y}_{0P}}\right)^{my_p} \left(1 - \frac{\bar{z}}{\bar{z}_{0P}}\right)^{mz_p} \quad (2)$$

where  $P$  represents any of the four void topology parameters ( $n$ ,  $A.R.$ ,  $\rho_{rel}$ , and  $\theta$ ),  $P_0$  is its value at the origin ( $x = 0, y = 0, z = 0$ ) and  $P_1$  is its extreme value at  $x = \bar{x}_{0P}$ ,  $y = \bar{y}_{0P}$  and  $z = \bar{z}_{0P}$ . In all cases, an overbar indicates dimensionless coordinates defined as:

$$\bar{x} = \frac{x}{L_{tot}}, \bar{y} = \frac{y}{W_{tot}}, \bar{z} = \frac{z}{T_{tot}} \quad (3)$$

Moreover,  $mx_p$ ,  $my_p$  and  $mz_p$ , introduced in Eq. (3), are even integers indicating the distribution profile function. If  $mx_p$ ,  $my_p$  or  $mz_p$  equals zero, the property in the  $x$ ,  $y$  or  $z$  direction results in a constant value, respectively; i.e. a homogenous distribution of cellular materials in the respective direction. If  $P_0 = P_1$ , the property has a constant value  $P_0$  all over the domain.

### C. Formulation of Functionally Graded Cellular Plates

In this study, the effective elastic properties of all the cells modelled by the superellipse formulation are obtained by standard mechanics homogenization [17]. The material property chart, or so-called Ashby chart [1], is an effective presentation giving an overview of solid materials properties lying in a certain characteristic range. As a result, Fig. 3 presents the Ashby chart for well-known solid materials along with 2D extruder cellular materials with superellipse topologies. Fig. 3 shows that the range of Young's modulus for cellular materials can be extended to regions which cannot be achieved by fully dense solid materials.

To develop a methodology which can be implemented for thin and relatively-thick cellular plates, Reddy's third-order shear deformation theory (TSDT) [18] was used. According to TSDT, the transverse shear stresses are presented as a quadratic

function through the plate thickness. Therefore, unlike the first-order shear deformation theory (FSDT), it is not necessary to introduce any shear correction factor in the formulation.

Based on the abovementioned assumptions and by applying Hamilton's approach [18], the governing equations for the present problem, in which the cell topology and subsequently elastic properties are varying in multiple directions, will be obtained as:

$$N_{xx,x} + N_{xy,y} = I_0 \ddot{u}_0 + J_1 \ddot{\varphi}_x - c_1 I_3 \ddot{w}_{0,x} \quad (4)$$

$$N_{yy,y} + N_{xy,x} = I_0 \ddot{v}_0 + J_1 \ddot{\varphi}_y - c_1 I_3 \ddot{w}_{0,y} \quad (5)$$

$$c_1 P_{xx,xx} + 2c_1 P_{xy,xy} + c_1 P_{yy,yy} + Q_{x,x} + Q_{y,y} - 3c_1 (R_{x,x} + R_{y,y}) + q = c_1 (I_3 \ddot{u}_0 + J_4 \ddot{\varphi}_x - c_1 I_6 \ddot{w}_{0,x})_x + c_1 (I_3 \ddot{v}_0 + J_4 \ddot{\varphi}_y - c_1 I_6 \ddot{w}_{0,y})_y + I_0 \ddot{w}_0 \quad (6)$$

$$M_{xx,x} + M_{xy,y} - c_1 (P_{xx,xx} + P_{xy,xy}) - Q_x + 3c_1 R_x = J_1 \ddot{u}_0 + J_2 \ddot{\varphi}_x - c_1 J_4 (\ddot{\varphi}_x + \ddot{w}_{0,x}) \quad (7)$$

$$M_{yy,y} + M_{xy,x} - c_1 (P_{yy,yy} + P_{xy,xy}) - Q_y + 3c_1 R_y = J_1 \ddot{v}_0 + J_2 \ddot{\varphi}_y - c_1 J_4 (\ddot{\varphi}_y + \ddot{w}_{0,y}) \quad (8)$$

where comma represents partial differentiation with respect to  $x$  or  $y$ , dots denotes differentiation with respect to time and  $u_0$ ,  $v_0$ ,  $w_0$ ,  $\varphi_x$  and  $\varphi_y$  are the displacements and rotations of the transverse normal on the plane  $z = 0$ . Moreover,  $c_1 = \frac{4}{3I_{tot}^2}$  and  $N_{\alpha\beta}$ ,  $M_{\alpha\beta}$ ,  $P_{\alpha\beta}$ ,  $Q_{\alpha\beta}$  and  $R_{\alpha\beta}$  are stress resultants,  $I_i$  and  $J_i$  are moments of inertia and  $q$  is the transverse mechanical load.

Equations 4-8 are discretized and solved using rectangular conforming element combined with Lagrangian and Hermitian interpolation functions as presented in reference [18].

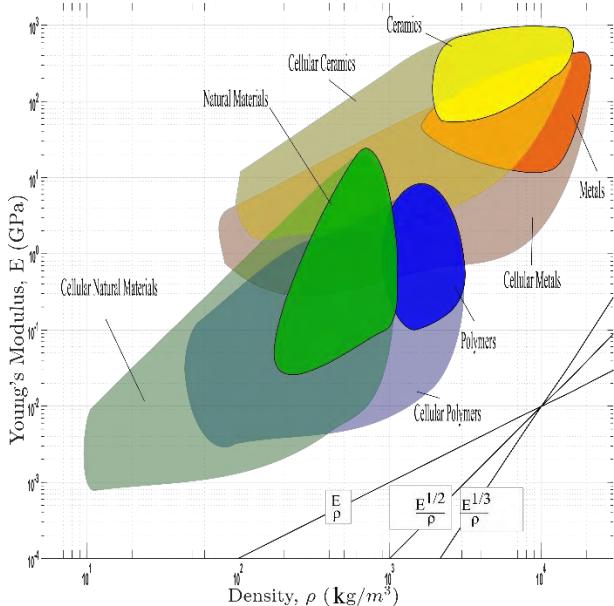

Fig. 3- Ashby chart for cellular materials of superellipse cell topology

### III. RESULTS AND DISCUSSION

In this section, the numerical results are presented for homogenous and functionally graded cellular materials. The non-dimensional parameters used to represent the mechanical responses of FGC plates are defined as:

$$\bar{W}_{max} = 100 W_{max} \frac{E_s W_{tot}^3}{F L_{tot}^2} \quad (9)$$

$$\bar{\Omega} = \Omega \frac{L_{tot}^2}{W_{tot}} \sqrt{\frac{\rho_s}{E_s}} \quad (10)$$

$$\bar{N}_{cr}^{xx} = \frac{10^4 \hat{N}_{xx} \lambda L_{tot}^2}{W_{tot}^3} \quad (11)$$

where  $F$  is the resultant of the uniform transverse load ( $F = qA_{solid}$ ), while  $W_{max}$ ,  $\Omega$  and  $\hat{N}_{xx}$  are the maximum deflection of the plate, natural frequency and in-plane compressive load, respectively. Moreover, the size of each constituent unit cell is considered to be the same. Therefore, the total relative density of the cellular plate can be written as:

$$\rho_{rel,plate} = \frac{\sum_{i=1}^N \rho_{rel,i}}{N} \quad (12)$$

where  $\rho_{rel,i}$  is the relative density of  $i^{\text{th}}$  cell and  $N$  is the total number of cells in a cellular plate.

#### A. Structural Response of Homogenous Cellular Plates

An optimized structural design requires lightweight but stiff structural elements with minimum deflection, maximum mechanical buckling load, and maximum fundamental frequency. The variation of maximum bending deflection as a function of relative density is shown in Fig. 4. The highest stiffness among all the topologies studied in this article is associated with square void. Consequently, it is observed that the maximum deflection of a plate made of square shape voids is the lowest.

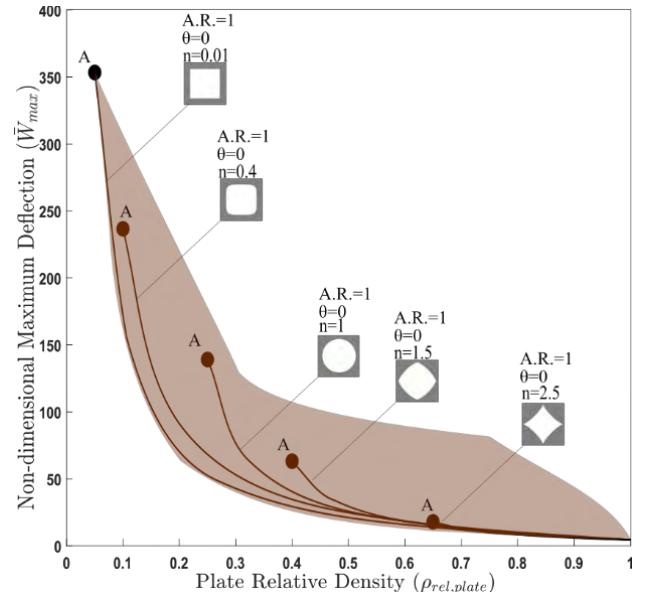

Fig. 4- Non-dimensional maximum deflection of a SSSS cellular plate with  $\frac{L_{tot}}{T_{tot}} = 10$  made of  $10 \times 10$  cells of super ellipsoidal void

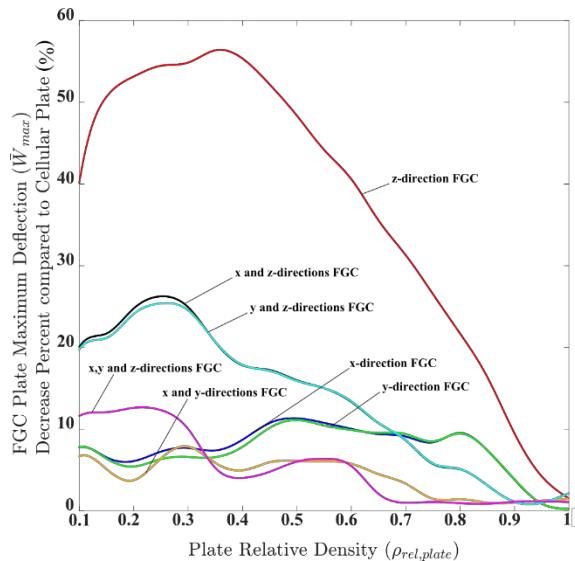

Fig. 5- Decrease of the maximum deflection of alternative multi-directional FGC square plates made by square void shape as a function of the relative density for SSSS plate with  $\frac{L_{tot}}{T_{tot}} = 10$

### B. Structural Response of Multi-Directional FGC Plates

The effect of density variation in different directions on the stiffening of FGC plates subjected to a uniformly distributed load is presented in Fig. 5. It can be observed that density gradient in the z-direction has the most dominant effect on the maximum deflection variation, while directional density variation in the x- and z-directions can decrease the maximum deflection by 26%, the maximum improvement attainable by one directional density variation in the z-direction can be up to 56% for the maximum deflection of architected FGC plates. It is important to note that our conclusion here is only limited to the proposed variation formula defined in Eq. (2) for multi-directional graded cellular materials and for SSSS plates.

To gain insight into the most effective density gradient, the percentage of increase in the critical buckling load is plotted in Fig. 6 as a function of  $(\rho_{rel1} - \rho_{rel0})$ , where  $\rho_{rel1}$  is the relative density at  $\bar{x}_{0\rho} = \bar{y}_{0\rho} = \bar{z}_{0\rho} = 0.5$  and  $\rho_{rel0}$  represents the relative density at the origin. Figure 9 shows that for a density gradient in the z – direction, the maximum improvement occurs when  $(\rho_{rel1} - \rho_{rel0}) < 0$ ; i.e. when the center of the FGC plate is more porous than the origin at the FGC plate edges. When the density varies in the x-direction or y-direction, the conclusion is reversed. Fig. 6 implies that a z – directional FGC plate can have a maximum buckling load when the density at the center of the thickness (mid-plane) is higher at the top and bottom of the plate. For the x – directional and y – directional FGC plates, higher relative densities at the sides than in the center is more desirable for increasing the critical buckling load. It is also concluded that for all one-directional FGC plates, a higher difference between the side and center density  $|\rho_{rel1} - \rho_{rel0}|$ , usually leads to a higher critical buckling load increase. It must be noted that the effect of local buckling is not taken into account in the buckling results.

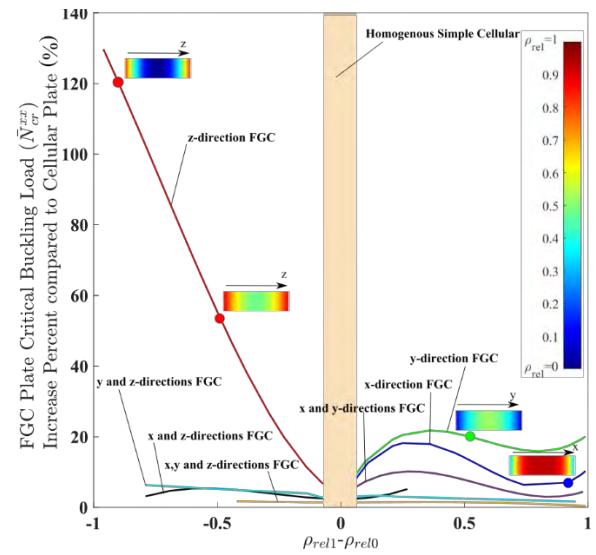

Fig. 6- Effect of the difference between the extreme values of relative density gradient ( $\rho_{rel1} - \rho_{rel0}$ ) on the critical buckling load (x-direction) achievable by FGC design for SSSS plate with  $\frac{L_{tot}}{T_{tot}} = 10$

### IV. CONCLUSION

In this work, the concept of multi-directional functionally graded cellular materials was used to produce architected advanced materials. In particular, the mechanical and structural performance of FGCMs were investigated to be used as constitutive elements for lightweight plates. The results showed their important advantages compared to homogenous cellular materials. The superellipse formula was implemented to model the topology of the architected cells and a general power-law function was introduced to control the cell distribution attributes in three different orthogonal directions. The effective cells properties were predicted by standard mechanics homogenization and the functionally graded cellular plate was modeled based on TSDT. The governing equations were solved by using a finite element method. The results clearly showed that architected cellular materials, in the form of superellipsoidal voids, can significantly expand the range of elastic and structural properties leading to lightweight but stiff solutions for advanced materials and structures. Moreover, it was shown that tailoring the topological features of cellular materials through the graded cellular plates thickness more significantly affected their structural response than changing the corresponding features in planar directions.

**Abstract**—A model for the deformation of an elastic solid reinforced by embedded fibers is presented in which elastic resistance of the fibers to bending is incorporated. We developed the equilibrium equations and necessary boundary conditions, Within the framework of strain-gradient elasticity, which describe the finite plane deformations of fiber-reinforced composite materials. The resulting nonlinear coupled 4<sup>th</sup> order partial differential equations are numerically solved by using the FEM. Within the limitation of superposed incremental deformations, a complete analytical solution is also obtained.

**Finite elasticity; strain gradient theory; fiber-reinforced materials; flexure; superposed incremental deformations; finite element method; finite plane deformations**

## I. INTRODUCTION

The mechanics of fiber-reinforced materials is a well-established subject [1–4] that has significantly advanced our knowledge on and practices in the development of composite materials. One way of addressing this problem is to examine the local behavior of an individual microstructure-matrix system including the interfacial region. Such investigations are essential to extracting the mechanical properties of those materials, yet rather inefficient at predicting the general behavior of the composite materials under prescribed forces and/or displacements. Within this prescription, much theoretical work has been developed based on the simple concept of an anisotropic material where the material response function depends on the classical deformation gradient with the augmented constraints of bulk incompressibility and fiber inextensibility. A general theory for an elastic solid with fibers resistant to flexure, stretch and twist is presented in [4].

In the present work, we develop a continuum model in which the fibers accommodate elastic resistance to flexure. The fibers are treated as continuously distributed spatial rods of the Kirchhoff type where the kinematics are based on their position field and a director field. We seek a complete model describing the finite plane deformation of fiber composites which offers fiber resistance to flexure loading. The basic kinematics and constitutive framework are presented in Section II. Via the computation of variational derivatives and the virtual-work statement, in Section II the corresponding equilibrium equation

is derived in which the bulk incompressibility condition is augmented in a weak sense. In section III, we also consider an example in the case of Neo-Hookean materials with necessary boundary conditions. In section IV, a set of numerical solutions is obtained via a finite element analysis. In Section V, a complete analytical solution of the linearized system is obtained for the case when the fiber composite is subjected to uniform bending moment at its edge. It is good to mention that the presented model can serve as an alternative 2D Cosserat theory of nonlinear elasticity.

## II. KINEMATICS AND EQUILIBRIUM EQUATIONS

We propose that the mechanical response of the fiber material is governed by the following strain energy function:

$$W(\mathbf{F}, \mathbf{G}) = \widehat{W}(\mathbf{F}) + W(\mathbf{G}),$$

$$W(\mathbf{G}) = \frac{1}{2} C(\mathbf{F}) |g|^2. \quad (1)$$

where  $\mathbf{F}$  and  $\mathbf{G}$  are the gradient of the deformation and the second gradient of the deformation, respectively. Further,  $C$  refers to the material property of fibers which, in general, independent of the deformation gradient. The orientation of a particular fiber is given by

$$\lambda = |\mathbf{d}|,$$

$$\tau = \lambda^{-1} \mathbf{d}. \quad (2)$$

Where

$$\mathbf{d} = \mathbf{F} \mathbf{D} \quad (3)$$

in which  $\mathbf{D}$  is the unit tangent to the fiber trajectory in the reference configuration. Equation (3) can be derived by taking the derivative of  $r(s) = \chi(\mathbf{X}(s))$ , upon making the identifications  $\mathbf{D} = \mathbf{X}'(s)$  and  $d = r'(s)$ . The expression for geodesic curvature of an arc ( $r(s)$ ) is then obtained from (3) as

$$\mathbf{g} = \mathbf{r}'' = \frac{d(r')}{ds} = \frac{\partial(\mathbf{F} \cdot \mathbf{D})}{\partial \mathbf{x}} \frac{d\mathbf{x}}{ds} = \nabla |\mathbf{F} \mathbf{D}| \mathbf{D} \quad (4)$$

To accommodate the bulk incompressibility condition, we consider the following energy functional

$$E = \int_w U(\mathbf{F}, \mathbf{G}, p) dA,$$

$$U(\mathbf{F}, \mathbf{G}, p) = W(\mathbf{F}, \mathbf{G}) - p(J - I). \quad (6)$$

where  $J$  is determinant of  $\mathbf{F}$  and  $p$  is a Lagrange-multiplier field. The induced variation of the energy is then evaluated as

$$\dot{E} = \int_w \dot{W}(\mathbf{F}, \mathbf{G}) dA \quad (7)$$

Where

$$\dot{U}(\mathbf{F}, \mathbf{G}, p) = W_F \cdot \dot{\mathbf{F}} - W_G \cdot \dot{\mathbf{G}} - p \dot{J} \quad (8)$$

So we have

$$P_{iA} = \frac{\partial W}{\partial F_{iA}} - p F_{iA}^* - C g_{iB} D_B D_A \quad (9)$$

Therefore, the corresponding Euler equation can be obtained as

$$P_{iA,A} = 0 \text{ or } \text{Div}(\mathbf{P}) = 0 \quad (10)$$

### III. NEO-HOOKEAN MATERIALS

In the case of incompressible Neo-Hookean materials, the energy density function is given by

$$\widehat{W}(\mathbf{F}) = \frac{\mu}{2} \text{tr}(\mathbf{C}) = \frac{\mu}{2} \text{tr}(\mathbf{F}^T \mathbf{F}) = \frac{\mu}{2} \mathbf{F} \cdot \mathbf{F}$$

$$W(\mathbf{F}, \mathbf{G}) = \frac{\mu}{2} \mathbf{F} \cdot \mathbf{F} + \frac{1}{2} C |g|^2 \quad (11)$$

where  $\mu$  and  $C$  are the material constant of the matrix and fiber, respectively. Accordingly, the corresponding Euler equation can be obtained as

$$P_{iA,A} = \mu F_{iA,A} - p_{,A} F_{iA}^* - C g_{iB} D_A D_B = 0 \quad (12)$$

where  $\varepsilon_{ij}$  is the 2-D permutation;  $\varepsilon_{12} = -\varepsilon_{21} = 1$ ,  $\varepsilon_{11} = -\varepsilon_{22} = 0$ . Equation (12) together with the incompressibility condition furnishes a coupled PDE system for  $\chi_1$ ,  $\chi_2$  and  $p$ . i.e.

$$\begin{aligned} \mu (\chi_{1,11} + \chi_{1,22}) - p_{,1} \chi_{2,2} + p_{,2} \chi_{2,1} - C \chi_{1,1111} &= 0, \\ \mu (\chi_{2,11} + \chi_{2,22}) + p_{,1} \chi_{1,2} - p_{,2} \chi_{1,1} - C \chi_{2,1111} &= 0, \\ \chi_{1,1} \chi_{2,2} - \chi_{2,1} &= 1. \end{aligned} \quad (13)$$

When the fiber's directions are either normal or tangential to the boundary, we have

$$t = P_{iA} N_A,$$

$$m_i = C g_i D_A N_A D_B N_B,$$

$$f_i = 0. \quad (14)$$

where

$$\begin{aligned} P_{iA} &= \mu F_{iA} - p F_{iA}^* - g_{iB} D_A D_B, \\ g_i &= F_{iA,B} D_A D_B. \end{aligned} \quad (15)$$

### IV. FINITE ELEMENT ANALYSIS OF THE 4TH ORDER COUPLED PDE

It is not trivial to demonstrate numerical analysis procedures for coupled PDE systems, especially for those with high order terms, since the piece wise linear function adopted in FE analysis has limited differentiability up to second order. For preprocessing, Equation (13) can be recast as

$$\begin{aligned} \mu (R + \chi_{1,22}) - p_{,1} \chi_{2,2} + p_{,2} \chi_{2,1} - C \chi_{1,1111} &= 0, \\ \mu (Q + \chi_{2,22}) + p_{,1} \chi_{1,2} - p_{,2} \chi_{1,1} - C \chi_{2,1111} &= 0, \\ Q - \chi_{1,11} &= 0, \\ R - \chi_{2,11} &= 0, \\ A - \mu (\chi_{1,11} + \chi_{1,22}) - CR_{,11} &= 0, \\ A - \mu (\chi_{2,11} + \chi_{2,22}) - CQ_{,11} &= 0. \end{aligned} \quad (16)$$

where  $Q = \chi_{1,11}$  and  $R = \chi_{2,11}$ . By employing the Picard iterative process, the nonlinear terms in the above can be treated as

$$\begin{aligned} -A_{\text{initial}} \chi_{2,2}^{\text{initial}} + B_{\text{initial}} \chi_{2,1}^{\text{initial}} &\Rightarrow -A_0 \chi_{2,2}^0 + B_0 \chi_{2,1}^0 \\ A_{\text{initial}} \chi_{1,2}^{\text{initial}} - B_{\text{initial}} \chi_{1,1}^{\text{initial}} &\Rightarrow A_0 \chi_{1,2}^0 - B_0 \chi_{1,1}^0 \end{aligned} \quad (17)$$

Thus, we write

$$\begin{aligned} -A_{N-1} \chi_{2,2}^{N-1} + B_{N-1} \chi_{2,1}^{N-1} &\Rightarrow -A_N \chi_{2,2}^N + B_N \chi_{2,1}^N \\ A_{N-1} \chi_{1,2}^{N-1} - B_{N-1} \chi_{1,1}^{N-1} &\Rightarrow A_N \chi_{1,2}^N - B_N \chi_{1,1}^N \end{aligned} \quad (18)$$

where the values of  $A$  and  $B$  continue to be refreshed based on their previous estimations as iteration progresses. The weak form of Eq. (16)1 is given by

$$0 = \int_{\Omega} w_1 (\mu (R + \chi_{1,22}) - A \chi_{2,2} + B \chi_{2,1} - CR_{,11}) d\Omega \quad (19)$$

where  $\Omega$ ,  $\partial\Omega$  and  $N$  are the domain of interest, the associated boundary, and the rightward unit normal to the boundary  $\partial\Omega$  in the sense of the Green-Stoke's theorem, respectively. The unknowns,  $\chi_1$ ,  $\chi_2$ ,  $Q$ ,  $R$ ,  $A$  and  $B$  can be written in the form of Lagrangean polynomial. Finally, we assemble the local stiffness matrices and obtain the following systems of equations in the Global form.

For demonstration purpose, we consider a rectangular fiber composite where one end is fixed and the other end is subjected to uniform bending in order to examine fibers' reinforcing effects against to flexure. We also note here that data are obtained under the normalized setting. The convergence criteria are set for both nonlinear terms (i.e. A and B) and the deformed profiles at  $y = 0$ .

$$\begin{aligned} |A_{n+1} - A_n| &= \epsilon_1 \leq \epsilon, \\ |B_{n+1} - B_n| &= \epsilon_2 \leq \epsilon, \\ \epsilon &= \text{Maximum error.} \end{aligned} \quad (20)$$

It is clear from Fig. 1 that the adopted numerical method demonstrates fast convergence within 20 iterations. The deformation profile and contour show smooth transitions as they approach the boundary (Figs. 2, 3).

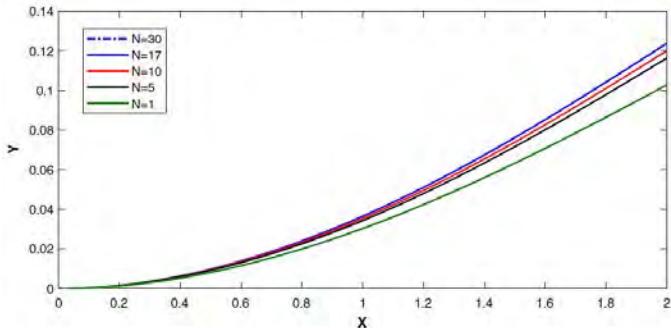

Figure 1. Convergence of the numerical solutions at  $y = 0$

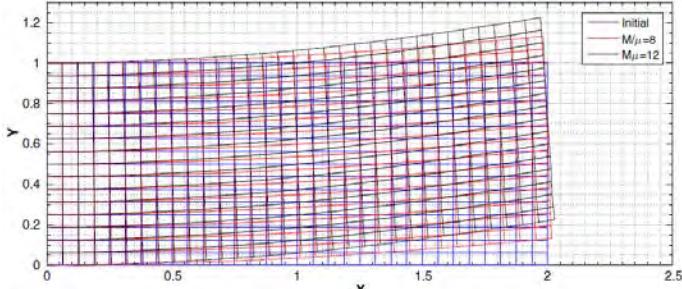

Figure 2. Deformed configurations with respect to  $M/\mu$  when  $C/\mu = 150$

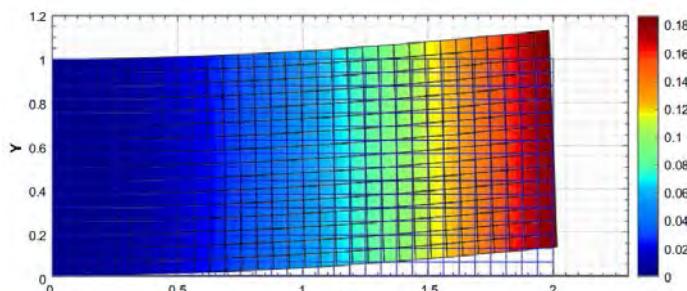

Figure 3. Deformation contour when  $C/\mu = 150$  and  $M/\mu = 8$

## V. SOLUTION TO THE LINEARIZED PROBLEM

We introduce scalar field  $\phi$  as

$$\begin{aligned} \mathbf{u} &= \mathbf{k} \times \nabla \phi, \quad \mathbf{k}(\text{unit normal}), \\ u_i &= \varepsilon_{\lambda i} \phi_{,\lambda}, \end{aligned} \quad (21)$$

The linearized Euler equation can be rewritten as

$$P_{,i} = \mu \varepsilon_{\lambda i} (\phi_{,\lambda 11} + \phi_{,\lambda 22}) - C \varepsilon_{\lambda i} \phi_{,\lambda 1111} \quad (22)$$

So the final equation will be

$$\begin{aligned} \Delta H - \alpha H_{,1111} &= 0, \\ H = \Delta \phi \text{ and } \alpha = \frac{C}{\mu} &> 0. \end{aligned} \quad (23)$$

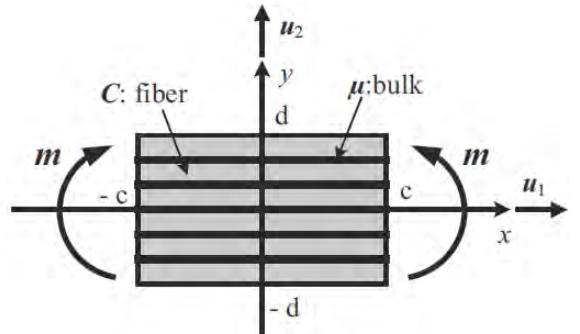

Figure 4. Schematic of problem

The general solution for the above equation can be found as

$$\phi = \sum_{m=1}^{\infty} \left[ \left\{ e^{a_m x} (A_m \cos b_m x + B_m \sin b_m x) + \right\} \right] + K \quad (24)$$

where  $K$  is a solution of Laplace's equation given by

$$K = \sum_{n=1}^{\infty} [(G_n \cosh nx + H_n \sinh nx)(I_n \cos ny + J_n \sin ny)] \quad (25)$$

In above equations  $a_m$  and  $b_m$  are

$$a_m = \frac{\sqrt{2m\sqrt{\alpha} + 1}}{2\sqrt{\alpha}}, \quad b_m = \frac{\sqrt{2m\sqrt{\alpha} - 1}}{2\sqrt{\alpha}}. \quad (25)$$

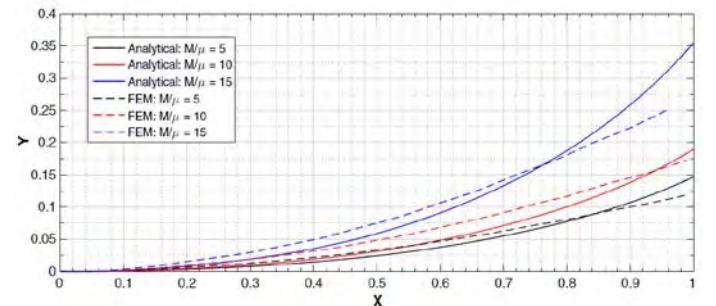

Figure 5. Solutions of the bending problem with  $C/\mu = 150$ . Nonlinear solution (dashed line), linear solution (solid line)

The analytical (linear) solution shows good agreement with nonlinear solution (FEM) for the small deformation regime, while larger values of  $M$  induce a significant discrepancy between the linear and nonlinear solution (see, Fig. 5). As a result, the obtained analytical solution has limitations in large deformation analysis. However, it can still be used in the design and analysis of fiber composites, particularly for CNC-reinforced composites, where the deformations of the systems are expected to be relatively ‘small’.

## VI. CONCLUSION

A continuum-based model is developed in finite plane elasto-statics in which fibers resistant to flexure is taken into account. The fibers are regarded as continuously distributed spatial rods of the Kirchhoff type in which the kinematics are based on a position field and a director field. The equilibrium equation of the fiber-reinforced composite materials is derived by the variational computation and method of virtual work.

These constitute a highly nonlinear coupled PDE system which is treated numerically via the FEM. Within the prescription of superposed incremental deformations, a complete linear theory is developed through which an analytical solution of the corresponding linearized PDE system is obtained. The obtained analytical solution demonstrates good agreement with nonlinear solution for the small deformation regime, yet has limited predictions for large deformation analysis.

## ACKNOWLEDGMENT

The author would like to thank Dr. Steigmann for stimulating his interest in this subject. This work was supported by the Natural Sciences and Engineering Research Council of Canada via Grant #RGPIN 04742 and the University of Alberta through a start-up grant.

**Abstract**— Many of 2D mechanical models have been developed to simulate liquid sloshing of a partially filled tank with different shapes. However, those models didn't represent properly the complex liquid motion, especially in the case of portable tanks. Indeed, forces exerted on the liquid can be lateral, longitudinal and vertical. Then, liquid displacement and pressure forces applied to the tank walls are undervalued and may cause design flaws. In this case, 2D mechanical models are ineffective for liquid motion simulation. In previous studies, a 3D equivalent mechanical model has been developed. This dynamical model is used to simulate different liquid motion in a partially filled tank that consider any sort of excitement forces and get more accurate results in terms of displacements and pressure forces. In this study, a brief description of the new dynamical model is given, including the liquid discretization process, stiffness and damping coefficients computing method and equations of motion. Afterward, the model is applied to an elliptical cross section tank to obtain displacement and pressure forces of the liquid. Finally, the results are compared to the literature.

**Keywords:** *liquid sloshing, tank truck, equivalent model, elliptical tank, 3D simulation.*

## I. INTRODUCTION

There are several equivalent mechanical models that simulate 2D liquid movement in a partially filled tank with different shapes such as spring-mass and simple pendulum models [1-4]. The use of such models in the liquid simulation provides convincing results when it comes to lateral sloshing. However, they didn't represent the global liquid motion in a tank. On the other hand, 3D mechanical models as spring-mass lattice are used for modeling complex motions of deformable bodies. Especially in computer graphical animation, spring-mass systems are often used for their simplicity and rapid implementation [5-7]. Moreover, the use of these models in the simulation of deformable bodies provides both geometrical and physical aspects. In a previous study, a new equivalent 3D dynamical model was developed to simulate the global motion of the liquid in a horizontal tank [8]. A mathematical method for liquid discretization showed that liquid splits in multiple

particles along each axis. Then, the mass and coordinates of the center of mass of each particle are computed. The movement of each particle is simulated by the displacement of its center of mass. All centers of mass constitute the nodes of the mesh. Each two adjacent nodes are linked by flexible edges having a parallel spring and damper. To adapt the model to all used forms of tanks, the generic tank cross-section, developed by Kang [9], was employed. In another study [10], we showed how to obtain stiffness and damping coefficient depending on the liquid and the tank design. Afterward, equations of motion were obtained and solved using a computation software program, namely Maple 16 [11]. In this study, the 3D dynamical model is applied to simulate liquid motion and pressure forces in a partially filled tank with an elliptical cross-section. Indeed, this tank shape is one of the most used shapes. Many researches have been dedicated to study this tank geometry. It allows a lower center of mass comparing to a cylindrical tank. We show a brief description of the dynamical model. Afterward, some results are generated and compared to the literature.

## II. 3D DYNAMICAL MODEL

### A. Liquid discretization

In this study, the tank lateral walls are assumed to be straight without any camber. The liquid discretization is made by dividing the length  $X$  of the tank by  $M$  parts, the height  $Z_h$  of the free surface by  $P$  parts and each portion between two heights  $k.Z_h/P$  and  $(k-1).Z_h/P$  by  $N$  parts in each direction of the  $\overrightarrow{OY}$  axis (left side and right side of the  $\overrightarrow{OZ}$  axis), with  $1 \leq k \leq P$  and  $M, N, P \in \mathbb{N}^*$ . Thus, we obtain  $M.2N.P$  particles, noted  $p_{i,j,k}$  with  $1 \leq i \leq M$ ,  $1 \leq j \leq 2N$  and  $1 \leq k \leq P$ . Note that the positions of each couple of particles  $p_{i,N-(l-1),k}$  and  $p_{i,(N+1)+(l-1),k}$  are symmetric with respect to the  $\overrightarrow{OZ}$  axis ( $1 \leq l \leq N$ ). Each particle is represented by its center of mass, noted  $G_{i,j,k}$ , which are the nodes of the model. Mass  $m_{i,j,k}$  and coordinates  $\vec{p}_{i,j,k}$  of each node are computed depending on its location [8]. The following figures show an example of the liquid discretization for a half full elliptical tank with  $M = 12$ ,  $N = 4$  and  $P = 5$ :

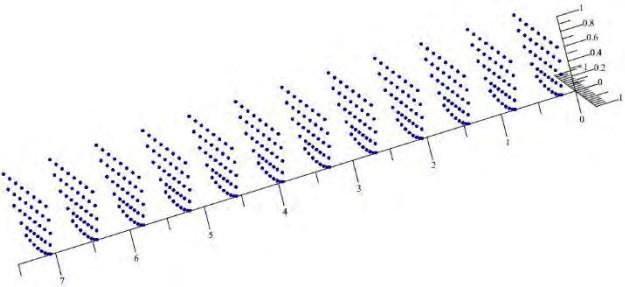

Figure 1: Example of liquid discretization in 3D

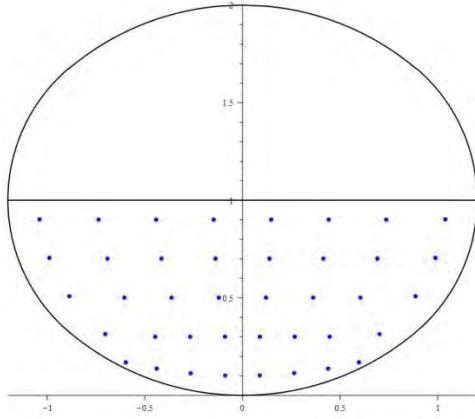

Figure 2 : 2D view of the liquid discretization.

In this example, the model contains of 480 nodes. Then, we will obtain 1440 equations of motion, three equations for each node.

#### B. Stiffness and damping coefficient

Each node  $G_{i,j,k}$  is linked to six links: two links  $A_{1,i,j,k}$  and  $A_{1,i+1,j,k}$  along the  $\overrightarrow{OX}$  axis, two links  $A_{2,i,j,k}$  and  $A_{2,i,j+1,k}$  along the  $\overrightarrow{OY}$  axis and two links  $A_{3,i,j,k}$  and  $A_{3,i,j+1,k}$  along the  $\overrightarrow{OZ}$  axis as shown in the following scheme:

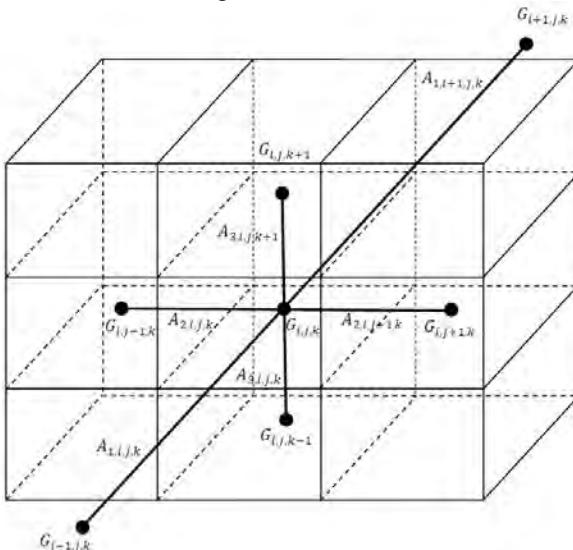

Figure 3: Links between a node  $G_{i,j,k}$  and its adjacent nodes.

Each link  $A_{q,i,j,k}$ , with  $q = 1, 2, 3$ , contains a parallel linear spring with a stiffness  $K_{q,i,j,k}$  and linear damper with a damping coefficient  $c_{q,i,j,k}$  as shown in the figure below:

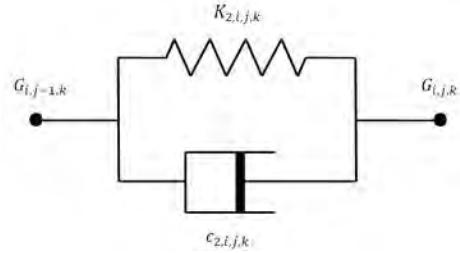

Figure 4: composition of the flexible link.

The nodes contacting the tank walls  $G_{1,j,k}$ ,  $G_{M,j,k}$ ,  $G_{i,1,k}$ ,  $G_{i,N,k}$  and  $G_{i,j,1}$  are attached to the structure by the same type of the links. Another special case of the nodes  $G_{i,j,P}$ , that represent the free surface of the liquid, are linked by only 5 links because they have no contact with the tank structure. The methodology used to compute stiffness and damping coefficient of the model is discussed as follows:

Firstly, stiffness  $K_{1,i,j,k}$  along the  $\overrightarrow{OX}$  axis is computed. It is supposed that the liquid is divided along the  $\overrightarrow{OZ}$  axis. Each part of the liquid between two heights  $Z_{k-1}$  and  $Z_k$  represents a vibration mode. The following formula is used to compute the natural frequency  $\omega_n$  of each vibration mode  $n$  of the liquid in rectangular tank [12]:

$$\omega_n^2 = \pi(2n-1) \frac{g}{a} \tanh \left[ \pi(2n-1) \left( \frac{h}{a} \right) \right] \quad (1)$$

Where  $a$  is the width of the tank,  $h$  is the height of the liquid and  $g = 9.81 \text{ m.s}^{-2}$  is the gravity acceleration. This formula is adapted to our model and becomes:

$$\omega_{xk}^2 = \pi(2n-1) \frac{g}{L} \tanh \left[ \pi(2n-1) \left( \frac{Z_h}{L} \right) \right] \quad (2)$$

Where  $n = P - k + 1$ . Indeed, when the cylinder is placed horizontally, the tank may be considered as rectangular [1]. Then, stiffness  $K_{xk}$  of each spring that simulate each mode  $k$  is computed by:

$$K_{xk} = m_{xk} \cdot \omega_{y_k}^2 \quad (3)$$

Where  $m_{xk}$  is the mass of the liquid between two heights  $Z_{k-1}$  and  $Z_k$ . Afterward, it is supposed that each spring  $K_{xk}$  is a set of  $M + 1$  springs in series with equal stiffness  $K_{xk,i}$  computed by the following formula:

$$K_{xk,i} = (M + 1) \cdot K_{xk} \quad (4)$$

Then, it is supposed that each spring  $K_{xk,i}$  is a set of parallel springs with the same stiffness  $K_{1,i,j,k}$  such as:

$$K_{1,i,j,k} = \frac{K_{xk,i}}{2N} \quad \text{with } 1 \leq j \leq 2N \quad (5)$$

Finally, proceeding by the same way for each part of the liquid between two heights  $Z_{k-1}$  and  $Z_k$ , all stiffness along the  $\overrightarrow{OX}$  axis are obtained.

Secondly, stiffness  $K_{2,i,j,k}$ , along the  $\overrightarrow{OY}$ , axis are computed. The method is identical to the one used previously for stiffness along the  $\overrightarrow{OX}$  axis. It is supposed that the liquid is divided along the  $\overrightarrow{OZ}$  axis. The formula (1) that compute natural

frequencies of each part of the liquid between  $Z_{k-1}$  and  $Z_k$  is adapted as follows:

$$\omega_{yk}^2 = \pi(2n-1) \frac{g}{Y_{k-1} + Y_k} \tanh \left[ \pi(2n-1) \left( \frac{Z_h}{Y_{k-1} + Y_k} \right) \right] \quad (6)$$

Where  $Y_k$  is the half width of the tank corresponding to the height  $Z_k$ . In fact, the width of the tank along the  $\overrightarrow{OY}$  axis varies depending on the height of the studied liquid part. Therefore, the value of width  $a$  in the formula (1) is replaced by the average width between the heights  $Z_{k-1}$  and  $Z_k$ . The stiffness  $K_{yk}$  describing each mode is computed by:

$$K_{yk} = m_{yk} \cdot \omega_{yk}^2 \quad (7)$$

Where  $m_{yk}$  is the mass of the liquid between  $Z_{k-1}$  and  $Z_k$ . It is supposed that the spring  $K_{yk}$  is a set of  $M$  parallel springs with the same stiffness:

$$K_{yk,i} = \frac{K_{yk}}{M} \text{ with } 1 \leq i \leq M \quad (8)$$

Afterward, we split each stiffness  $K_{yk,i}$  in  $2N+1$  springs in series with equal stiffness, noted  $K_{2,i,j,k}$ , with:

$$K_{2,i,j,k} = (2N+1) \cdot K_{yk,i} \quad (9)$$

All stiffness  $K_{2,i,j,k}$  values along the  $\overrightarrow{OY}$  axis are then obtained by the proposed computational procedures.

Thirdly, the stiffness  $K_{3,i,j,k}$  of springs along the  $\overrightarrow{OZ}$  axis is computed. In this case, there is no formula in the literature that can be used to compute natural frequencies of vertical sloshing. For this, an important assumption is considered. Indeed, the vertical displacement of the liquid is usually limited. For conventional shapes of the tank, vertical displacement  $\Delta z$  of the liquid center of mass is 0.04 m on average [9]. Considering this assumption, first, it is supposed that there is only one spring, namely  $K_z$ , attached to the center of mass of the liquid. The maximum stretch of this spring should be  $\Delta z$ . Assuming that the mass of the center of mass is the total liquid mass  $m_t$ , then, stiffness  $K_z$  is computed as follows:

$$K_z = \frac{m_t \cdot g}{\Delta z} \quad (10)$$

Then, the spring  $K_z$  is considered as a set of  $P$  springs in series with equal stiffness, noted  $K_{zk}$  with  $1 \leq k \leq P$ . Each stiffness  $K_{zk}$  to be calculated by the formula:

$$K_{zk} = P \cdot K_z \quad (11)$$

Afterwards, each spring  $K_{zk}$  is considered to be a set of  $2MN$  parallel springs  $K_{3,i,j,k}$  computed as follows:

$$K_{3,i,j,k} = K_{zk} / 2MN \quad (12)$$

Stiffness of each spring  $K_{3,i,j,k}$  along the  $\overrightarrow{OZ}$  axis is then obtained.

Finally, the damping coefficients  $c_{q,i,j,k}$  with  $q = 1, 2, 3$  are assumed to be equal to 100 times the dynamical viscosity coefficient  $\eta$  of the liquid multiplied by the corresponding link length. For example, the damping coefficient of a link between two nodes  $G_{i,j,k}$  and  $G_{i+1,j,k}$  along the  $\overrightarrow{OX}$  axis

$$c_{1,i,j,k} = 100 \cdot \eta \cdot \|\vec{p}_{i,j,k} - \vec{p}_{i-1,j,k}\| \quad (13)$$

Where  $\|\vec{x}\|$  is the Euclidian norm of the vector  $\vec{x}$ . To obtain consistent results, a calibration factor is added to the model such that all the values of stiffness along  $\overrightarrow{OX}$  axis and  $\overrightarrow{OY}$  axis to be multiplied by this factor. The value of this factor is used

depending on the number of nodes in the model. Virtually, as the number of nodes decreases extremely, the calibration factor increases. This factor can be explained by the lack of precision when the mesh is less refined. In this case, parameters of the links are underestimated and should be corrected.

#### C. Equations of motion

Displacement, velocity and acceleration vectors of a node  $G_{i,j,k}$  are noted respectively  $\vec{r}_{i,j,k}(t)$ ,  $\vec{v}_{i,j,k}(t)$  and  $\vec{a}_{i,j,k}(t)$ . The forces applied on each node are: stress force  $\vec{T}_{i,j,k}$  of the springs attached to the nodes, damping force  $\vec{A}_{i,j,k}$  and input force  $\vec{F}_{i,j,k}$ . Stress force  $\vec{T}_{i,j,k}$  is calculated by the following formula:

$$\vec{T}_{i,j,k} = \vec{T}_{1,i,j,k} + \vec{T}_{1,i+1,j,k} + \vec{T}_{2,i,j,k} + \vec{T}_{2,i,j+1,k} + \vec{T}_{3,i,j,k} + \vec{T}_{3,i,j,k+1} \quad (14)$$

Where the stress force of each spring attached to the node is computed by the Hook law. For example:

$$\vec{T}_{1,i,j,k} = -K_{1,i,j,k} (\|\vec{r}_{i,j,k} - \vec{r}_{i-1,j,k}\| - \|\vec{p}_{i,j,k} - \vec{p}_{i-1,j,k}\|) \cdot \frac{\vec{r}_{i,j,k} - \vec{r}_{i-1,j,k}}{\|\vec{r}_{i,j,k} - \vec{r}_{i-1,j,k}\|} \quad (15)$$

Damping force  $\vec{A}_{i,j,k}$  of each node is computed by:

$$\vec{A}_{i,j,k} = \vec{A}_{1,i,j,k} + \vec{A}_{1,i+1,j,k} + \vec{A}_{2,i,j,k} + \vec{A}_{2,i,j+1,k} + \vec{A}_{3,i,j,k} + \vec{A}_{3,i,j,k+1} \quad (16)$$

Where the damping forces applied by each attached damper is computed by the viscosity law. For example:

$$\vec{A}_{1,i,j,k} = -c_{1,i,j,k} \cdot (\vec{v}_{i,j,k} - \vec{v}_{i-1,j,k}) \quad (17)$$

The input force  $\vec{F}_{i,j,k}$  is calculated by the formula below:

$$\vec{F}_{i,j,k} = m_{i,j,k} [a_x \ a_y \ a_z]^t \quad (18)$$

Where  $a_x$ ,  $a_y$  and  $a_z$  are respectively the longitudinal, lateral and vertical accelerations applied on the tank. Using the Newton second law, we obtain for each node  $G_{i,j,k}$  the following equations of motion:

$$\vec{T}_{i,j,k} + \vec{A}_{i,j,k} + \vec{F}_{i,j,k} = m_{i,j,k} \cdot \vec{a}_{i,j,k} \quad (19)$$

To obtain the global system of motion equations, the global displacement vector is computed by  $\vec{r}$ , the global velocity vector by  $\vec{v} = \dot{\vec{r}}$  and the global acceleration vector by  $\vec{a} = \ddot{\vec{r}}$ . These 3 vectors contain  $3MNP$  components. Moreover, note by  $[\mathcal{M}]$  the  $3MNP \times 3MNP$  diagonal mass matrix such as each mass  $m_{i,j,k}$  is repeated 3 times. The global input forces vector is then given by:

$$\vec{F} = [\mathcal{M}] \cdot \vec{a}_{ext} \quad (20)$$

where  $\vec{a}_{ext}$  is given by:

$$\vec{a}_{ext} = [a_x \ a_y \ a_z \dots \ a_x \ a_y \ a_z]^t \quad (21)$$

The global stress forces  $3MNP$ -vector  $\vec{T}$  is equal to:

$$\vec{T} = [T_{x,1,1,1} \ T_{y,1,1,1} \ T_{z,1,1,1} \dots \ T_{x,M,N,P} \ T_{y,M,N,P} \ T_{z,M,N,P}]^t \quad (22)$$

Similarly, global damping forces  $3MNP$ -vector  $\vec{A}$  is obtained by the same manner. Finally, the global system of equations of motion is given as follows:

$$[\mathcal{M}] (\vec{r} - \vec{a}_{ext}) + \vec{A} - \vec{T} = 0 \quad (23)$$

### III. RESULTS AND DISCUSSION

In this section, the new 3D dynamical model is used to simulate liquid sloshing in a partially filled elliptical tank that is one of the most used geometry of portable tanks. The purpose of this simulation is to compare liquid displacement and pressure forces obtained by this model to the results obtained in the literature by two different methods [13]. The first model is an analytical model considering the liquid as a rigid body. Liquid motion is simulated by the movement of center of mass of the body. The second method is obtained by using a numerical simulation software. We compare maximum, both lateral and vertical, displacements of the center of mass of the liquid and maximum pressure forces generated by liquid sloshing.

To obtain lateral displacement  $Y_g$  and vertical displacement  $Z_g$  of the center of mass of the liquid using the 3D model developed in this study, the following formulas are used:

$$Y_g = \frac{1}{m_T} \sum_{\substack{i=1, j=1, k=1 \\ M, 2N, P}}^{M, 2N, P} m_{i,j,k} \cdot y_{i,j,k} \quad (24)$$

$$Z_g = \frac{1}{m_T} \sum_{\substack{i=1, j=1, k=1 \\ M, 2N, P}}^{M, 2N, P} m_{i,j,k} \cdot z_{i,j,k}$$

Where  $m_T$  is the total mass of the liquid,  $y_{i,j,k}$  and  $z_{i,j,k}$  are respectively lateral and vertical displacement of the node  $G_{i,j,k}$ . Using the forth order numerical derivation, lateral acceleration is computed to obtain lateral pressure force  $F_y$ .

A 50% filled elliptical tank is considered in this simulation with  $X = 7.5 \text{ m}$ ,  $a = 1.2 \text{ m}$  and  $b = 1 \text{ m}$ . The liquid is supposed to be a domestic oil with a density  $\rho = 966 \text{ kg.m}^{-3}$  and a dynamic viscosity  $\eta = 0.048 \text{ kg.m}^{-1}.s^{-1}$ . The selected values for the discretizing model are  $M = 12$ ,  $N = 4$  and  $P = 5$ . Therefore, the dynamical model consists of 480 nodes and 585 links (Figure 1). Firstly, a vehicle engagement in a curve maneuver is used as an input force with maximum lateral acceleration  $A = 3 \text{ m.s}^{-2}$ . The following table shows maximum displacements and lateral pressure forces obtained by three different models.

TABLE I. COMPARING RESULTS OF LIQUID DISPLACEMENTS AND PRESSURE FORCES ACCORDING TO THE NEW 3D MODEL AND THE LITERATURE.

	Literature		New 3D Model
	Analytical Model	Numerical Model	
Lateral displacement (m)	0.18	0.27	0.246
Vertical displacement (m)	0.023	0.073	0.111
Lateral pressure force (KN)	40.5	52	51.05

The table above shows accurate results in term of displacements and lateral pressure forces. Indeed, the numerical model using the simulation software is supposed to be the most accurate with respect to real displacements and lateral pressure forces. Note that the results obtained by the new 3D model are closer to the numerical model than the analytical model of the literature [13]. We can also notice that the lateral pressure forces are undervalued by the analytical model while the new 3D

model developed in this study is more accurate. Thus, these results validate the new 3D model and it is possible to use it for tank design and for the study of vehicle stability. Note also that for the simulation of the center of mass motion for a duration of 12 seconds, the computer required approximately one hour of computation time. Which is much shorter than the computation time of a numerical simulation software which requires hours, or even days of computation. Then we can show the real results obtained by the new model by evaluating displacement of each node of the mesh. The figure below shows the displacement of the liquid after one second of motion in a curve:

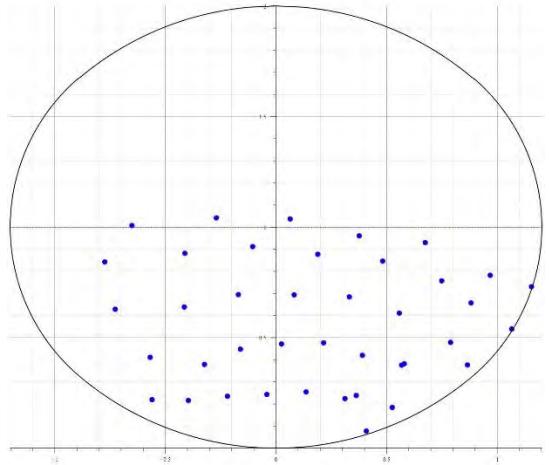

Figure 5: liquid displacement after 1 s of the vehicle engagement in a curve.

Figure 6 shows displacement of each node representing the liquid after two seconds of the vehicle movement in a curve:

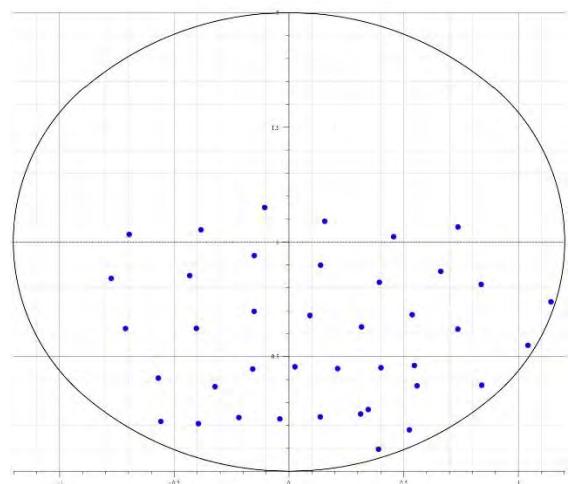

Figure 6: liquid displacement after 2 s of the vehicle engagement in a curve.
